Applicability. The long tom uses much less water than a sluice but at the expense of more labor. It saves a given amount of gold in a shorter linear distance. It has, therefore, been used in small-scale placer work where water and lumber were scarce, and has also been rather widely used on dredges for cleaning up black-sand concentrate (*115 P 825, 113 J 251*). Williams (*56 MM 218*) states that the tom is used widely in GUIANA. Usual crew there is 3 men: hoeman, spademan, and an alternate; additionally 1 or 2 bailers may be necessary. Capacity with such a crew is 5 cyd. per day. In loose, sandy ground 50¢ gravel can be worked, but in the smaller creeks it is doubtful whether gravel carrying less than $1 per cyd. is workable. Great disadvantage is the lack of transport of tailing and consequent tendency to cover unworked ground.

Surf washer (*IC 6786*) is similar to long tom, but made wider and shorter, and is set so that surf runs up, washes material through screen box and, on receding, carries away tailing. One man can run 2 and has run 8 cyd. in 10 hr. A variant comprised a simple sluice 3 to 4 ft. wide, 8 to 10 ft. long, 4 to 5 in. deep, sloped 8 to 10 in. in 12 ft., with 1 × 1-in. riffles, spaced 1 in., arranged transversely at the ends and longitudinally in the center section. The whole was set on sills weighted down with stones at a point such that waves ran to the top but receded from the lower end sufficiently to carry away tailing. With a good surf, 2 men shoveling-in could be kept busy.

Dry washer. See Art. 36.

Gold traps are small cones or pyramidal boxes, usually less than 18 in. across at the top, with hydraulic water supply near the bottom, with or without various types of internal baffles, which are placed in the line of flow of pulps carrying coarse gold. A bed is maintained in them by the stirring action of the pulp stream and the hydraulic water. They are provided with a locked cover and a locked plug valve; concentrate is drawn intermittently, as necessary. They are extremely effective in catching coarse gold; they also catch a considerable part of all but the finest, if not so baffled as to set up strong scour. Some mines report as much as 75 to 80% of total gold recovery made in traps following the grinding mills. (See Sec. 2, Fig. 50.)

SINK-FLOAT SEPARATION

General. Sink-float separation is, superficially, the heavy-liquid test of the mineralogist modified for continuous treatment of large tonnages. Ostensibly it consists in subjection of a mixture of solid particles of different specific gravities to the buoyant action of a quiescent body of fluid characteristics, having such density that it will float the lighter solid particles while the heavier sink, gravity being the only impelling force. Such an operation is typified familiarly by introducing a mixture of sand and sawdust into a pail of water. Actually, however, in commercial operations, the solid particles are introduced into the heavy-fluid body with considerable downward momentum; the fluid body is constrained

to flow in more or less regular paths in the separating vessel, at velocities that have definite effects on the separation; the viscosity, real or pseudo, of the medium is an important element in the motion of the solid particles therein, and time may be an element in the separation.

Flowsheet of a plant employing sink-float separation is, of course, dependent upon the raw feed. In coal separation sink-float may be the only concentration method employed, or it may be supplemented by table treatment of fines. In treating the usual ores, the function of sink-float separation is to discard tailing, hence the flowsheet comprises (*a*) crushing to a size that frees tailing (3/4-in. to 2-in. is the range of maximum sizes in present-day commercial operation); (*b*) screening out undersize too fine for satisfactory sink-float treatment (1/2- to 3/8-in. is usual today—1941), (*c*) washing oversize to remove slime and soluble salts which might affect the suspension properties of heavy-medium slime and accidentally introduced slime, (*d*) floating tailing in a heavy medium; (*e*) crushing heavy-medium concentrate and joining it with undersize from raw feed for treatment by gravity concentration, flotation, or other applicable method.

Sink-float processes may be classified as QUICKSAND processes, in which the heavy medium is sand maintained in suspension in water (or dilated by differential air pressure); SUSPENSOID processes, in which very fine sand and slime are maintained suspended largely by chem-electrical means; and HEAVY-LIQUID processes in which the heavy medium is a true liquid.

Quicksands

Quicksands have a lower effective density than beds, because their greater dilation lowers both composite density and plastic resistance. They must, therefore, employ continuous and appreciable upward impulse to supplement buoyancy in order to effect separation. They are formed either by causing water or air to flow upward through a column of sand with sufficient velocity to cause dilation of the column; or by stirring a sand-water mixture; or by utilizing both means together. Quicksand concentrators differ from bed-type in the continuity of the dilating force; there is little difference in buoyancy between a light bed and a heavy quicksand.

27. DIAMOND PAN

Description. The diamond pan is a quicksand separator in which the sand-supporting force and the upward impulse are obtained by rotary agitation alone. The apparatus comprises a shallow tub in the form of a cylindrical annulus, 5 to 20 ft. outside diameter, inside diameter about 0.3 times outside, outer wall ranging from 10 to 18 in. high as diameter ranges from 5- to 20-ft., and inner wall 3 to 6 in. lower than outer. A post supported by a step and an overhead bearing is set on the axis of the tub and carries a number of radial arms (6 on 5- and 6-ft. pans, 8 on 8- and 10-ft., 10 on 14-ft., etc.) at a level slightly above the outer rim. From these arms KNIVES or TINES extend downward to within 1/4 to 1 in. from the bottom of the pan. They are 3/4- or 1-in. high-carbon steel rod, forged triangular for the lower 6 or 8 in., tempered hard, and clamped to the arm. Tines are spaced about 4 1/2 in. apart on the arms, with corresponding tines on successively following arms spaced each 3/4 in. farther from the center of rotation. Successive impulses on a given particle of settled material are therefore as though from an expanding spiral. This effect is accentuated by so forming or pointing the blades as to have a component of push radially outward.

Feed enters tangentially through a subsurface slot near the bottom of the outer wall; tailing overflows an adjustable weir on the inner wall so placed that the runs of the feed and tailing streams are parallel and in the same direction; concentrate discharges across the annulus from tailing, at a point about two-thirds of the way around the tank from the feed inlet, through a shuttered hole, 1 1/2 or 1 3/4 in. diam., either in the bottom or at the bottom of the side wall. Best speed is a matter of experiment for a given feed, but is in the range of 300 to 400 f.p.m. peripheral.

Action in pan. Feed, which should contain a relatively high percentage of fine sand and considerable clayey material, and which, if thus composed, may have a limiting size as large as 1-in. (better about 3/16-in.) is introduced with enough water (±25%) to form a thick pulp. The stirring combined with the tangential feed entry sets up a swirl sufficient to cause vortical flow of the pulp mass as a whole. Hence the entering feed stream is introduced at a flat angle into a rising current of a quicksand made up to a large degree of the grains of intermediate specific gravity brought in by the feed. In this quicksand light grains of its size range float readily; large light grains are lifted by the rising current; heavy grains settle, or, at least, do not rise as far in the up-current as do the lighter grains. At the top of the swirling mass the surface layer, comprising the light material, flows down toward the center of the vortex and is skimmed off over the tailing weir. The heaviest grains gradually work to the bottom and are then plowed spirally outward to the outer wall and bled off through the concentrate shutter.

Since the carrying effect of the vertical stream depends both on the average specific gravity of the particles of intermediate gravity composing the quicksand and upon the plasticity of the mass as

determined by its clay content and the size of the sand grains, it follows that velocity, density, and plasticity must be properly correlated for optimum results. A heavy-grain quicksand requires less stiffness and less velocity of vortical flow; a lighter-grain quicksand must either carry more sand in suspension or be made less plastic; it can be made to do the former by increasing the rake speed; plasticity is decreased (stiffness increased) by increasing the clay content.

The quicksand minerals in the South African diamond fields, which minerals must be drawn off with the settled concentrate at a sufficient rate to prevent them from building up to overflow level, are olivine (sp. gr. 3.3), staurolite (3.7), other ferromagnesian and ferroaluminum silicates, ilmenite (4.5–5.0), rutile (4.2), corundum (4.0), hematite (5.0), limonite (3.8), tourmaline (3.0), and diamond (3.5). The principal gangue mineral is quartz. A quicksand composed of these minerals alone in proportions to give an average sp. gr. of 3.5, would, at 25% solids, have a sp. gr. of 2.2. But because of a considerable content of coarser quartz, it is doubtful whether it will average higher than 2.0.

Operating controls are speed, pulp density, setting of tines, height of discharge, and feed rate. Essentially, control is a balance between buoyancy of bed and time-factor. Time-factor must be great enough to permit small diamonds to settle; rake speed, tine setting, and pulp density control the settling rate; feed rate and height of discharge determine time-factor.

Capacity is close to 1/4 ton per sq. ft. of pan floor per hr. This corresponds to a time-factor of about 3 min. for good operating conditions (*119 J 997; 47 MM 208*).

Power consumption is reported at about 0.3 hp. per sq. ft. of floor area (*ibid.*).

Recovery of 95% is considered good, using 2 or 3 pans in series; ratio of concentration is about 25 : 1 (*ibid.*) For further treatment of concentrate, see Sec. 3, Art. 2, and Sec. 12, Art. 17.

Applicability. The only extensive commercial use of the diamond pan has been in diamond recovery. Use is reported at a small copper mine in Rhodesia where 77% recovery was made on an ore containing 12% Cu as chalcocite; concentrate assayed 27% Cu. This is not, of course, as good work as could have been done on the same ore by jigging and tabling (disregarding flotation in both cases) but would have been cheaper.

Battelle gravity-flow concentrator (*50 MI 636*) maintains a quicksand and applies the necessary upward impulse by rising water. Apparatus is a trough inclined 8 to 17° (usual slope 12 to 15°) with cross pipes near the bottom perforated at the sides with holes 1/2 to 1 in. apart through which a small amount of water is introduced into <10-m. material fed at the upper end. The water and the flow down-slope form a stirred bed of the pulp through which the heavy material settles into an inactive zone below the pipes from which it is withdrawn through water-fed discharge pockets similar to the deep-pocket classifier. Tailing discharges at the lower end. The apparatus is applied to materials such as iron ore containing a high percentage of heavy mineral of low unit value.

28. CHANCE CONE

Chance cone separator for coal utilizes vigorous stirring in a conical tank, supplemented by a rising current of water both to effect suspension of the sand and to supply additional, upward impulse. For detailed description of apparatus and its performance, see Vol. 2. For general discussion of the action of suspensions in gravity separation, see Art. 29.

Suspensoid Media

Terminology. The word SUSPENSION, when used in this article, without qualification, denotes simply a solid dispersed in water with no regard to particle size, or to the force or forces causing the suspension. If Brownian movement and its attendant forces are the dominant elements in the suspension, and it is substantially devoid of sand-size grains it is COLLOIDAL or NEAR-COLLOIDAL. A SUSPENSOID is a mixture of a colloidal suspension and sand-sized grains, so fine as to require but a small amount of agitation to maintain them suspended.

29. PRINCIPLES OF SUSPENSIONS FOR GRAVITY CONCENTRATION

Introduction. The buoyant power of a suspension is familiar to most country boys in the form of the ubiquitous quicksand, which is remarkable not for its alleged power to drag down and engulf unwary animals, but because it supports them to the extent that it does. A heavy-medium separator is simply a controlled quicksand. The first utilization of its properties in commercial ore dressing was undoubtedly in washers like the Robinson coal washer (*Ed. 1*), or the diamond pan.

Properties of suspensions. Very finely divided particles of most solids will remain suspended in still fluids more or less indefinitely, provided the fluid is of such character that the particles are in Brownian movement (see Sec. 12, Art. 8). The mixture has many true fluid properties. The suspended solid particles increase the apparent specific weight of the fluid, roughly in proportion to the weight fraction present. If the concentration of

solid is high, there is a marked increase in viscosity. As a result of these two changes, the power of the fluid to suspend sand-size solid is increased and the added sand causes further increase in the apparent specific weight and viscosity of the mixture, although now a certain amount of energy in the form of mechanically induced agitation must supplement the thermal agitation of the suspending fluid, if the suspension is to maintain homogeneity. Without the colloidal solid present the amount of mechanical energy input required is greater.

Apparent viscosity of a suspensoid (CONSISTENCY) is the time required for a given volume to flow through a tube under controlled conditions relative to the time required for an equal volume of water to flow through the same tube under the same conditions; in other words it is similar to the relative viscosity of a liquid. Apparatus for such measurements (CONSISTOMETER) and results of measurements therewith are given by DeVaney and Shelton (*RI 3469–R*). A summary of their results is shown in Fig. 74.

Nature of apparent viscosity may be inferred from study of Fig. 74, items *A* and *B*. Fine quicksands (item *A*) were made with 200∼325-m. solids of various specific gravities. The apparent viscosity increased at a relatively slow linear rate with increase in density of the suspension until a CRITICAL POINT was reached at from 17 to 30 volumetric per cent. of solids, whereupon the rate of change of viscosity increased rapidly through a relatively small change in pulp density until the mixture would no longer flow.

At the critical point the mean fraction of any plane through the mixture occupied by solid is $F^{2/3}$ and the mean distance along any line similarly occupied is $F^{1/3}$, where F = volumetric fraction of solid present. Table 91 gives values of these and other properties of these mixtures at the critical points.

Table 91. Critical and zero-fluidity values for several fine quicksands (*After DeVaney and Shelton*)

Solid	W	Critical values					Zero fluidity, 75 *cp.*			
		R_c	U_c	F_c	$F_c^{1/3}$	$F_c^{2/3}$	R_0	F_0	$F_0^{1/3}$	$F_0^{2/3}$
Quartz	2.65	1.3	7	0.182	0.567	0.321	1.8	0.461	0.772	0.596
Magnetite	5.2	1.7	4	0.167	0.551	0.303	2.8	0.419	0.748	0.560

Notation for Table 91.

W, specific gravity of solid
R, apparent mean specific gravity of quicksand
U, apparent viscosity of quicksand
F, volumetric fraction of solid present
c, subscript; critical value
0, subscript; zero fluidity

It is apparent from Table 91 and from Fig. 74, item *A*, that when the particles of a quicksand are so dispersed that there is on the average a diameter or more of clear liquid between them, they act in one way on the internal friction of the mixture, and that when they become more crowded than this, their effect and, inferably, their behavior change. Visual study (*CU*) shows that below the critical point collision between particles is rare; above it collision becomes increasingly frequent. The inference is that below the critical the particles act as obstructions or keys in the sliding planes of the liquid, offering resistance to sliding in proportion to their number and the nature of their surfaces; that above the critical there is superimposed on this resistance a further resistance due to the energy losses in inelastic impacts between the particles, that this loss cumulates with increasing frequency of collisions, and is greater the rougher the surfaces because of greater loss of momentum in oblique collisions. This hypothesis is supported by the fact that the most nearly equiaxed particles, *viz.*, atomized lead, can stand the greatest crowding before the critical point is reached; that galena stands closer spacing than quartz, and that rounded quartz and abraded ferrosilicon (Fig. 74, item *B*) show the effect at closer spacings than more angular fragments of the same materials.

Zero fluidity (chosen by DeVaney and Shelton as corresponding to 75 cp. apparent viscosity) occurs for all the fine quicksands studied within the narrow range of 0.419 to 0.461 volumetric solid fraction (Table 91), corresponding to a mean particle spacing of 1/3 of mean particle diameter. The volumetric solid fraction of spheres rectangularly packed is only 0.52. Hence very little differential motion (*e.g.*, the streamline flow in the consistometer) is required in such a mixture to effect a multitude of substantially inelastic impacts, whereupon packing occurs and friction between particle surfaces is added to the other resistances to flow to such an extent that fluidity disappears, and the mixture becomes a compacted bed (Art. 2).

Size of particle has a marked effect on the consistency-specific gravity relationship (see Fig. 74, *C* and *D*). The coarser the suspended particles the lower the apparent viscosity for a given specific gravity, but more agitation is necessary to effect and maintain dispersion, and consequently the coarse-particle media are the less satisfactory for close separations. The presence of slime of the medium material with coarser particles seems to have remarkably little effect on consistency within the normal working suspension-gravity range. Thus curve G_A, Fig. 74, item *D*, which is a reproduction of the galena curve on

Fig. 74, item *A*, and curve B on Fig. 74, item *D*, are both for <200-m. galena, but for curve G_A the <325-m. material was removed, yet at gravities between 2.6 and 3.0 the differences in apparent viscosity are almost within the limits of experimental error. Above

FIG. 74. Consistencies of heavy media (*after Shelton and DeVaney*).

the critical points the differences are great. This is due largely to the much higher percentage of angular sand in the quicksand (curve G_A) as compared with the suspensoid of equal sp. gr. (curve B).

Certain ore and added clay slimes have, however, marked effects on the gravity-consistency curve (Fig. 74, item *F*).

Sizing tests of several media discussed are given in Table 92. The relatively small amount of coarse material in the commercial media appears to be tramp middling, presumably from the ore, *i.e.*, the galena is somewhat hardened by the contained sphalerite and silica, which is shown by the chemical analyses. The degradation that occurs in use is seen by comparing the MASCOT and CENTRAL pulps with the <100-m. galena, which is representative of the make-up feed.

Note. Fractions of PATRICK, CENTRAL, and MASCOT media coarser than 65-m. are composed largely of ore particles.

a Contains 4.8% nonmagnetic material.

b Analysis: 63% lead and 4.1% zinc, comprising 73% galena, 6.2% sphalerite, and 20.8% gangue minerals, principally dolomite. The coarse galena removable by tabling is absent.

DeVaney and Shelton (*loc. cit.*) report comparative degradation tests in which >100-m. material, after 2 hr. tumbling, comprised 64.3, 56.8, 39.7, and 2.1% with quartz, 15% ferrosilicon, magnetite, and galena respectively; the corresponding percentages of <10-micron material were 1.8, 3.7, 5.2, and 20.3.

The maximum size of medium particle that can be suspended depends upon the medium gravity; with galena, 2.80 gravity is needed for 100-m. size, if agitation is to be slight.

Contamination in use increases apparent viscosity, or conversely, decreases medium gravity for a given working consistency. Fortunately the increase in consistency is not great, with galena at least, in the ordinary working gravity range (compare the curves labeled CENTRAL and GALENA on Fig. 74, item *E*). Fig. 74, item *F*, shows the effect of known contaminants; even clay has a relatively small effect on consistency, however, in the usual working gravity range. Contamination with low-gravity solid to the extent of 10%, as found in the CENTRAL medium, and 20%, as found at MASCOT, does, however, produce an important decrease in sp. gr., which must be remedied by cleaning (see p. 116). Contamination and degradation also cause marked decreases in sedimentation rates, which is important from the standpoint of thickening diluted medium. Fig. 75, item *G*, shows that 5% clay decreases the settling rate of <100-m. galena in the 2.2- to 2.6-gravity range to 1/20 or 1/30 of the rate of the uncontaminated material, and item *H* shows a similar decrease for mill contamination.

Slow settling at high densities, if accompanied by rapid settling at greater dilutions, would be of practical benefit, in that it would make for a self-supporting medium in the separator, where agitation is undesirable, and yet would require relatively small thickening area while preventing loss of medium solid in overflow. DeVaney and Shelton (*loc. cit.*) propose addition of bentonite to effect this end. Results of their experiments are given in Fig. 75, items *I* and *J*.

Self-sustaining medium is the desideratum for close separations, since it would eliminate all current effects; it would also be desirable from a purely operating standpoint, because it would not require running out when power failed, to prevent settling out and packing. Some operating galena suspensions are so nearly self-maintaining that they will not pack for several hours after agitation ceases, but pure galena must be ground very fine to attain this consistency. Normally media containing less than 70% solids by weight require stirring and upflow for maintenance; media containing more than 85% solids are usually too viscous for satisfactory operation.

Settling velocity in a suspension. When solid bodies that are large in proportion to the mean spacing of the particles of a suspension are introduced thereinto, the resistance

FIG. 75. Effects of contaminants on settling rates of suspensoid media.

offered is of the same nature as that offered by a true fluid in free settling, but both the buoyant force and the inertia resistance are larger by reason of the greater effective density, while the plastic resistance increases at a rate which visual observation indicates to be greater than the rate of rise in apparent viscosity. Experiment (*CU*) shows that the pressure at any depth in a high density suspension exceeds that at the same depth in a body of the supporting liquid alone by an amount directly proportional to the weight of solid suspended above the level of the plane of investigation. Visual observation of relatively dense sand suspensions, as in a jig bed, shows that in the process of gravitational penetration by a particle large with respect to the suspended particles and their mean spacing, the frictional resistance of the medium comprises both the internal plasticity of the suspension, such as is indicated by the consistometer tests, and a surface friction between the penetrating particle and a more or less consolidated mass of the suspended grains, which is of the nature of a slow-moving sand blast (Art. 2).

No data have been published on which to found an expression for settling velocities of introduced particles in suspensions in terms of the measurable quantities D (= mean diameter of introduced particle), S (= specific gravity of introduced particle), R (= effective specific gravity of suspension), and U_a (= apparent viscosity of the suspension relative to water = consistency). The best that can be done at present is to set up a general equation, on the assumption that the penetrating particle is free-settling with respect to the suspension and that the resistance is that due to inertia ($\propto V^2$), plasticity ($\propto U_a$), and skin friction ($\propto f$). Such an equation follows, in which V is the settling velocity of the introduced particle; K is a constant that takes care of units; f is a variable increasing at an unknown rate from an initial value of 1.0 as the volumetric fraction of solid in the suspension increases and as the angularity and roughness of the suspended and/or penetrating particles increase; and the other symbols have the meanings above stated.

$$V = \frac{KD^2(S - R)}{fU_a}$$

Solution of this equation for known cases when $R = 1$, $U_a = 1$, and $f = 1$, D is in mm. and V is mm. per sec., gives K. Using this value, and setting $f = 1 + F$ where F = the volume fraction of solid in

the suspension = $(R - 1)/(W - 1)$ where W = specific gravity of the medium solid, and using values of U_a estimated from Table 91, gives values of V that may be used for rough estimates of the effects of rising currents on separations.

Material for suspensions. Heavy media for commercial separations have been made with clay, quartz, slate, magnetite, galena, and ferrosilicon, as well as with mixtures of these solids; hematite, barite, pyrite, copper, high-carbon steel, and lead have been proposed and used experimentally. Water has been used universally as the suspending liquid, but there is no reason why a heavy aqueous solution or even a heavy organic liquid should not be used, except that such use would bring into play the disadvantages noted in Art. 31.

The factors important to consider in choice of a heavy-medium solid are: specific gravity, hardness, resistance to corrosion or other chemical action in aqueous solution; grain size, size distribution, and shape; sedimentation characteristics; properties lending themselves to separation from the products of concentration, recoverability, chemical composition, source, and cost.

Specific gravity must be higher than that of the mineral to be floated, as the combination of solid and water must have a combined gravity at least equal to that of the float mineral. Calculation of medium gravity is made from the equation

$$R = W/[p + W(1 - p)] \quad \text{or} \quad p = W(1 - 1/R)/(W - 1)$$

where p = decimal fraction of solids in the pulp by weight, and W and R have the meanings already assigned. The limiting values of p are not independently definable, but in general they lie in the range of 70 to 85%, being higher the coarser the solid particles and the smaller the content of colloidal slime. W must be >7 to produce a medium of 2.5 top gravity with proper liquidity. In general the maximum workable R for a medium with water the fluid is about $W/2$. The higher the value of W, the more fluid the suspension for a given value of R, but there is a practical limit in this direction in that suspensions with low volumetric solid fractions are hard to maintain.

Quartz-sand suspensions are used for coal cleaning; for most of this work R = 1.5 is sufficient. The maximum workable R attainable with quartz is about 1.8. This limits its use to a very small number of minerals.

Clay suspensions are not as dense as those made with sand, but they have been used for coal (*40 MI 656*). They are more viscous than sand for the same density, and hence the currents in the separating vessel have greater carrying power. Fine coal, which acts as a gravity-lowering contaminant, can be removed by froth flotation.

Magnetite (sp. gr. 5.0 to 5.2, but that available in commercial quantities varies considerably according to purity; hardness, 5.5 to 6.5) can be used for floating minerals heavier than coal, *e.g.*, brucite, chrysocolla, graphite, gypsum, or sulphur, but since 2.55 is about the maximum R of magnetite suspensions sufficiently mobile for use, it cannot be employed for floating the usual gangue minerals. It may also be used in conjunction with ferrosilicon.

Galena (sp. gr., 7.4 to 7.6; hardness, 2.5 to 2.75) will make a workable suspension of 4.3 sp. gr., if pure; with the normal impurities found in galena concentrates, however, and normal operating contamination, the usual maximum R at workable consistency is 3.3. It slimes badly in use and is more difficult to recover than either ferrosilicon or magnetite. Size used in one plant was:

Mesh	65	100	150	200	325	<325
Weight, % retained	1.2	0.8	1.2	2.1	6.8	87.9

Ferrosilicon, which is an alloy of iron and silicon with a small amount of carbon, has a sp. gr. over the range of usefulness from corrosion, permeability, and brittleness standpoints of 7.0 at 10% Si to 6.3 at 25% Si. Alloys of somewhat higher and lower sp. gr. at each composition can be obtained, the variation being due to differences in porosity. Alloys containing >22% Si are substantially nonmagnetic; those with less than 15% Si rust too rapidly. The maximum R for an alloy with 15% Si is about 3.5; 3.4 has been maintained in test operation at Butler Bros., but with normal plant contamination it falls to about 3.2; minimum is about 2.5 at about 70% solids. It is prepared by dry grinding in air-swept ball or rod mills. Dewatering is aided by magnetic clotting; dispersion is re-established by demagnetization in an a.-c. coil.

Ferrosilicon medium containing 15% Si is obtainable in standard grades No. 80 and No. 100 from Electro-Metallurgical Sales Corp. Typical screen analyses of the grades are:

Mesh	65	100	150	200	325	<325
Weight, % retained:						
Grade 80	1.4	8.6	5.9	9.7	15.4	59.0
Grade 100	2.4	4.1	4.2	9.2	14.9	65.2

The coarser grade is used for the higher sp. gr. Finer grades may be made by further grinding in a ball mill. Sp. gr. of this ferrosilicon is 6.7 to 6.8. Hardness is 7.3 to 7.6.

Ferrosilicon is difficult to wet. It should be wetted by stirring to a slurry and then permitting it to stand for several days in water. It must be thoroughly wet for satisfactory magnetic separation.

Lead is commercially available in atomized form, and from such powder a suspension of 6.2 sp. gr. can be made; suspensions of 5.2 sp. gr. are quite fluid. Oxidation in water or air to lighter products is

very rapid, however, and protective agents such as $S^{=}$, $CrO_4^{=}$, etc., would also cause more or less lightening of the suspension by reason of the reaction products.

Mixed minerals have been proposed as medium solid, one, usually clay or the like, contributing sustaining power, the other density. The higher the sp. gr. of the latter the less of it, of course, need be used.

Hardness is important in that it prevents loss of medium and increase in viscosity by reason of degradation. On the other hand, hardness great enough to prevent rounding off of edges and smoothing up of the surface is disadvantageous, because it induces such high viscosity that loading up to produce high specific gravity is not permissible. Ferrosilicon in the hard range (14 to 24% Si) suffers in this respect.

Resistance to corrosion and chemical action. The oxidized minerals and rocks (clay, quartz, shale, barite, magnetite, and hematite) neither corrode nor otherwise react harmfully with water. The sulphide minerals oxidize readily, to such an extent that their floatability, which is depended upon for separation from medium contaminants, is appreciably reduced. High-carbon steel rusts rapidly; lead oxidizes, probably to basic carbonate, to such an extent that heavy suspensions permitted to settle cement into a mass; copper oxidizes sufficiently for the suspensions to lose some density; ferrosilicon in the range of 10 to 15% Si is satisfactorily resistant to corrosion, and this resistance may be enhanced by adding a small amount of lime to the suspension.

Grain size, size distribution, and particle shape have somewhat related effects. In general the coarser the average grain size the more fluid the suspension, but the more agitation is required to maintain suspension. Correlatively, the longer the size range with a given maximum size, the more plastic and self-sustaining the suspension; the larger the weight fraction of very fine material, the higher the viscosity for a given loading and the lower the gravity, consequently, for limiting plasticity. The ideal size-distribution curve is one with a hump in the colloidal size range, contributing sustaining power, and another hump in the coarse end, adding density without corresponding loss of fluidity. Angular grains produce stiffer suspensions than rounded grains.

Quartz-sand suspensions, such as are used in the Chance process for anthracite and bituminous coal, are usually made of rather closely sized beach sand (20~100-m. with the great bulk of 40~80-m.). Galena and ferrosilicon used to make suspensions of 2.6 to 3.3 sp. gr. are ground to pass 100- or 150-m., with the grinding performed in such a way as to produce a maximum of slime (see Table 92). According to Rakowsky *et al.* (*U.S. 2 190 637/1940*) the coarsest galena sand in a self-sustaining medium of 2.5 top R is 150-m. At Mascot galena jig concentrate is crushed to 3-m. only before addition to the medium supply as make-up, but by the time it gets to the separating cone, attrition has reduced it to 20-m. maximum and the percentage of this size present is too small to give any trouble. Isern (*PC*) states that with <5-μ. galena the maximum working R is 2.5, while with <100-m. R can be run up to >3.

Sedimentation character is important from the standpoint both of making and operating the suspension, and of reconditioning used medium. The ability of a solid particle to attain Brownian movement, or to attain the surface state which results in Brownian movement, if the particle is small enough, whereby, in either case, sedimentation is greatly retarded, depends upon its capacity to take on and hold an electric charge against its surroundings, and this in turn depends on a chemical reaction with those surroundings resulting in the formation of an ionized film at the particle surface. $CO_3^{=}$ and $PO_4^{\equiv}$ produce such films on galena; $PO_4^{\equiv}$ will produce them on iron compounds; OH^- is effective for quartz and clays, it may be present in sufficient quantity in the water itself, but usually a slight excess over pH 7 increases the effect markedly. On the other hand H^+, and bivalent and trivalent metallic ions tend to have a flocculating effect, probably by decomposition or solution of the ionized surface compound, or suppression of the ionization. Hence colloidal suspension of minerals is a result of a proper combination of a mineral and its chemical surroundings. Unfortunately the chemistry of the complicated solutions resulting from the immersion of ore pulps in water is not sufficiently well known as yet to enable prediction of the kind and amount of ion necessary to effect Brownian movement in any particular medium-ore combination, and this must, therefore, be a matter of trial in most cases, with agitation always a standby for loss of viscosity.

Bentonite disperses (attains Brownian movement) with remarkable ease in water over a wide pH range and thus dispersed in low concentrations has a remarkable effect in retarding sedimentation of other solids without greatly affecting the consistency of the suspension (*RI 3469-R*).

From the standpoint of operation, the settling rate of the coarsest medium particles must be less than that of the smallest sink particles, otherwise the latter would become a part of the medium or the former would settle and pass out with the concentrate.

When thickening is the desideratum, as is the usual case after washing of medium from the products of separation, flocculation of the medium is desired to enhance sedimentation.

Then the chemical treatment is the reverse of that employed in dispersion. With magnetic materials, magnetic flocculation is induced. The safest procedure for calculating thickener size is to use the method of Coe and Clevenger (Sec. 15, Art. 6).

Recovery properties. No matter how clean a feed is washed in commercial operation before introduction to the heavy-medium bath, it always adds thereto a certain amount of sand and, usually, a greater amount of slime material. In so far as this derives from the lighter minerals of the feed, it lowers the density of the bath; in so far as it is clayey, it is likely to increase viscosity to the point that the suspension must be diluted to keep it workable, or the contaminant must be removed. With coarse-sand suspensions clay can be removed by sedimentation, but with slime suspensions gravity methods of reconditioning and recovery of medium solid are not available. Galena is recovered by flotation and this method is likewise available for pyrite and for metallic copper; coal may be tabled or floated from quartz sand; magnetite and ferrosilicon of less than 15% Si are highly permeable and are readily recovered on low-intensity wet magnetic separators. Efficient methods for reconditioning hematite and barite are not known.

Chemical composition of medium solid must be such that the small amount remaining in concentrate after washing (see p. 116) will not constitute a harmful contaminant. From this standpoint the use of galena at EAGLE PICHER (Sec. 2, Fig. 117) and of ferrosilicon at BUTLER BROS. (Sec. 2, Fig. 87) is ideal.

Source of medium solid is ideally the ore itself, but circumstances usually impose an extraneous source. Cherty-slate sand screened from tailing has been used in the Chance process; clay from a seam directly underlying the coal was used at PITTSBURG MIDWAY COAL CO. (*40 MI 656*); and the galena used at EAGLE PICHER is flotation concentrate produced in the same mill; the tailing from reconditioning is thrown back into the mill-flotation circuit.

Differential-density separation is the term applied to a sink-float operation in which the medium is purposely *not* maintained homogeneous in density from top to bottom at the specific-gravity figure at which separation is desired, but is so controlled, by agitation, and by feeding medium of different gravities at different depths, as to increase in density from the top downward, through a sp. gr. range of 0.1 to 0.2 points, the CRITICAL or SEPARATING DENSITY being placed at some point in the medium body well below the surface, and top density being held at about 0.05 less than that of the lightest float. Feed is introduced, either by plunging through the surface or by introduction into the side of the medium body at a point below the level of critical density, so that the initial or rough separation takes place at a density above the critical, whereupon clean heavy material sinks and clean light material floats part way to the top immediately, while middling, rising more slowly, assumes an intermediate position.

With top density maintained at a lower value than that of the desired float, further work must be done on the float particles to overflow them. This is done by maintaining a rising current of medium in the body, controllable in velocity by the rate at which medium is fed. Middling is displaced by further middling brought in by new feed, the downward reaction of the body of middling continuously suspended plus that of the rising float serving to give the displaced material a resultant downward motion. The rate of variation in medium density from top to bottom is rarely uniform. Small changes in the location of the zone of critical density are not serious.

A rising current of suitable velocity has controlling effect only on the particles that normally would remain just suspended in the medium at rest. These comprise the middling particles and the smaller particles of sink. The unmistakable sink and float particles are little affected.

The asserted ADVANTAGE of differential-density operation is that it separates in a zone of real and controllable depth rather than at a horizontal plane, with the results that the float layer is not crowded (RAFTING) and that middling and sink particles do not have to penetrate downward through a float layer. Another advantage is that water carried in by the feed is largely swept out immediately and does not dilute the bulk of medium in the separating vessel. The DISADVANTAGES are the large volume of overflow medium that must be recovered from the float and pumped back, and the fact that separation is actually dependent on current forces rather than simple buoyancy and is consequently subject to the irregularities caused by eddying. There is also a tendency toward sedimentation of large medium solids, which causes a bottom condition called CROWDING, in which the viscous resistance of the medium is so great that the settling sink has difficulty in penetrating it and so discharges in surges, carrying masses of the crowded medium with it.

30. PLANT OPERATION WITH SUSPENSOID MEDIA

Foreword. The material of this article, except as indicated otherwise by annotation, was compiled from patents, from sales literature issued by the licensing companies, and from articles in the technical press written by employees or representatives of these companies.

Apparatus comprises essentially a tank for containing the medium, means for agitating the medium as desired, and means for feeding ore and for taking away the SINK and FLOAT products.

Separating tanks (Fig. 76) are designed to fulfill the usual requirements in a separator, *viz.*, presentation of feed, maintenance of a flexible separating zone, and removal of products. In item *A* the structural elements are the conical tank *t*, with cylindrical rim *r*, edge overflow *v* for float, and central column *d* carried by girders *m*, which, by reason of air introduced through *p*, serves as an air lift for removal of sink. Hollow shaft *s*, surrounding *d*, carries scraping blades *n* on arms *q*, and is driven slowly by a bevel gear at the top. Make-up medium is fed through pipe *k* and medium drained from products by a launder *l*.

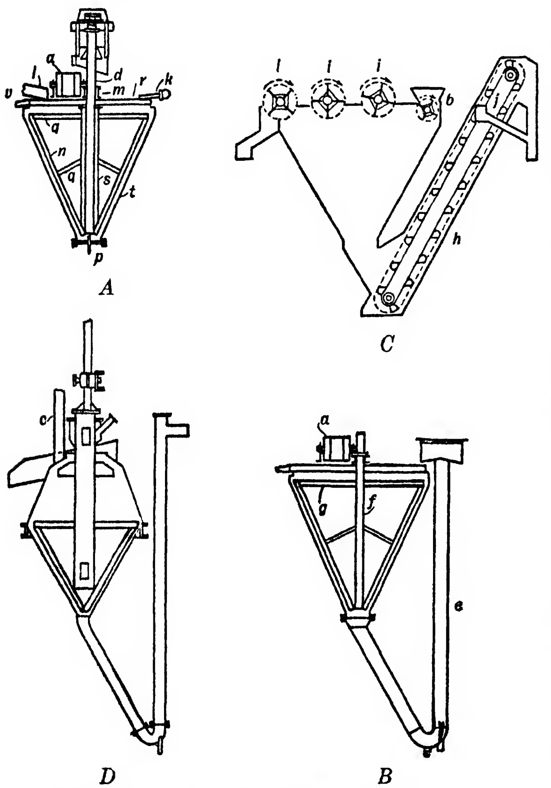

Fig. 76. Separating tanks for heavy-medium operation.

In two-product sink-float separators the fundamental design requirements are best satisfied by a downward pointed tank; this is conical in items *A*, *B*, and *D*, pyramidal in *C*.

Separating zone in all forms extends from the surface of the suspension downward to the point to which the heaviest feed particle eventually discharged as float penetrates under the impetus of introduction. Below this point the tank converges, in order to utilize gravity to move the sink to the discharge point. Above, it diverges, as in items *A*, *B*, and *C*, to afford increasing freedom of movement to rising particles and opportunity for entrapped sink to disengage, if the primary aim is clean float; it converges above, as in item *D*, and a sensible rising current of medium, increasing upward because of the convergence, is maintained, if high capacity is the prevailing desideratum, and float assay is secondary. Thus item *A* is the form used at MASCOT (Sec. 2, Fig. 102); item *B* at EAGLE PICHER, Central mill (Sec. 2, Fig. 117); and item *C* at HALKYN (Sec. 2, Fig. 107), to rough out low-grade tailing from zinc and zinc-lead ores; item *D* is used at several hematite mills (Sec. 2, Art. 28) to sink a salable iron product while, owing to the low unit value of this product, a relatively high-grade float is permissible, but high tonnage is essential. DIAMETERS of tanks used in ore separation range from 3 to 20 ft.

Feeding. In items *A* and *B* (Fig. 76) initial submergence to a considerable depth is obtained by causing the incoming stream of feed to plunge from the head pulleys *a* of belt conveyors. Such submergence is desirable to prevent rafting by a mass of crowded float, and to insure that middling shall be below the float so that it will be pressed down by it. In *C* submergence is effected by star feeder *b*, which is rotated in such a direction at such a speed as to insure the desired penetration. In *D* the feed is introduced relatively quietly, subsurface, through pipe *c;* this method has the advantage that loose water carried with the incoming material is floated on the column of suspension standing in *c* and may be drawn off without entering the cone proper and diluting the suspension therein. Subsurface feed chutes at BUTLER BROS. had to be widened at the bottom to prevent arching and clogging. Feed should be wetted initially to prevent adhesion of particles into clots or islands in which there is no freedom of movement and from which, therefore, sink and float particles do not readily disengage. Such wetting, however, usually exists already as a result of preliminary washing to remove fines.

The pointed shape of the separating vessel, together with a rising-medium current, tends to produce a teeter column of ore particles, the volumetric and gravimetric densities of which both increase downward; new feed entering this mass displaces some of its components and is itself displaced; the increase in top density of the mass caused by the heavy components in the new feed produces upward displacement of light material, and the initial momentum of the incoming particles serves to overcome some of the tendency of the heavier constituents to rise.

Removal of sink is the most difficult part of separator design. The aim is discharge of the relatively large particles of sink without at the same time removing sufficient of the immersing medium to cause disturbing downward currents in the tank. The method employed with suspensoid media is discharge into a separate chamber or pipe which has permanent open under-water connection with the separating tank, has walls not lower than the lip of the tank, and is provided with some sort of elevating device, *e.g.*, mechanical or air-lift.

In item *A* (Fig. 76) sink is lifted through central air-lift *d*, air being introduced through the bottom of the cone. In item *B* the air lift *e* is outside the cone in order to accommodate the central hollow perforated shaft *f*, which serves both to distribute medium throughout the depth of the cone and also to carry the stirring frame *g*. A similar arrangement is used in item *D*. In item *C*, sink is discharged by the perforated buckets on the elevator line in the housing *h*. The air lift is not suitable for very coarse sink, but is the simplest from a structural standpoint, and its operation is cheap and easily controlled—it is, therefore, the one most used in ore separation. Air consumption at MASCOT is 100 cu. ft. per min. per cone. Rate of sink discharge is controlled either by control of the speed of the discharge mechanism or by variation in cross-section of the sink outlet, as by a diaphragm valve. Clean-out gates should be provided at the bottom of air lifts, if possible, although R. Ammon (*PC*) reports that a conveyor idler was discharged up the air lift at EAGLE PICHER. The elevator discharges less medium than the air lift. An intermittent lock is used for discharge of coarse slate in coal separation.

Float is discharged in items *A*, *B*, and *D* by overflow of medium; in item *C* it is moved across the tank and scraped off by the four-armed rotary scrapers *i*, which may be operated at controlled speeds. In *C*, level of medium is maintained by an adjustable weir on box *j*, which affords auxiliary control of float discharge. The path of float from the critical separating level to the overflow lip should be as long as possible in order to afford time for winnowing out middling. With subsurface feeding and rotary agitation this path is an expanding spiral which, in addition to its length, produces constantly increasing spacing of the particles, with consequent increasing freedom of motion.

Capacity depends upon the specific gravities of the sink and float materials, the size of feed, and the closeness of cut required; at BUTLER BROS., treating iron ore at 1 $^1/_2$~$^3/_8$-in., with a relatively large leeway as to tailing (float) grade, a 4-ft. cone treated 40 long t.p.h.; a 6 $^1/_2$-ft. cone 110 long t.p.h.; and a 7 $^1/_2$-ft., 175 t.p.h., the rate per sq. ft. of cross-section for the latter cone being 8 long t.p.h.; in anthracite-coal practice (CHANCE PROCESS), again with considerable laxity as to tailing requirements, treating 4 $^1/_4$~$^1/_2$-in. feed, the usual capacity rating is 1 to 1.3 t.p.h. per sq. ft. of medium surface; at MASCOT and at EAGLE PICHER the duties of the cones on 1 $^1/_2$~$^3/_8$-in. and 1 $^1/_4$~$^1/_4$-in. feeds respectively are 2.7 and 1.3 t.p.h. per sq. ft. of medium surface. Capacity reduction with small feeds is more than proportionate to the reduction in minimum size of particle, and capacity also decreases with a given kind of feed as the proportion of sink increases.

Agitation is effected either by stirrers mounted on a vertical shaft, or by up-feeding of new and circulating medium (or water), or by both means acting in conjunction. The degree of mechanical agitation is small in the ore-separating cones, the stirring arms serving almost as much to prevent crowding and to move sink down the cone sides as to stir medium, but in the Chance cones using relatively coarse granular medium, the tip speed of the longest arms may be 300 f.p.m. At MASCOT stirring blades comprise essentially 4 vertical paddles cut out so that only a 3- or 4-in. rim remains; this is run at 5 r.p.m. About 150 f.p.m. peripheral speed is recommended as maximum in ore separators.

Feed point of up-fed medium is normally well below the zone of critical density, to permit merging of the multiple inflowing streams into a general rising current before this important level is reached. In differential-density operation the feeding of several streams of different densities at several different levels, either through annular pipes around the shaft or through pipes piercing the cone wall, has been proposed, but not reported in practice.

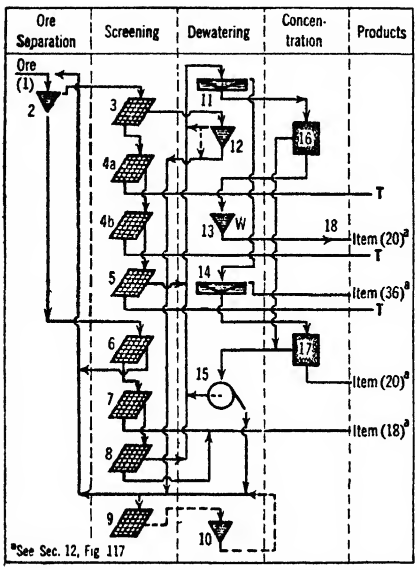
Rising rate of medium should be between that of the falling rates of coarse medium-solid and fine ore middling. Middling (as regards medium density) may be caused to rise or sink as desired by control of the rate of rising current.

Level of medium in the separator is maintained by an automatic control of medium-circulation rate actuated from a float in the separating tank.

Apparatus for multiple separation is described by Wuensch (*US Pat. 2 135 957*). It comprises a troughlike tank with sloping bottom, fed at the deep end. A jigging mechanism situated below the feed point receives the rapid sink and stratifies it. A screw conveyor transports the upper stratum of the jig bed together with delayed sink up the sloping bottom of the separating tank and in working it over effects further stratification. An outlet trap underneath the spiral skims off a lower stratum while

the upper layer is carried on to a second trap in and above which medium density is lowered by controlled injection of water. A second middling sinks and is removed here and residue is mechanically carried on to join the float.

Cleaning of medium and maintenance thereof at the proper density and consistency are the most fussy and expensive parts of heavy-medium sink-float operation. Essentially, the steps in order are: (1) Drainage of the cone products separately on screens of such aperture that the medium solid in suspension in water, together with any correspondingly small solid particles abraded from the ore, passes through, while the cone product with adhering medium remains as oversize. (2) Washing of the cone product by water sprays on a screen whereby adhering medium-solid is washed through the meshes. Wuensch (*US Pat. 2 151 175/1939*) recommends countercurrent washing in which drained medium is



Legend for Fig. 77.

1. Ore is sized down to 1/4- to 3/16-in. minimum and washed free of slime.
2. 2 @ 9-ft. Wuensch separating cones. Medium is a suspension of galena flotation concentrate in water, sp. gr. about 2.70 to 2.74.
3. 6 draining screens in parallel, 3 to each cone.
4. 2 @ 2-deck vibrating screens, *a* = upper deck, 1-in. aperture; *b* = lower deck, 1/4-in. aperture. The purpose of these screens, in addition to washing, is to size tailing for the crushed-stone market.
5. Trommel, 2 1/2-mm. aperture.
6. 2 draining screens, one for each cone.
7. Vibrating screen, 1/4-in. aperture.
8. As (5).
9. Leahy screen, to effect disintegration of any lumpy medium solid.
10. Storage tank, no overflow. Circulation is maintained through (9) and (10) with medium drawn off as necessary to keep up volume and density in (2).
11. 1 @ 20-ft. Dorr thickener.
12. Dewatering cone used to thicken drained medium, if this is necessary; when unnecessary, overflow, if any, joins spigot product in return to the medium-circulating circuit.
13. Dewatering cone; overflow wasted; spigot returns to main mill flow.
14. 1 @ 80-ft. Dorr thickener; removes colloids from medium circuit.
15. Filter.
16. Battery of Denver sub-A flotation cells.

FIG. 77. Recovery system for galena medium at Eagle Picher.

first washed with desanded slimy water originating from a fresh-water final wash. This process may have more than two stages, with desanding of the washings between successive advances. (3) Cleaning products from (1) and (2), by whatever means are applicable. Flotation is used at EAGLE PICHER (Fig. 77); magnetic separation at BUTLER BROS. (Fig. 78); at MASCOT, granular medium-solid is separated from granular gangue by tabling, and slime gangue and colloidal galena are separated from fine galena by sedimentation. At coal plants using sand, mechanical classification is sufficient to make sand-slime separation and coal is readily removed from the sand product by froth flotation or table flotation (Sec. 12, Art. 30). (4) Reclaimed medium-solid is returned to the medium-thickening and circulating system, to which is also added the requisite amount of new medium-solid and water to maintain the desired density. Spiral classifiers replace thickeners for ferrosilicon on account of the rapid settling of this medium, especially when magnetically clotted. With cheap medium-solid, regulated bleed off of thickener feed may be sufficient to maintain medium gravity and may be cheaper than concentration. Control of *p*H and the use of selective dispersants are useful in thickening both in order to give better control of the consistency of the underflow and to effect some further removal of gangue in overflow. Automatic devices for regulation of thickener underflow and classifier overflow are desirable and economical. Control of density to a range of 0.02 in sp. gr. for a day's run is reported (*PC*). The cleaner the medium, the more efficient the operation.

Of the relatively large amount of medium overflowed in differential-density operation only about 5 to 10% is diluted and requires reconditioning.

Loss of fine medium amounts, in general, to considerably less than 1 lb. per ton of cone feed. MASCOT reports 0.3 lb. of galena; EAGLE PICHER sends 2 lb. of galena flotation concentrate to the 2-stage cone treatment (Sec. 2, Fig. 117) per ton of original cone feed, but returns washings to the main plant, so that net consumption, although unknown, is known to be much less than this. Ferrosilicon consumption is reported to be 0.9 lb. per ton of cone feed at the HARRISON plant and 0.35 lb. at the MERRITT plant of BUTLER BROS., treating iron ore, and 0.7 to 0.85 lb. at BARTON MINES, floating garnet. The SINK AND FLOAT CORP. claims galena consumption as low as 0.1 lb. per ton of cone feed (*Tref 10/42*). The price of medium solid, conditioned for use as medium, will normally be double or more than double the market price for the crude material. The cost (1940) of galena lost at MASCOT was 6¢ per ton of mill feed and of ferrosilicon at BUTLER BROS. 3¢ per ton of feed to the heavy-medium separator.

The difficulty involved in washing medium from concentrate is decreased by not bringing medium into contact with dry feed; on the other hand, washed feed should be drained as thoroughly as possible before introduction to the separator in order to prevent undue lowering of top gravity by dilution.

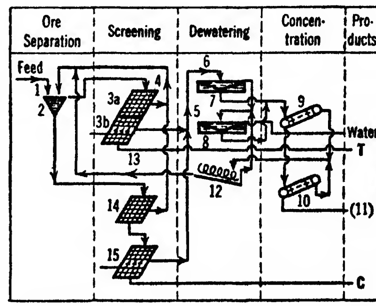

FIG. 78. Recovery system for ferrosilicon medium at Butler Bros.

Both desiderata are served in differential-density operations by wetting down incoming feed with low gravity return medium in a feed trough.

Capacity of the medium-reconditioning plant is relatively small; at MASCOT it is about 2.5% of the capacity of the cone plant, while at EAGLE PICHER about 50 tons of galena per day is withdrawn for reconditioning from a medium circulation of 1,500 g.p.m., the total galena in the medium stock being 350 tons.

Control. Wuensch (*US. Pat. 2 151 175/1939*) summarizes operating difficulties and remedies therefor as follows: DIFFICULTIES are (1) contamination of medium with ore fines and with oil, the first resulting in lowered medium gravity and probable increase in apparent viscosity, and the second in frothing and loss of medium in overflow in the reconditioning circuit; (2) settlement of medium particles, which produces crowding. REMEDIES are (1) to wash incoming feed thoroughly to remove both sand and slime from feed; (2) reduce oil drip preceding and in the sink-float plant; (3) remove contaminating substances in reconditioning. Wuensch further gives certain RULES FOR OPERATION: (1) Feed should be moist (dry feed clots; wet feed dilutes medium). (2) Introduce conditioned feed together with more or less medium at top of separator near center with enough momentum to carry it well below the surface. (3) Withdraw products continuously, otherwise crowding and rafting will occur. (4) Recondition circulating medium to remove sand, slime, and froth-producing contaminants (much of the medium should be recovered by drainage and recirculated directly in order to reduce the amount requiring thickening. The volume to be thickened may be further reduced by countercurrent washing). (5) Bleed off part of thickener overflow to keep down the amount of gangue colloids. (6) Place froth traps on thickener overflow to remove oil. (7) Supply new water as required to make up loss on moist products and in bleed. (8) Maintain medium density uniform or uniformly variable throughout the separator. (9) Keep viscosity as low as possible and yet maintain the medium without excessive agitation.

Fine feeds require a medium of relatively high fluidity and must be treated in the trough-type rather than the cone separator.

Feeding. The rate of feed should be constant and the grade of feed should be held as constant as possible. If feed containing a much larger percentage of sink than normal is fed to a cone, the sink displaces medium to the overflow, rising rate is increased, tending to throw middling into the tailing and, with sand media, the increase in rising velocity of the water carries sand out of the separating tank, which decreases medium density unless immediately compensated.

Notes on page 119.

a Jig concentrate ground in a small ball mill to pass a 2-mm. screen.
b Flotation concentrate made in mill. Reported at A.I.M.E., Feb., 1943 meeting, as changing to ferrosilicon on account of the difficulty in cleaning galena.
c <65-m.; 83% Fe, 14 to 15% Si and 0.5% C best from standpoint of high resistance to oxidation coupled with satisfactory magnetic susceptibility.
d Based on a price of 8 mills per kw-hr.
e All reject products of medium-cleaning system are sent to the main flotation plant (Sec. 2, Fig. 117), hence the only loss is that abraded into galena slime too fine for recovery (see Sec. 12, Art. 35). Loss reported at Feb. 1943 meeting of A.I.M.E. was 0.8 lb. per ton of raw feed for the two cones.
f Based on a price of 9 mills per kw-hr.
g Based on a price of 1.5¢ per kw-hr.
h Does not include royalty, depreciation, and overhead.
i MBI Bulletin.
j *Ore dressing notes No. 11*, American Cyanamid Co., July 1942.
k Primary cone.
l To each of two in parallel.
m Total for primary and secondary cones.
n Secondary cone taking recrushed primary-cone sink combined with <3/16-in. mill feed, all screened on 7-m.
o Per ton of cone feed.
p Crude ore.
q Ratio of concentration, 1.31 : 1.
r Jig tailing.
s Ratio of concentration, 1.64 : 1.
t Lean ore.
u $\frac{\text{Weight cone concentrate}}{\text{Weight cone feed}}$
v At Feb. 1943 meeting of A.I.M.E., a paper by Holt gave losses of ferrosilicon per ton of cone feed as 0.6 to 0.9 lb. per long ton on dense Mesabi ores, 0.73 lb. on manganiferous ores, and 0.9 to 1.2 lb. on porous iron ores.

Density of medium should range from somewhat below that of the heaviest float desired to slightly above that figure, according to the extent to which rising currents contribute to overflow. In general the gravities used in Chance operations for bituminous coal separation are from 1.30 to 1.45 and for anthracite from 1.50 to 1.60; limestone gangue at MASCOT is floated at 2.80 top gravity, chert at EAGLE PICHER at 2.84, and ferruginous chert at BUTLER BROS. at 2.90 to 3.05. Holt (*PC*) reports that with ferrosilicon medium the density can be held constant hour after hour; density change can be made in about 15 min., the bulk of circulating medium being kept as low as possible (45 tons medium-solid for 350 t.p.h.) to facilitate such change.

Variation in medium density from top to bottom of the separating tank occurs, even in the most stable workable suspensoid media. The extent of variation is partially controllable by the size and size distribution of the medium-solid, and, in operation, by the relative ratio at which medium is withdrawn at the top and bottom of the separating tank. At MASCOT sp. gr. of galena medium is maintained 2.84 at top and 3.05 at bottom; at BARTON MINES (separating garnet, sp. gr. 3.9 to 4.1, from hornblende, sp. gr. 3.0 to 3.4) top sp. gr. of ferrosilicon medium is 3.17, bottom 3.22. See also Table 93.

Circulation of medium by reason of withdrawals is at such a rate that tank content is replaced on the average once in 20 to 40 min.

Performances at several plants, as reported by Minerals Beneficiation, Inc., proprietor of patent rights in the heavy-suspensoid process, and by American Cyanamid Co., sales representative, are given in Table 93. Similar results have been published in the technical press by men from the plants (*141 #7 J 35*; *26 #9 MCJ 25; 141 #9 J 33; 153 A 429*).

The Sink & Float Corp. (*Tref 10/42*) reports that an 8×9-ft. Huntington-Heberlein tank at BUNKER HILL & SULLIVAN treats 70 to 83 t.p.h. of 1 1/4~1/8-in. feed comprising about 70% of run-of-mine, assaying 6.3% Pb and 3.5% Zn. Float is about 50% of tank feed and assays 0.42% Pb and 0.62% Zn. Sink, assaying 12.4% Pb and 6.5% Zn contains 96.6% of the lead and 90.9% of the Zn in separator feed Power consumption is about 1 hp-hr. per ton of mine ore. At BARTON MINES (*A TP 1578*) 1 1/4~3/16-in. garnet is separated from hornblende with ferrosilicon medium (all <300-m., 60% 800~1500-m., 30 to 40% <1500-m., at a sp. gr. which ranges from 3.10 to 3.25. Drained medium from sink returned to top of cone, that from float to bottom, in order to maintain top and bottom densities as nearly alike as possible. Cone feed is 60 to 70% of mill feed and cone tailing about 50 to 60% of mill tailing. Tailing >1/2-in. shows maximum garnet analysis of 0.3%; <1/2-in. tailing averages 3% and has run as high as 5% on difficult ore; total cone tailing averages 1.85% on normal ore. Loss of ferrosilicon is 0.70 to 0.85 lb. per ton of cone feed. Table 94 gives results of tests on a variety of ores made in the pilot plant of American Cyanamid Co.

Attendance is 2 men per plant at the metalliferous mills, more or less irrespective of tonnage, one on the cones and one on the medium circuit; or 3 men to a 2-cone plant. At BARTON MINES (*A TP 1578*), however, one man handles both cone and medium plants.

Water consumption is practically only that carried away on the washed coarsely granular tailing. This could, if necessary, probably be held to less than 5% on the separator feed.

Cost of treatment will probably fall between 6 and 20¢ (1939 prices) per ton of cone feed (exclusive of royalty), depending on the tonnage over which labor can be spread, and the cost of medium. The bulk of this cost is for medium recovery and for medium lost; power should not exceed 1 to 1.5¢ per ton.

b Top; bottom, 3.06.

c Top; bottom, 3.13.

d Sp. gr., 3.5.

e Calculated composite.

f Float, comprising upward of 60% of new feed, is of low enough grade to be discarded.

g Sink is of good grade and represents a good recovery on cone feed. Float and <10-m. would probably be ground for table or froth flotation (Sec. 12).

h The superior separation in the finer fraction is due to the better liberation of fluorspar at this size. Separate treatment of two sizes from 1/2-in. to 10-m. was superior to treatment of the longer-range combined product. Recovery was about 50% in a product of flux grade.

i Percentage rejections of lime and silica are high, but the product still contains too much contaminant. See specifications under "Washington magnesite," note **k.**

j See comment on preceding test.

k Specifications for "High-grade magnesite rock" are: Less than 1.5% CaO and 2.0% SiO_2; those for "Standard-grade rock" are: Less than 2.5% CaO and 3.27% SiO_2. All of the sinks but that at 2.90 sp. gr. satisfy the latter specification; only the last test at 2.95 sp. gr. satisfies the first. Rejection of lime and silica varied widely with the feeds, ranging downward from highs of 88% and 73% respectively. It is apparent that the grade of sink product and the concomitant rejections depend more upon the character of the feed than upon the sp. gr. of the medium within the range used.

l The calcine is marketable and the recovery of 60% is probably economically superior to any otherwise obtainable.

m Material rejection of SiO_2, sufficient to make the product marketable but insufficient to make it of metallurgical grade. The small increase in silica rejection with increase in sp. gr. of medium indicates that the silica in the sink is locked.

n 35% of feed rejected; high recoveries on material subjected to sink-and-float.

o Silica rejection in >10-m. was 84%. Recovery of iron was 89% in a concentrate carrying 7.7% SiO_2.

p Sink-and-float recovered 31% of the total feed or 70% of the >10-m. product amenable as a high-grade topaz product.

q At 2.80 sp. gr. can discard 70% of dump material, retaining a sink containing 62% of the Sn and 83% of the WO_3. Combining this material with the <10-m. yields 78% of total tin and 91% of total WO_3 in 30% of the total feed, in a product assaying 0.78% Sn and 0.59% WO_3.

Applicability. Present (1943) methods of sink-float separation may be applied to the coarse (>1/4- or 3/8-in.) fraction of any ore or mineral mixture provided only, (1) that valuable and worthless minerals differ in specific gravity, and (2) that the dissemination is sufficiently coarse that an economically clean light fraction is freed in sufficient quantity by crushing to, say, 3/4-in. as a minimum. If finer crushing is required to free clean float, the easily treatable >1/4-in. fraction is likely to be too small in weight to justify the relatively elaborate installation for medium cleaning and reconditioning; if only heavy mineral is freed by coarse crushing, the medium density required is too high except in special cases of low-gravity minerals such as coal, brucite, sulphur, and the like.

Maximum size treatable is limited only by the size of passages required for removal of sink; coal is treated as coarse as 8-in. and ores up to 2-in. at present, but Holt (*PC*) asserts knowledge that 6-in. material can be treated.

Minimum size treatable easily at present (1943) is about 1/4-in. Below this size viscosity and surface friction become so large in view of the small downward gravity resultant that fine middling material tends to float and, with the fine float, form a mat or raft, which holds up coarser middling and carries it into the overflow. Fine heavy material is correspondingly slow settling and tends to crowd near the bottom, increasing the resistance to settlement of coarser lighter material and either choking the apparatus or driving more middling into the overflow. Laboratory and pilot-plant operation can go down to 10-m. (see Table 94). Spread between maximum and minimum sizes must not be too great, if differential-density operation is practiced, since this involves some reliance on rising currents to lift tailing, and the current required to lift coarse tailing would also lift small particles of rich middling and concentrate.

Sharpness of the gravity split demanded for economic recovery sets limits to applicability. Heavy liquids in the laboratory will make splits over a sp. gr. range of ±0.05; patentees claim a range of ±0.1 in commercial operation of heavy-medium processes; even with a larger range this is superior to jigs or tables which require ±1.0 difference in sp. gr. for anything approximating a clean separation unless a large amount of middling is to be made. This is because of the fact that both size and sp. gr. enter into the relative weights that determine resistances to movement by currents, while sp. gr. only enters into normal sink-float operation. It follows, of course, that sink-float products are cleaner; it is claimed that on Mesabi jigging ores (see Sec. 2, Art. 28) heavy-medium treatment puts less than 1% of true float in the sink (*vs.* about 10% by jigging) and not more than 2% true sink in the float.

Tables 95 and 96 give analyses of TRI-STATE and MESABI ores on which heavy-medium treatment has been economically successful.

Tonnage of ore treated by sink-float operation in 1940 was about 5.5 million. In 1943 eight plants treated 10.5 million tons of lead, zinc, iron, tin, tungsten, and garnet ores.

Treatment difficulties increase with increase in sp. gr. of float and in quantity of middling; the former requires high-gravity suspensions, while the latter leads to a high rate of entry into and departure from the middling teeter column, with consequent danger of entrainment.

Capital costs of sink-float plants in Mesabi district (1938–39) were $14.80 per daily ton of feed for a plant to treat 350 long t.p.h. and $20 for one to treat 125 t.p.h. The MASCOT plant cost $35 per daily ton.

Sink-float *vs.* jigging. Table 97 compares performances by the two methods on iron ore at PATRICK plant of Butler Bros. G. J. Holt (*PC*) states that the sink-float operation recovered flats and porous material that the jig lost. Elmer Isern (*PC*) compares the sink-float plant at EAGLE PICHER with the former roughing jig plant as follows: Capacity increased 90%; connected horsepower decreased 30%; hp-hr. per ton treated decreased 21%; tons per man-shift increased 75%; tailing loss decreased 13%. Robert Ammon states (*PC*) that at MASCOT the recovery 1931–35 was 89% without sink-float operation and 1939–40 was 92–93% with sink-float; power consumption decreased 17% and tons per man-shift

increased 20%; roughing jigs formerly discarded 44% of mill feed as tailing with 11% of the zinc in the feed; the sink-float plant discards 57.5%, with only 5.5% of the original zinc.

Table 97. Comparison of sink-float and jig results on Western Mesabi iron ore at Patrick plant of Butler Bros. (*After Holt, 26 #9 MCJ 25*)

Recent jigging practice on the Mesabi circulates a relatively large tonnage of sandy middling, which tends to change the character of the roughing layer of the jig bed to a heavy quicksand. De Vaney (*Feb. 1941 meeting, AIME*) reported jig tests on sized Tri-state feeds of the character treated at Eagle Picher the results of which compared favorably with sink-float operation. Sink-float concentrate contained less than 0.5% of float material, all of which was fine; tailing contained less than 2% sink. Jig concentrate contained 6 to 9% of float and the tailing from 45 to 50% of sink at the separating density of the sink-float medium.

Heavy Liquids

Introduction. Heavy-liquid separation for commercial dressing has been described in a number of patents issuing over a period of 50 yr. (*Ed 1 636*). The liquids prescribed for use have been more or less concentrated aqueous solutions of highly soluble metallic salts, zinc chloride; or organic liquids of relatively high specific gravities such as carbon tetrachloride (sp. gr. $1.582^{21°C}$) and other halogenated hydrocarbons. The impractical elements in all of these proposals have been the corrosive, unstable, and/or toxic nature of the liquids prescribed, their high first cost, and the difficulty and expense involved in reclaiming them from the separated products.

31. DU PONT CHLORETHANE PROCESS

The nearest approach to commercial success with heavy liquids reported is an experimental coal-cleaning plant at Weston Coal Co., Shenandoah, Pa. (*139 #5 J 33*). The separating liquid used was pentachlorethane (C_2HCl_5; sp. gr. $1.678^{20°C}$); this liquid was available in commercial quantity at a unit price which, though high, was not beyond the limits of commercial practicability, if losses (consumption) could be kept to a low figure. This was attempted by thorough and complete filming of feed particles, prior to their introduction into the separating bath, with a water film, such wetting being aided and insured by the addition to the water of a small quantity (0.01% on the water) of a wetting agent such as starch acetate or tannic acid. Such an aqueous film resists displacement by the chlorethane, so that the latter cannot film or be absorbed by the solids, and the chlorethane being substantially immiscible with water drains away from the water-wetted surfaces readily when given an opportunity.

Treatment at the Weston plant, which had a capacity of 100 tons of raw anthracite per hr., comprised preliminary crushing, screening to commercial sizes, and water-washing of the raw feed in the main breaker. The sized products were then sent separately, in order, to: (1) a wetting-out section comprising a shaking conveyor onto which fishtail sprays delivered wetting solution; (2) a shaking dewatering screen with 1/4-in. round apertures on which the wetted feed was sprayed with water to wash away silt and clay disengaged by the detergent action of the wetting solution; (3) a separating box containing a 2-ft. depth of the chlorethane overlain by a 2-ft. layer of water, with mechanical means for scraping out separately the layer of sink that passed down through the chlorethane, and the layer of float (coal) that penetrated the water layer but did not enter the chlorethane, and a further adjustable mechanism for diverting middling, more or less suspended in the chlorethane layer, upward or downward into the sink or the float zone; (4) separate draining and washing screens for the sink and float products; (5) a recovery system for the chlorethane, comprising a settling tank in which the chlorethane and dirt settle, from which water overflows and the thickened sludge is drawn; and a batch-type steam still for distilling the sludge, vapor from which passes to a condenser that delivers condensate to a cooler and thence to a tank in which the chlorethane and water stratify and are separated.

All apparatus containing chlorethane must be liquid- and vapor-tight on account of the toxicity of the compound when inhaled, ingested, or absorbed through the skin. Any small quantity of the separating

liquid remaining on the products is asserted to evaporate without harm. There is no fire hazard connected with the use of the chlorethane or of others of the halogenated hydrocarbons, since they are non-flammable. Consumption of about 3/4 lb. of separating liquid per ton of cleaned coal is reported.

Performance, as measured by condemnations, was 19 3/4 cars (50-ton) out of 295; float in the sinks was less than 1% more than that in zinc chloride laboratory controls. The tests indicated that the capacity of the separating tank was about 50 tons of feed per hr. per sq. ft. of surface of separating bath, but, despite this high capacity and the relatively minute consumption of separating liquid, costs are still too high to justify adoption in anthracite practice.

WATER-IMPULSE SEPARATORS

Water-impulse separators are those in which the different inertias of particles of different sizes and specific gravities, when subjected to the impulse of moving streams of water, cause the different particles to travel separated paths.

Water impulse is utilized in the film sizers and in a small number of relatively ineffective concentrating apparatus utilizing the principles of free- and hindered-settling classification.

32. FILM SIZING

Film sizing is a form of gravity concentration in which settling plays the smaller part, separation is predominantly on the basis of particle size, but the difference in resistance to scour by particles of the same size and different specific gravities is utilized. Apparatus consists essentially of inclined planes, with smooth to finely rough surfaces, on which material to be separated is subjected to the scouring action of relatively thin layers of flowing water.

When a thin film of liquid flows over a plane solid surface, the layer next to the surface remains substantially at rest. The velocities of successive layers outward from the solid surface increases progressively to a maximum near, but not quite at, the free surface, where it falls slightly. Since the ability of a current of water to transport solid varies as a power of the velocity greater than one, the upper layers are the more effective. This has two results. A particle in suspension in the current is acted upon by a greater force near its upper than near its lower edge, an overturning motion the resultant of which is toward the lower layer of the film is imparted, and the settling rate is accelerated. After the particles reach the separating surface (and it is only such particles that can be saved), the current moves them down-slope by rolling, sliding, or by the movement of alternating suspension and deposition that Gilbert (*Prof. Pap. 86 USGS*) calls LEAPING. Rolling and sliding can be considered as due to a substantially non-eddying stream; leaping is caused by eddies. In rolling and sliding, the larger particles, being the ones that project farthest upward from the table surface, are the ones that are acted upon by the most powerful currents, and they move most rapidly, notwithstanding their greater mass. Of two particles of the same size but of different specific gravities, the heavier moves more slowly, under the equal forces applied, by reason of its greater mass. The result, then, of the rolling and sliding action of the film on the solid particles in contact with the separating surface, considered alone, is to cause a separation of fine from coarse and heavy from light, the finest heavy material remaining near the upper end and the largest light grains overflowing the lower edge. This is true film sizing. If any grain is so large as to stand above the water surface, the transporting force on such a grain, although the maximum that can be exerted by the film, will have less effect than on the large submerged grains, and such a projecting grain will remain near the feed point.

When, for any reason, the separating surface is rough, which, necessarily, is the case even on the smoothest bottom as soon as solid matter begins to settle out, several new effects enter. The depressions in the separating surface act as minute riffles in which fine particles settle and are protected from the sweep of the current, eddying within the depressions causes concentration of heavy mineral, the rough surface prevents sliding and retards rolling, and eddies are produced in the main stream which sweep smaller particles upward into momentary suspension and cause them to move down slope with a velocity equal to that of larger particles. The net result is to dull the sharpness of separation of heavy from light mineral.

The flowing stream advances in a series of waves. This fact aids in moving the larger particles, either because the waves strike definite blows against the larger particles, while failing to strike the smaller, or because, when the crest of a wave is passing, large particles that projected in the trough are submerged.

Davis (*86 J 905*) developed experimentally the following empirical relation between slope s, in degrees, of a ground-glass surface, water quantity w in lb. per min., and diameter in mm. D of the average grain of quartz to be washed from a quartz-galena pulp.

$$\sin s = \frac{1}{96}\left(\frac{275 - 50\sqrt{1/D}}{w} + \frac{10}{\sqrt[4]{1/D}}\right)$$

This equation gives no necessary clue to the real relation existing between these quantities and is useful only within the range of the experiments.

Classification of film sizers may be made on the basis of whether true film sizing or sluicing predominates in the action: in continuous buddles, it is the former; in building buddles and strakes, the latter.

33. REVOLVING ROUND TABLE

Description. This is the modern form of buddle. It consists (Fig. 79) of an obtusely conical surface, substantially smooth, carried on an umbrella-like frame, supported on a vertical shift resting in a step bearing at the bottom and carrying at the upper end a worm gear by means of which the whole is caused to revolve slowly. A fixed feed distributor supplies pulp to from one-third to three-quarters of the upper surface. Fixed launders around the periphery receive tailing, middling, and concentrate. Wash water is supplied over the remaining surface at the center and there may also be a spirally disposed spray pipe suspended over the surface along a line such as XX (Fig. 80) that will give a final wash to concentrate before its removal. A strong jet Y, placed just ahead of the tailing launder, insures removal of the last of the concentrate.

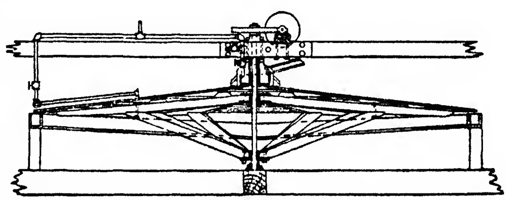

Fig. 79. Revolving round table (single-deck).

In Fig. 80, consider three particles of the same size but different weights, say concentrate, middling, and tailing, respectively, starting at point a. The motion of each with respect to the table surface is radial in direction, but the velocities will vary inversely as some function of the specific gravities. After a short interval of time, therefore, the radial components of travel will be as indicated by the vectors c, m, and t, respectively. The angular travel will be the same for all three, say to the position of radius r_1; the resulting positions will be c_1, m_1, and t_1, respectively, and the paths the dotted spirals connecting a with the respective points. After a second increment of time, during which the original radius has moved to the position r_2, and the radial travel of the particles has been less than in the preceding interval by reason of the lessened velocity of the pulp stream due to its increasing width and decreasing depth, the tailing particle will have left the table at position t_f, while middling and concentrate particles will be at m_2 and c_2, respectively. They will finally leave the table at positions m_f and c_f. Differences in rate of radial travel will, of course, be greater if the concentrate and middling particles are smaller than the tailing particle.

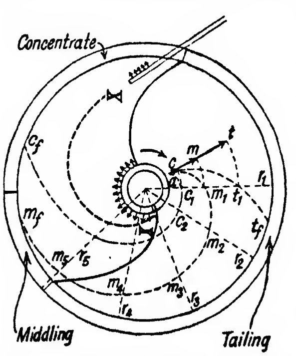

Fig. 80. Sketch of action of revolving round table.

Evans revolving round table was furnished with a fixed conical center head with spiral periphery, so arranged that concentrate depositing on the upper portion of the table in the feed sector would pass under the head and be protected from further washing by feed pulp, but would be exposed when the wash sector was reached. This type of table was extensively used in Lake Superior copper mills and in the early days at Anaconda.

Multiple-deck revolving round tables (Fig. 81) were devised to overcome the handicap of low capacity. The limit was reached in the 20-deck Anaconda table shown. The decks were 19 ft. diameter, built of concrete laid on sheet-steel support, spaced 1 ft. apart vertically. The 20 decks were carried on eight steel columns around the outer periphery and the columns rested on a steel ring running on wheels on a circular track. Motion was transmitted through a pinion to a circular rack carried on the lower side of the supporting ring. A central shaftway, 4 ft. in diameter, carried the distributing pipes for pulp and wash water and enclosed a 30-in. square ladderway.

Extensive tests were carried out at ANACONDA preceding the construction of the round-table plant (1912). The reports of these tests by Crowfoot (*49 A 417*) and Laist and Wiggin (*49 A 470*) are substantially a textbook on the subject and form the principal basis for the following paragraphs.

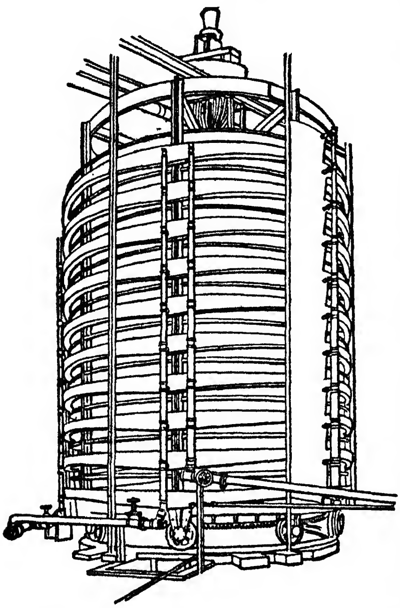

FIG. 81. Multiple-deck revolving round table.

Surface. Planed wood, linoleum, medium-weight canvas, and cement concrete troweled to a finish approximating that of the medium-weight canvas were tested. Results are given in Tables 98 and 99. Comparison between cement decks with rough and smooth finish is shown in Table 100.

When using rough-surfaced cement and canvas-covered decks, solids built up as much as 3/8 in. deep. Yet the tests showed that notwithstanding the building, the rough deck afforded better protection for sulphide and held it back against the wash water.

Fluted- and corrugated-glass surfaces have been tested against wood on revolving round tables in the CORNISH TIN MINES (*14 MM 32, 89, 90, 154, 333*). Various forms of glass surface have been tried, but the best results were obtained with about 16 flutes to the inch, 1/32 to 1/16 in. deep, with crests either sharp or rounded. In one 16-hr. test on an 18-ft. glass-top, concave table with corrugations set at right angles to the slope, slope 1.5 in. per ft., when running against a wooden deck of the same diameter sloped 1.25 in. per ft., the glass top yielded 847 lb. of concentrate assaying 32.2 lb. Sn per ton and the wood 1,557 lb. of 15-lb. concentrate. The tailing on both decks carried 6.5 lb. Sn per ton and the feed 9.2 lb. Sn per ton. The feed rate on the glass deck was 5.7 tons per 24 hr.; on the wood, 3.8 tons. The glass deck worked under the disadvantage that the deck was pyramidal rather than conical so that there was a rush of pulp in the valleys at the joints. Tailing assay at the center of a glass section was 5 lb. Sn per ton against 7.5 lb. at the joint. Trewartha-James (*14 MM 89*) says that the glass top is very sensitive to variations in size, pulp density, and mineral content and that the pulp density must be closely correlated to the slope. The glass top is said to be better than the wood on rounded particles.

Contour of surface. The length of the cross-section of the pulp or wash-water stream on a convex round table, cut along a line equidistant at all points from the center of the table, increases, obviously, as the distance from the center to the chosen section increases. Since the volume of water flowing down any given sector is substantially constant for any given position of the sector, the thickness of the film must necessarily decrease as the periphery is approached.

On any given sector in position for concentrate removal the solid near the apex of the sector is coarser and richer than that near the rim, which shows the action of the round deck as a whole is not true film sizing but rather progressive deposition of the heaviest particles as the velocity decreases toward the rim, after which film sizing removes the larger gangue particles.

Slope affects recovery, grade of concentrate, and capacity. It is interdependent with quantity of wash water, a flat slope requiring more water to produce a given grade of concentrate than steep slope. On the other hand, steep slope tends to lower recovery. Capacity is greater with steep slope. Standard practice is 1.25 to 1.5 i.p.f., being lower the finer the feed, the heavier the heavy mineral, and the greater the spread in specific gravities.

Table 98. Comparison of wood, linoleum and cement deck surfaces on revolving round tables at Anaconda Copper Co.

	Kind of deck		
	Wood	Linoleum	Cement
Tons solid per 24 hr.	4.4	4.5	4.5
Per cent. solids in feed	7.6	7.5	7.5
Assay of feed, % Cu	2.77	2.75	2.76
Assay of concentrate, % Cu	5.29	5.92	7.03
Assay of tailing, % Cu	1.55	1.65	1.61
Recovery, %	62.1	55.3	53.8 *a*
Ratio of concentration	3.1	3.9	4.7
Water, fresh, g.p.t. of feed	6,022	4,974	5,424

a Results on cement decks were greatly improved in later work. See Table 100.

Speed determines the horizontal component of velocity of particles and, therefore, fixes the radial velocity required to discharge products at the proper places on the periphery. High speed of revolution requires steep slope and much wash water; low speed, *vice versa*. In LAKE SUPERIOR copper mills the speed on relatively coarse sandy feeds is 1 r.p.m. In some of the slime-testing work at ANACONDA 1 rev. per 100 min. was tried, but channeling occurred. Increase to 1 rev. in 19 min. eliminated channel-

ing. One rev. in 4 min. was the speed for the 20-deck machines when run to make finished concentrate and tailing and a circulating middling. At Ohio Copper Co. the speed of 20-ft. machines was 1 rev. in 72 sec.

Diameter affects the length of separating surface parallel to the flow of material and determines the allowable duration of feed. With small diameter the time required for the sheet of concentrate to travel from feed to tailing-discharge point is relatively short and duration of feed to a given section must be made correspondingly short by increasing speed of revolution. Greater diameter or less slope permits lower speed.

Feed is usually unclassified slime not amenable to flotation. Results are invariably improved by de-colloiding (Sec. 8, Art. 7), in order to get away from suspensoid formation (Art. 29) with resulting loss in fine-sand values. Feed pulp should be near 10% solids. Percentage of surface fed varies with results desired; it is a matter of experiment for any particular case.

Water consumption depends upon the size of feed particles, grade of concentrate desired, and slope and character of deck surface. Water is supplied with the feed, as dressing water at or near the center, and as spray water for concentrate removal near the periphery. The 20-deck, cement-surface tables at Anaconda, treating 6 to 7 tons solid feed per deck per 24 hr., required 3 gal. dressing water and 6 gal. spray water per min. The feed pulp contained 10 to 15% solids. Coarse feed requires the most water; more water is required for high-grade concentrate than for low-grade. Canvas decks require more water than cement. Linoleum decks require less water than cement; wood decks require more. *Richards* gives the average water discharged per ft. at the periphery of 18-ft. tables in Lake Superior mills as 31.8 g.p.m. pulp water; 10.6, dressing water; and 9.5 spray water.

Table 99. Comparison of cement and canvas deck surfaces on revolving round tables at Anaconda Copper Co.

	Kind of deck	
	Cement	Canvas
Tons solid per 24 hr.	8.3	8.3
Per cent. solids in feed	9.3	9.8
Assay of feed, % Cu	3.36	3.46
Assay of concentrate, % Cu.	7.84	5.79
Assay of tailing, % Cu	0.93	0.94
Recovery	82.0	87.0
Ratio of concentration	2.9	1.9
Speed, r.p.h.	3	3
Slope of deck, i.p.f.	1.2	1.13
Water, fresh, g.p.t. of feed.	1,218	1,517

Note. Crowfoot states that the extra cost of handling, transportation and smelting of the lower-grade canvas-deck concentrate would probably more than offset the increased recovery.

Power consumption is about 0.15 to 0.25 hp. per deck for tables 15 to 18 ft. diameter, the lower figure applying to the multiple-deck tables. The 20-deck tables at Anaconda each had a 5-hp. motor and actually consumed about 3 hp.

Attendance required is low, especially if the feed is regular. At Anaconda each operator took care of four 20-deck tables.

Capacity depends largely on the size of feed and slope of deck, being higher for relatively coarse feeds and steep slopes. At Lake Superior mills 10 to 20 tons of relatively sandy feed was treated per deck per 24 hr., the decks ranging from 16 to 20 ft. diameter. Final figures on Anaconda slimes were 6 to 7 tons per 24 hr. per 19-ft. deck or about 45 sq. ft. of deck area per ton of total feed, including 8 to 10% returned middling. At Ohio Copper Co. a 20-ft. deck treated 12 tons dry slime per 24 hr. and could treat 15 tons without crowding, making, however, only 20% recovery as against 54% at Anaconda.

Table 100. Comparison between rough-finish and smooth-finish cement-deck round tables at Anaconda

Character of feed	Rough finish			Smooth finish		
	Medium	Fine	Fine	Medium	Fine	Fine
Tons solid per 24 hr.	31.5	12.3	4.8	20.2	14.0	6.3
Per cent. solids in feed	16.5	9.0	7.1	11.9	7.1	7.7
Assay of feed, % Cu	4.25	3.37	4.23	4.86	3.23	2.63
Assay of concentrate, % Cu	18.90	16.64	19.06	17.00	16.08	13.90
Assay of tailing, % Cu	2.21	1.47	1.82	2.34	1.51	1.01
Recovery, %	54.0	62.1	63.0	60.5	58.8	66.6
Ratio of concentration	8.2	8.0	7.2	5.8	8.4	8.0
Water, dressing, g.p.t. of feed	440	2,035	3,746	651	1,424	3,378
Water, concentrate removal, g.p.t. of feed.	814	2,480	6,078	1,094	1,171	2,491
Water in feed, lb. per min. per ft. of total circumference	4.15	2.88	1.70	3.88	4.74	1.95
Water, dressing, lb. per min. per ft. of total circumference	1.39	2.60	1.82	1.34	2.15	2.11
Water, concentrate removal, lb. per min. per ft. of total circumference	2.86	3.32	3.18	2.40	1.79	1.69
Speed, r.p.h.	2	2	2	2	2	2

Recovery. Probably 40 to 50% is the average range of recovery on slime feed. Some Lake Superior recoveries ran as high as 80%, making a low-grade concentrate. The average of all Anaconda experimental work showed 54% net recovery of silver and copper in a concentrate assaying about 6.5% Cu from a slime feed assaying 2.25% Cu.

Applicability. Round tables are used at present only for ores that contain mineral of high unit value and not at present susceptible to separation by flotation. Practically this means cassiterite. See Sec. 2, Fig. 44.

Circular stationary buddle is a stationary round table with the feed apron, spray pipes, and take-off launders carried on a revolving frame. Principles of operation of the two machines are the same.

Building buddle, in simplest form, is a rectangular box, usually with slightly sloping bottom, the lower or discharge end of adjustable height. Feed is distributed across the upper end by means of a distributor and flows through the box, the lighter material overflowing at the lower end. Solid particles deposit initially in order of size and weight, the heavier and larger particles near the pulp inlet, ranging gradually to the finest and lightest near the discharge. The slope of the surface of the deposited solids increases to a maximum, and with this increase the surface becomes smoother, owing to deposition of fine heavy mineral, and the pulp stream becomes thinner. Under these circumstances less and less coarse gangue is able to remain near the head end, but is rolled down-slope. When the slope of the settled solids becomes so steep that an excessive amount of concentrate is carried down, the height of overflow is raised, the slope thus lessened, and building again proceeds. If solids build up too rapidly at the head, the feed rate should be increased or feed pulp diluted to increase the velocity of the stream. After the overflow level has been raised to the maximum height feeding is stopped, the bed of solids is marked off into sections representing concentrate, middling, tailing and slime, and the respective sections are shoveled out separately. During the process of building, the surface of the depositing solids should be swept lightly with a cloth or broom to prevent the formation of banks and resulting channeling.

In a building buddle treating a feed containing relatively coarse sands, the action after the bed has begun to deposit is substantially the same as that on a canvas table. With very fine feed the surface of the deposited solids is substantially smooth and concentration takes place largely by film sizing.

Circular building buddles are a development from the foregoing in which the building box is a cylindrical tank usually 18 to 20 ft. diameter and about 18 in. deep with outlet pipes at various levels. A conical feed sole 5 to 6 ft. diameter at the center and overhead arms revolving 5 to 12 times per min. carrying sweeps of rags or twigs for brushing the building surface are provided. The products form concentric rings which are shoveled out separately.

34. STRAKE

Description. The strake is a shallow, usually broad, sloping trough with the bottom fine-roughened, used principally for saving gold from relatively fine pulps. Its action is both film sizing and sluicing; one or the other action predominates according, in part, to the construction, and, in part, to the conditions of operation. The collecting surface is blanket, plush, corduroy, carpet, canvas, silent felt, hides, or like material. These materials serve much the same purpose as riffles, but they have shallower depressions, which are sufficient to hold concentrate against the wash of the pulp-carrying current but not deep enough to form much of a bed.

The WIDTH is usually made that of the blanket or other bottom covering or some multiple thereof; the DEPTH of the sides is merely sufficient to guard against splash, say 3 or 4 in.; the LENGTH depends upon the ore and upon the results demanded but varies in general between 5 and 50 ft. The slope is usually between 1 and 2 in. per ft., and the feed pulp ordinarily carries from 5 to 25% solids, but may carry much more. Pulp is distributed evenly over the width and allowed to flow for a definite time, predetermined by experience and dependent upon the time required for the concentrate layer to build down to the discharge end. The feed is then cut off and, with or without a preliminary washing, the concentrate is removed, whereupon feed is again started. Variety lies in the form of covering and in the method of removing concentrate.

Frame is primarily a film-sizer consisting of a slightly inclined smooth-bottomed rectangular trough, open at the lower end to allow free egress of pulp and wash-water streams. It is from 3 to 5 ft. wide, 10 to 20 ft. long, with bottom of smoothly planed boards, and a slope ranging from 1 in. per ft. for the finest material to 2.5 in. per ft. for fine-sand feeds. It is fed over a distributing board with a thin stream of pulp. A thin bed of heavy material builds on the separating surface, gradually extending to the discharge end. The surface is worked over with wooden scrapers or brooms to prevent channeling. Just before the advancing sheet of concentrate reaches the discharge end feed is cut off, the deposit washed with clean water to discharge a middling, then concentrate is removed with a jet of water, or swept off. By building frames in pairs and providing for diversion of feed pulp to one or the other as desired, and by arranging them to tilt sidewise for washing, considerable time may be saved, one being fed while the other is being washed. Three frames, forming the sides of a triangular prism, mounted on a properly inclined axis, allow practically continuous operation. Water-tilting boxes lever-connected to diverting launders for the products have been used to make the work automatic. The frame is easily constructed and is a highly useful slime concentrator for small preliminary plants.

Capacity depends upon character and size of feed. If sulphides are to be saved, about 0.1 ton of solid per ft. of width per 24 hr., in a pulp containing about 10% solids, is a fair basis for estimate for slimes, and about 1 ton at 15 to 20% solids for sands. Capacity is higher for native metals.

Recovery is low; GRADE OF CONCENTRATE is higher than on rougher surfaces.

Canvas table has been widely used for treating slimes in gold and base-metal concentration. It is better adapted for treating fine feeds than the blanket strake, is usually wider, and the length is less in proportion to the width. Operation is the same as that of the frame. Canvas is not removed for washing concentrate, as is done with blankets, but feed is stopped, deposited mineral is washed with a stream of clean water, then swept off with a broom or flushed off with a flat-jet hose.

Wide use was made of canvas tables in California gold mills prior to the adoption of cyanidation, and in base-metal mills prior to the introduction of flotation. At present they are used, under the name of CANVAS FRAMES or RAGGING (ROUGHING) FRAMES in Cornish tin mills and, to a limited extent, supplementing cyanidation in small gold mills.

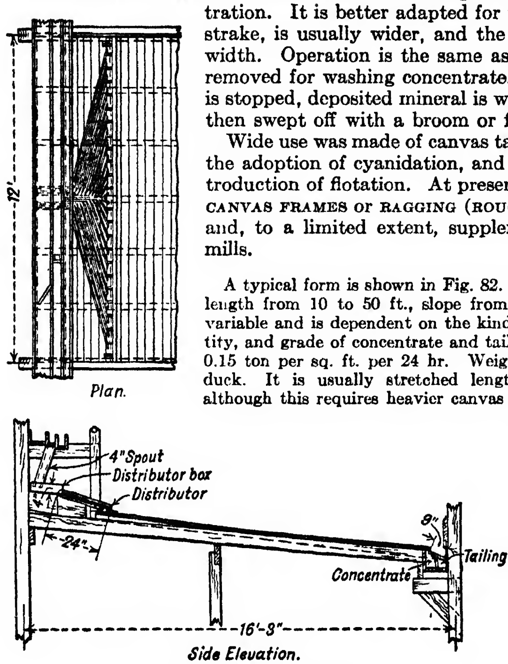

FIG. 82. Canvas table.

A typical form is shown in Fig. 82. Width ranges usually from 3 to 12 ft., length from 10 to 50 ft., slope from 0.5 to 3 i.p.f. Capacity is extremely variable and is dependent on the kind of ore, size of feed, slope, water quantity, and grade of concentrate and tailing demanded; average is about 0.01 to 0.15 ton per sq. ft. per 24 hr. Weight of canvas ranges from 8-oz. to 4-oz. duck. It is usually stretched lengthwise, for simplicity of construction, although this requires heavier canvas for a given degree of resistance to flow than would be required if the warp of the duck were placed across the stream. The life of canvas is from 8 mo. to 1 yr. under average service, according to the weight used, when protected from the fall of the feed stream by a board, turned when worn too smooth on the upper side, and slipped longitudinally at intervals to bring new places over the joints of the underlying boards. Automatic alternation of feed pulp, wash and flushing water, with automatic throw of the concentrate-tailing splitter has been operated by means of levers from a water-tilting box (see Sec. 19, Art. 3).

At TUL-MI-CHUNG (*119 P 808*) canvas tables were used for copper-gold-bismuth ore high in sulphide. The feed was tailing from Deister tables treating flotation tailing (about 0.2-mm. maximum size). Width, 7 ft.; length, 40 ft.; slope 1.25 to 1.75 i.p.f., the former best. One man attended 4 machines. Concrete strakes 4 ft. wide by 50 ft. long on 1.75-i.p.f. slope replaced canvas. Concrete was 3 to 6 in. thick tamped level, dressed to slope with a 0.75-in. layer of 1 : 1 cement mortar carefully troweled, which, when nearly dry, was dusted with dry cement and scored lightly transversely with a wire comb with teeth at 1/8-in. intervals. Three days were allowed for setting. Twelve of these strakes treated 450 tons solid per 24 hr. (0.13 ton per sq. ft.) in a pulp containing about 12% solids and recovered about 10¢ in gold per ton treated.

At SUAN mill (*119 P 920*) the ore was similar. The feed was tailing from cascade flotation, about 5% on 100-m. 21 strakes, 30 in. wide by 50 ft. long sloped 1 i.p.f. covered with 8-oz. duck, treated 250 to 280 tons solid per 24 hr. (0.11 ton per sq. ft.) and made a low-grade concentrate, but were overfed.

At the COMBINATION MILL, Goldfield, Nev. (*94 J 208*), milling gold-quartz ore, canvas tables treated 54% of the total mill feed and made from 7 to 13% of the total recovery. Feed contained 85.8% material through 200-m. and 93.1% of the gold recovered came from this size. The cost per ton (1912) was divided as follows: Labor, 18.5¢; repairs, 3.0¢; power, 3.0¢ (including vanners for retreatment of concentrate); acid for removing calcareous deposit from canvas, 0.5¢; sundry supplies, 5.0¢; total, 30¢.

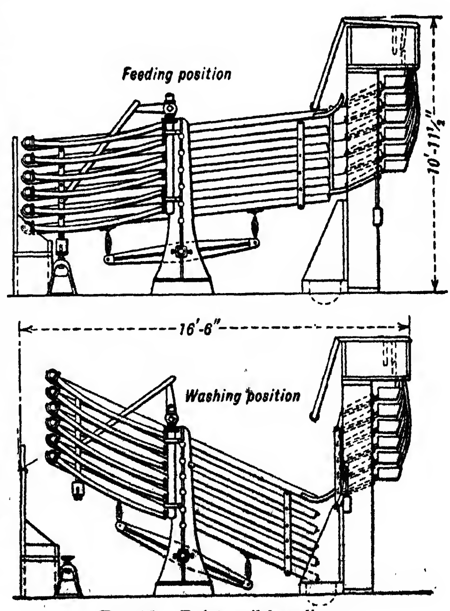

FIG. 83. Deister tilting slimer.

Tilting canvas table. Several forms have been built. The DEISTER is shown in Fig. 83. It consists of a series of relatively small canvas tables mounted on a tilting framework actuated by a timing device. When in feeding position, pulp flows over the canvas decks from the multiple feed box, concentrate adheres to the deck, and tailing passes into the tailing launder. After a time predetermined by experiment, the feed is shut off, the decks tilt into washing position, and flushing water is introduced with sufficient velocity and for sufficient time to remove concentrate, when the decks again tilt to the feed position and feed is again turned on automatically. (See also *116 J 766* and *34 MW 453*.) The feeding period ranges from 10 to 30 min. and the washing period from 30 sec. to 1 min. The capacity per square foot of canvas surface is the same as for stationary canvas tables. WILFLEY multiple-deck tilting slimer combined with the multiple tilting deck a simple eccentric shake to aid in stratification of the pulp, and a preliminary water-washing period preceding the flushing period, during which wash the worst of the gangue was removed.

Rotary-tray canvas table is described by Martin (*32 M & M 428*) as having been used successfully in several Mother Lode Gold mills. It consists essentially of a plurality of trays carried on a revolving framework and successively presented to fixed sources of feed and wash water, with final removal of concentrate by a strong, broom-shaped jet. Trays are 4 ft. wide by 3 ft. deep, 21 to 24 trays to a deck and 6 to 10 decks. Speed, one revolution in 15 to 20 min. Canvas, felt, and sanded asphaltic paint were used for tray surfacing. Another machine with the same idea had the trays mounted on wheels running on an undulating track which acted to increase the slope of the tray when the discharge position was reached.

Planilla is a Mexican device that has its counterpart in China and the East Indies. It consists of a concave sloping surface, a part of which is usually roughened in some way. The apparatus shown in Fig. 84 was built of masonry and concrete and had a concrete concentrating floor. Brick, wood, and

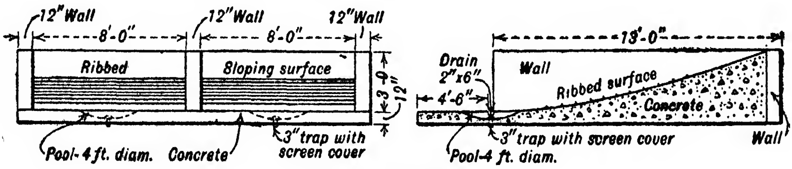

FIG. 84. Planilla.

sod turned root-side out have also been used for floors, the wood and sod for treating very fine material. The slope and curvature of the surface vary widely.

Baron (*30 M & M 377*) gives the materials in one planilla such as pictured as 1 bbl. cement, 1,000 lb. lime, 5 tons crushed waste, and sufficient large rocks for walls and foundations. The labor required was about 5 days for one native mason and two helpers.

Operation. A batch of crushed ore is shoveled onto the higher part, then drawn forward a small amount at a time and washed by throwing water on it or directing a stream against it from a hose. The rough concentrate remaining on the slope after this preliminary washing is turned over and over and coarse material raked up-slope while any impoverished surface layers resulting from the turning and washing are carefully scraped off and thrown aside. Concentrate collects in a hard layer beginning at about the point of change of curvature; middling collects below the concentrate and down to the water level; tailing is washed into the sump. Middling is recleaned by another washing either with or without further crushing.

Performance. At the SAN ROBERTA MINE, Zacatecas, Mex. (*30 M & M 377*), a silver ore with lime-silica gangue and small percentages of iron and copper sulphides, crushed and carefully sized through 5-m., was concentrated 5 into 1 at the rate of 1 to 2 tons of feed per 9-hr. shift by 1 operator and 2 boys. Concentrate assaying 32 to 40 oz. silver was made from 8-oz. ore, and 48- to 60-oz. concentrate from 13-oz. ore, but this was exceptionally good work, obtained by careful sizing of the feed, and close supervision and management. The usual performance on such ore is from 0.5 to 1 ton per shift concentrated 3 or 3.5 into 1 with a recovery of 50 to 60%.

A brick-floored device of the same variety for coarse ore and a board-floored form for cleaning fine middling from the first are described by Collins (*19 IMM 191*) as used in China for treating vein tin Concentrate is recleaned in pans.

Blanket (Corduroy) tables are essentially finely riffled sluices in which the pile or mesh of some fabric or similar material forms small, irregular pockets in which heavy material settles and is held in miniature beds, where suspension is effected by eddies set up by the overflowing stream of pulp, by ripples, or, when gravel is running, by the light hammering of the gravel particles.

Use. Blanket tables, nowadays ordinarily covered with corduroy, had a tremendous upswing in popularity with the building of the Canadian gold mills, and with the political markup in the price of gold. The blanket is the cheapest method of saving moderately fine gold (30 to 35 μ) in ground pulps, from the standpoint both of first cost and of operation, provided it is not charged with tailing losses. It will scavenge gold out of tailing from careful and efficient flotation (*16 MMt 331; IC 6972;* Sec. 2, Fig. 37). It will rough coarse gold substantially completely from cyanide and flotation feeds and thus reduce materially cyanide time-factor and flotation-tailing assays; this is its most frequent use; it is in competition with jigs and unit flotation cells in such service, and they are generally preferred in large plants. It catches gold that an amalgamating plate fails to catch (*IC 6433*); it will catch and hold as

much or almost as much free-milling gold as such a plate; it requires much less skilled operators; and it can be screened against theft, with observation through the screening, while the plate must be left open for dressing. It is more effective the less sulphide there is in the ore, since sulphide tends to mat down the surface. On the other hand, it is not fouled, as are plates, by ores containing As, Bi, Sb, Pb, talc, clay, graphite, and acid mine waters. It is ideal for small gold mills treating oxidized ores in which there is not enough sulphide present to justify shaking tables or flotation, it has replaced amalgamation on the Rand (*112 A 760*) and at DOME (*IC 7085*). In the grinding circuit, it prevents build-up of coarse gold. It is used successfully in some small gold mills as the sole concentrating method. It is used in the TRANSVAAL as the sole concentrator for the platinum minerals (*IC 7085*).

Construction. The usual blanket table is a shallow trough, 3 or 4 ft. wide and 5 to 10 or 12 ft. long. It should be built with a floor that is plane and will not warp or crack in service, and lined as with linoleum or sheet metal, to prevent leaks and losses in corners and joints. Slope is normally 1 1/2 in. per ft. and the usual range is from 1 3/8 to 2 or 2 1/2 in.; a range of 3/4 to 3 in. will cover all contingencies. At SUYOC (*IC 7085*), treating a complex sulphide ore, slope required was 1 1/2 i.p.f. for <6-m. ball-mill discharge and 1 i.p.f. for 95% <200-m. classifier overflow. Slope on the scavenging section in the tailing line at UTAH COPPER is 3/16 i.p.f. Provision for variation in slope may be built in, as by hinging the table on its support and raising or lowering by gear or shims, but unless variation is contemplated as an operating control, it can be effected satisfactorily and more cheaply by shimming under the frame.

COST of 3×12-ft. and 3×19-ft. tables at DEMONSTRATION (1930's), built by the mill carpenter, averaged $25 per table (*IC 7085*).

It is better, when length is to be increased beyond the normal 5 or 6 ft., to break the deck transversely to provide steps of a few inches; the resulting pulp drops aid recovery.

Launder-type tables, used principally for scavenging, are made about 1 ft. wide by 75 to 500 ft. or more long, according to the fineness of the gold, the quantity, and the depth of pulp running.

Covering may be blanket, carpet, loose-weave canvas, skins with hair, coco-mat, burlap, ribbed rubber mat, or sponge rubber, but the common covering is a cotton corduroy, English pulp-sifting cloth, which has a long and relatively stiff pile with wide (3/8-in.) and relatively pronounced ribs (Fig. 85). It comes in bolts, 28 and 36 in. wide by 77 yd. long, and is ribbed lengthwise of the roll. Price (1939) is $2 to $3.50 per yd. according to width and quality. For use, it is cut into strips of length sufficient to cover the table transversely and project up the sides. It is laid in with ribs at right angles to the flow and the nap against the stream (high side of the rib upstream). The strip at the lower end is laid in first and successive strips are then laid in with a 2- or 3-in. overlap. Covering is usually held down by flat iron bars laid along the sides and a flat plate laid across the top to take wear of the feed stream. At DEMONSTRATION (*loc. cit.*) 1/2 × 2-in. cleats are wedged across the corduroy at the joints, serving both to hold down and as riffles to aid in gold saving.

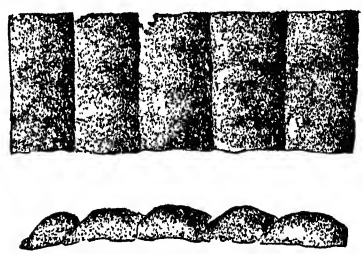

FIG. 85. Table corduroy (full size).

Life of corduroy varies with tonnage and size of feed, frequency of washings, care in handling, and provisions made for reinforcing. Usual range is 3 to 18 mo. At DOME life is prolonged by a backing of cheesecloth, and by light canvas binding at the ends of the strips.

Operation is principally confined to washing the cloth at intervals determined fundamentally by the progress of concentrate filling down the table, but usually, except with rich spotty ores, on a predetermined schedule, ranging normally from once per hour to once per shift. Often only the top strip is washed at the short interval, the others as they fill up. Scavenging tables are washed less frequently, *e.g.*, once every day or two, to once in 40 days at UTAH COPPER.

Washing is done in a hopper-bottomed iron tub or tank, somewhat larger than the stretched strip of blanket. A heavy screen, about 1-in. mesh, is fitted to the tub so that it forms a diaphragm about 1 ft. below the rim, and is padlocked into place. The tub is filled with water to a level a few inches above the screen. At DOME a deeper tub is used, without the submerged screen, and the blanket is sloshed up and down therein with the riffles held vertical.

When removing blankets, feed is cut off, clear water run for a short interval to wash off current ore, the hold-down means are taken out, and the strips of blanket are rolled up, top side in, and lifted out. Washed strips are then put in and pulp flow restarted. A better arrangement, which eliminates stoppage of the feed stream, is to provide one or more spare tables to which feed may be diverted.

The filled blankets are taken to the wash tub, unrolled inverted thereover, and vigorously sloshed in the water and against the screen. Scrubbing is unnecessary.

Frequent washing is essential to successful operation. The effectiveness of corduroy is due in large measure to the eddying caused by the uneven surface. As soon as the valleys fill this advantage is lost; the surface becomes smooth and hard, and not only concentrating but gold-holding power is lost.

Slope should be watched and so adjusted that the heaviest sulphide is just carried over the ribs.

Pulp density affects both slope and recovery. It is as it falls when the table is in a grinding circuit, and may be 50% solids or higher. When it is controlled for maximum recovery, it is usually brought to a point near 20% solids.

Size of feed may be as coarse as 1/4-in., but 10-m. is a better maximum, and it is usual when using blankets in grinding circuits to screen to some such size, if possible. Coarse material requires steep slopes, and causes excessive blanket wear as well as lowered recovery.

Capacity depends upon service. When the blanket is depended upon for final recovery 0.2 to 0.5 tons per 24 hr. per sq. ft. of blanket is the usual range, depending upon the size of the gold. The same surface allowance should be made for careful scavenging of fine gold; in scavenging coarse gold after flotation 1 to 3 t.p.d. per sq. ft. may be run. For roughing out coarse gold, 2 to 4 t.p.d. per sq. ft. is usual, and 10 to 15 tons have been run.

Performance. At PASSAGEM MINE, Brazil (*20 IMM 18*), the ore is gold-bearing quartz containing heavy constituents deleterious in cyanidation. Blanket strakes take <30-m. stamp product in a pulp containing about 8% solids. Slope is 1.5 i.p.f. 200 tons of ore per 24 hr. are treated on 400 sq. ft. of blanket and each ton passes over 120 sq. ft. Recovery is about 50% and the ratio of concentration about 40 to 1. Concentrate assays about 10 oz. Au per ton. Blankets are 48 × 18 in. The life of a blanket is 3 weeks. The rough concentrate, amounting to 5 tons per 24 hr., is passed over 12 strakes, 18 in. wide × 20 ft. long, sloped 1.5 in. per ft., the first 8 and the last 4 ft. covered with blankets and the intermediate 8 ft. with canvas. Blankets are washed half-hourly. Concentrate assays about 160 oz. Au per ton and between 650 and 900 lb. per 24 hr. is produced from 5 tons of the rough concentrate. Tailing from this operation assays about 1.3 oz. Au per ton. The concentrate is further treated on two blanket strakes each 18 in. wide and 6 ft. long, producing between 65 and 90 lb. of final concentrate containing 48 to 64 oz. Au. Tailing assays 16 to 19 oz. Au per ton. This final washing requires about 3 hr., and about 16 g.p.m. of water per strake is used.

At OURO PRETO, Brazil (*20 IMM 30*), the ore is gold-bearing quartz containing considerable sulphides deleterious in cyanidation. Blanket strakes treat <30-m. stamp product in a pulp containing not more than 3% solids. Slope, 1.5 i.p.f. Blankets are 18 in. wide × 4 ft. long and are changed two to three times per hour, or as soon as the nap becomes loaded with concentrate; 32 blankets can be changed and washed in 10 min. Concentrate assays 8 to 9.6 oz. Au per ton and contains 40% sulphide. The ratio of concentration is about 40 to 1. The rough concentrate, amounting to about 5 tons per 24 hr., is reconcentrated on 6 strakes each 18 in. wide × 15 ft. long, sloped 1.5 i.p.f. Concentrate assays about 230 oz. Au per ton and tailing about 0.8 oz., all included gold. The ratio of concentration is about 26 to 1. This concentrate is next treated on a table covered with short-nap blanket, 12 ft. long, sloped 2 i.p.f. Concentrate assays 2,160 oz. Au per ton and tailing 16 oz.; ratio of concentration 10 to 1. This makes a final over-all ratio of concentration of about 10,000 to 1. Water used on the reconcentrating strakes is a weak solution of the extract from the leaf of *Solanum paniculatum*, a local saponin-bearing plant. This solution lowers the surface tension of the water and prevents or lessens flotation of metallic particles.

At DOME, 28 tables, 27 sq. ft. each, 1 3/8-in. slope, treat 1,500 t.p.d. primary ball-mill product, plus 2,000 tons circulating load. Two men change blankets on a 1 1/2-hr. cycle while a third washes; 40 min. is required for the actual change. There are 3 blankets per table. Life of blankets, 90 days aver. At PICKLE CROW (*41 CIMM 125*) classifier overflow at 100 *mog*, 170 t.p.d., is split into 6 streams each of which flows over a 2×11-ft. corduroy table. Slope is ± 2 1/2 i.p.f., adjusted to suit pulp density, and kept as low as possible without building up. The strip of corduroy at the top of each table is washed every 3 hr.; all others every 8 hr. Total concentrate, about 100 lb. per day with about 100 oz. Au.

At BRITANNIA (Sec. 2, Fig. 31) general mill tailing amounting to 5,500 t.p.d., 15 to 20% >65-m., 20% solids, assaying 0.005 oz. Au per ton, is run over 5,300 sq. ft. of English corduroy blanket (life 1 yr.) laid over 1/2×3/4-in. longitudinal wood strips on 1 1/4-in. centers in 27-in.×42-ft. launders sloping 1 in. per ft. Purpose of under-grid is to induce down-flow of water through blanket, which is thought to aid in saving gold. Concentrate assays 1.5 to 2 oz. Au per ton; recovery amounts to 6 oz. Au daily. Attendance is 4 to 5 man-shifts per day for 56 strakes. Clean-up (6 times daily) comprises switching feed from one section (of 7) to an adjacent section (or sections); washing the 8 strakes lightly with a small stream from a hose; throwing rubber flap valves at the ends of the strakes, which serve to divert concentrate; washing down with high-pressure water; throwing back flap valves, and turning feed in again (*Bul 342 CIMM 407*).

See also Sec. 2, Figs. 52, 78.

Recovery depends not only on the ore but also upon the purpose of the operation. With a free-milling ore, when traps (Art. 26) and blankets are the only gold savers, and operation is, consequently, adjusted primarily for high recovery, 80 to 90% of the gold in the ore can be and is saved by these means (*7015 IC 26; 50 #3 SAMEJ 11*). In roughing service, applied only when some of the gold is relatively coarse, 25 to 75% of the gold in the feed is the usual range. In scavenging, the recovery based on the mill feed depends entirely upon the character and efficiency of the treatment preceding; based on the feed to the blanket, it ranges, in general, from 50 to 75%, being higher, of course, the coarser the gold.

Cost of operation (exclusive of clean-up) is 1 to 5¢ per ton, depending upon the frequency of blanket change and the size of the plant. At DEMONSTRATION (*loc. cit.*) it was 1¢; average on the RAND is 2.8¢ (*37 #8 JCM 30*); WEST AUSTRALIA, 2¢.

Clean-up. Concentrate varies in richness from a few oz. per ton to as high as 1 oz. per lb. Low-grade concentrate is usually run up in grade by further tabling. Final clean-up of rich concentrate is made by barrel amalgamation (Sec. 14, Art. 8).

At UTAH COPPER the burlap is partially dried, burned in a stove, and the ash sent to the smelter. Low-grade concentrate generally is sacked (moist to prevent dusting) and shipped. Old cloth in all plants is burned; ash may be shipped, returned to the mill flow, or amalgamated, according to value.

Mechanical strakes of various kinds have had some use. A shaking form is used for platinum at POTGIETERSRUST, Transvaal (*IC 7085*). Gayford (*112 A 562*) shows a form in which the blanket is stretched over a head and tail rollers and is driven to bring concentrate continuously out of the feed zone into a washing zone. At MORRO VELHO, Brazil (*421 MM 202*), 3×12-ft. decks covered with coarse cotton duck are mounted to permit side tilt into a vertical position over concentrate launders. Feed cutoff, preliminary washing in place, tilt, wash-off of concentrate, and return to operation are effected automatically about once per 1/2 hr. by a timer-operated carriage that travels on a track over a line of 18 tables set side by side. Concentrate passes to a second line of 18 tables, similarly operated.

Johnson rotary concentrator consists of a cylindrical steel tube, 12 ft. long by 3 ft. diameter, mounted with 6% slope on tires and rollers, and rotated 7 r.p.m. (1/2-hp. motor). The inside is lined with specially formed corrugated rubber. A deep, narrow launder, with the steepest possible pitch toward the discharge end, occupies the axis of the tube and receives concentrate washed into it by a longitudinal spray pipe above it. Another pipe sprays the material adhering to the lining as it rises out of the pulp stream entering the high end of the tube. Clean spray water is essential, since stoppage of any jet reduces efficiency of separation.

In an early test, a concentrator fed at 220 tons ore per day, in pulp containing 46% liquid, recovered concentrate amounting to 4% by weight and carrying 58% of the gold and 51% of the pyrite in the feed. As operating in the CASON mill in 1927, each of 10 concentrators, receiving its feed direct from a tube mill at 310.7 t.p.d. (of which 240.3 tons @ 4.974 dwt. Au and 2.38% pyrite was new feed), extracted 55% of the gold and 44% of the pyrite in the new feed as a concentrate (20.7 tons) averaging 31.74 dwt. Au and 12% pyrite. The concentrate sized: 15.5% on 60-m., 33.6% on 90-m., 26.4% on 200-m., and 24.5% below 200-m. On a monthly basis of 73,000 tons to the mill, introduction of the concentrators reduced the assay of sand tailings from 0.442 dwt. (in best previous year) to 0.283 dwt., and of total tailings (of which cyanided slimes constituted 56%) from 0.262 dwt. to 0.180 dwt. As an experiment, the 315-ton per day output of one tube mill was divided between two concentrators, with some improvement in recovery but notable enrichment in grade of concentrate (Au, 52 dwt.; pyrite, 23%).

35. CLASSIFIER SEPARATORS

Classifier separators are those which utilize free- or hindered-settling classification (Sec. 8) to make a rough separation between valuable mineral and waste in cases in which the valuable mineral has low unit value, and removal of a relatively high grade tailing suffices to lift concentrate to a salable grade.

Humphreys spiral concentrator (Fig. 85*a*) consists of a spiral curved-bottom launder *a* wound, at constant spiral diameter, around a vertical axis. When fed with a dilute deslimed pulp of a mixture of minerals of different specific gravities (*e.g.*, placer sands), the lighter minerals, being the more readily suspended by the impulse of the water, attain sufficiently greater tangential velocities than the nonsuspended heavier grains to cause them to climb toward the outer rim of the spiral trough. Similarly the coarser grains work toward the outer edge by a mechanism that is probably a combination of reverse classification in a stirred bed and of film sizing. As a result, after a short time, the heaviest mineral is progressing by saltation along the lowest part of the launder cross-section, while the gangue works along the outer sloping side. Concentrate (and middling) bleed-offs *b* are spaced along the bottom of the launder, somewhat toward the inner rim, and removable and adjustable splitters *c*, held in place by spring clips *f*, lead more or less of the concentrate stream toward the respective discharge outlets. Wash water is skimmed out of water channel *d* by adjustable pipes *e*, clipped onto the rim of the launder at desired locations, and set to withdraw the amounts of water wanted at the particular place. Volume of stream decreases toward the lower end of the spiral, owing to withdrawals with concentrate; as a result, carrying power becomes less and middling settles down to the lowest portion of the trough to be withdrawn. Final tailing discharges at the end of trough.

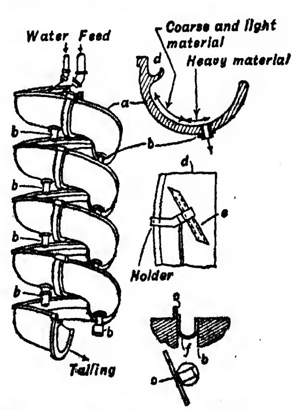

FIG. 85*a*. Humphreys Spiral concentrator.

Performance. At HUMPHREYS GOLD CORP., near Bandon, Oreg., four spirals, occupying a space some 20×20 ft., treat 1,000 t.p.d. of chromite-bearing gold-placer sand tailing, assaying 6% Cr_2O_3, making a recovery of 90% in a concentrate assaying 25% Cr_2O_3 (*144 # 10 J 68*).

Ainlay bowl is a bowl-shaped basin 12- to 36-in. diameter at the rim, rubber-riffled on the inner surface, mounted rim upward on a vertical shaft driven to give about 1,000 f.p.m. peripheral speed at the bowl rim. Placer sand and fine gravel are fed with water around the shaft; centrifugal force causes a film of pulp to travel upward toward the bowl periphery; gold catches between the riffles, and the overlying lighter sand passes on upward and over the rim. When the riffles fill up with gold and heavy sand, feed is shut off and the concentrate is washed out. CAPACITIES claimed by the manufacturer are 1/2 to 1 1/2 cyd. of <5-m. gravel per hr. for the 12-in. bowl and 5 to 10 cyd. of <3/8-in. material per hr. for the 36-in. size. The apparatus has been used to a limited extent on doodlebugs and small placers operations (L. D. Drake, *PC*).

Vertical-current washer is essentially a hydraulic classifier. The machine is satisfactory when used in easy service, such as the separation of clay and fine sand from lump iron ore; or because the amount of cleaning to be done is relatively small, as in the removal of slate from sized coal in the Draper washer (*Ed. 1*).

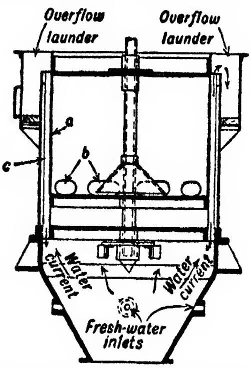

FIG. 86. Wetherbee concentrator for wash iron ores.

Wetherbee iron-ore concentrator (Fig. 86) combines mechanical agitation with free-settling hydraulic classification to effect separation of fine silica and clayey material from coarse and fine hematite in Mesabi wash ores. It is a direct competitor of the log and turbo washers (Sec. 10, Art. 4). Feed passing a 1/2-in. aperture is introduced into the revolving tub *a* and discharged by centrifugal force through the holes *b* into annular space *c* through which a current of water is rising. The theory of the machine is that the swirl in this annular space is sufficient to keep the lighter particles in suspension and that consequently a small rising current will lift them into the overflow, while the heavier particles will settle into the hopper-shaped bottom from which they may be removed by a drag or screw conveyor, or, if sufficiently fine, by a pipe-and-plug spigot.

Machines 3 ft. and 6 ft. in diameter have been used. Working on one particular ore, 28 r.p.m. for the 6-ft. machine and 36 r.p.m. for the 3-ft. machine were found to be the best speeds, and hydraulic water consumption was from 80 to 150 g.p.m. The 6-ft. machine readily treated 50 tons <1/2-in. feed per hr. and produced concentrate assaying 57 to 62% Fe from feeds carrying 39 to 54% Fe. Comparative results on two Mesabi mills, one using the Wetherbee machine and the other a turbo washer and tables to treat log-washer tailing, showed 81.4% recovery with a concentrate assaying 59.8% Fe for the first mill and 78.6% recovery with 58.8% Fe in the concentrate for the other (*103 J 301*).

Mechanical classifiers are used as wash-type concentrators for sandy feeds, particularly in iron-ore concentration. See Sec. 10; also Sec. 2, Fig. 84.

PNEUMATIC CONCENTRATORS

Pneumatic concentrators are those in which a gas, invariably air, is used to effect differential movement of particles of different specific gravities. They parallel the water-gravity concentrators in that beds, quicksands, and the direct impulse of air on feed particles are all utilized.

36. BED-TYPE PNEUMATIC CONCENTRATORS

This group is made up of those machines in which separation is effected by differences in settling rates of particles in a pulsated bed of which they themselves are parts. The group includes all of the pneumatic machines best known and most used. The essential elements in all are a porous supporting surface for a mass of grains; an air supply flowing upward through the supporting surface and thence through the interstices of the mass of grains; means to produce flow of the mass of grains and to constrain layers at different vertical depths therein to move in different directions to different discharge points. These are the essential elements of a water jig, except for the difference in interstitial medium. The kind of stratification effected, with large, heavy material of a given specific gravity at the bottom of the layer of that material, is the same in both machines; the responses to controls are, of course, also the same. In other words, these apparatus, though having the general form and appearance of shaking tables used for water-gravity concentration, and called PNEUMATIC TABLES, are actually pneumatic jigs.

Types of tables differ in the methods of effecting intermittent dilation of the bed, and in the means of causing and controlling flow of the different strata.

Hooper pneumatic jig (Fig. 87) utilizes a pulsating air current to dilate the bed and gravity to move both upper and lower layers down-slope, guided along divergent paths

by suitable baffles. Deck *a*, covered with broadcloth or other porous material supported on slots *b*, and adjustable as to longitudinal inclination, is otherwise stationary. Above the broadcloth are two sets of metal riffles, which act as the guides above mentioned; the lower set, 1/4 in. high and spaced 1 in. run toward one side of the deck, while the upper set, 3 1/2 in. high and spaced 3/4 in., run toward the other side. Air is caused to pulsate through the porous deck by pulsation of a leather diaphragm *d*, actuated by eccentrics on drive shaft *e*, the diaphragm being fitted with upward-opening flap valves. The original bed, comprising the mixed feed, stratifies roughly near the feed end; during the balance of the travel, stratification is perfected by flotation of lighter material from the lower layer and gradual acceptance of heavy material from the upper layer. The primary split between upper and lower layers is by a horizontal splitter at the discharge end located at the top of the lower riffles; secondary splits are possible with each stream by use of vertical splitter blades.

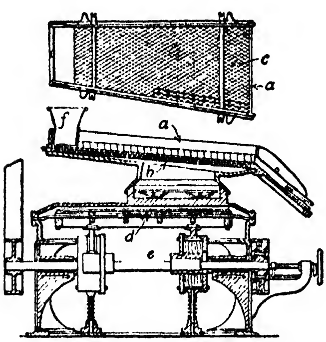

FIG. 87. Hooper pneumatic jig.

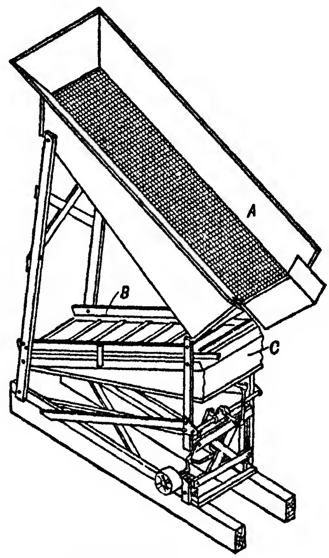

FIG. 88. Dry rocker.

Dry rocker (Fig. 88) may be used where water is scarce (*IC 6786*). Gravel must be completely dry and disintegrated. The essential elements are a steeply inclined screen *A* and a riffle box *B* with porous bottom through which air is forced in powerful blasts from bellows *C*. Screen aperture is 3/8- to 1/2-in. Undersize runs to the head of the riffle box, sloped 5 to 6 i.p.f. (more in a hand-operated machine). The porous surface is about 8 oz. single-weave duck over copper fly screen. Other porous materials such as silk and rayon concentrate well, but permit excessive entry of dust into the bellows. Bellows sides are tight 36-oz. duck. Riffles are arranged to maintain a lively bed deep enough to protect settled gold. A power machine 11 in. wide by 40 in. long driven 250 @ 3-in. s.p.m. by a 3/4-hp. gas engine had a capacity of 0.8 cyd. per hr. Hand machines have about the same capacity as a rocker of corresponding size. Clean-up is made by wet panning, if water is available; otherwise rough concentrate is collected and re-run to high enough grade for shipment.

"Air-float" table (Fig. 89) effects dilation by a combination of the throwing action of a shaking deck and a continuous stream of air upward through the deck; transport of the lower layer is due to the motion and the restraint of longitudinal riffles; transport of the upper layer is largely gravitational, modified by the effect of table shake. The machine comprises a trapezoidal riffled deck *a*, forming the top of a shallow air box *b*, tiltably mounted on inclined spring supports *c*, reciprocated longitudinally by an eccentric, and connected by a flexible air pipe with a blower located in the box support *d*. The deck consists of a cellular metal gridwork, with diamond-shaped cells about 2 1/2 in. on an edge, carried on the trapezoidal deck box, itself carrying wooden nailing plugs for the riffles, and supporting a perforated cover on top of which the riffles are nailed, parallel to side rail *e*. Head rail *f* forms right angles with the two side rails; the fourth rail makes an acute angle with *e* and joins with the back side rail at about the third-point from the feed corner *g*. Riffles taper, on tables meant for 3/8-in. maximum feed, from 1/2 in. at rail *f* to a feather

along the diagonal. The cells beneath the deck are fitted with bottom dampers, adjustable as to tilt, which permit regulation of the amount of air admitted to each cell. A crowding plate *h*, variously conformed to suit the designer's idea for a particular job, is fastened along the diagonal and back sides of the deck, and extends also along the feed end. Deck motion is Ferraris type (Art. 16). Longitudinal slope against the travel and side slope with the travel are both adjustable, as are also speed, stroke length, and volume of air. Standard deck size is 40×60 in. Capacity of such a table on fluorspar-quartz separation is said by Jarman (*PC*) to be 5 t.p.h. on 8∼20-m. feed and 7 t.p.h. on $^3/_8$∼$^1/_4$-in. Motor for the same table is 15-hp.

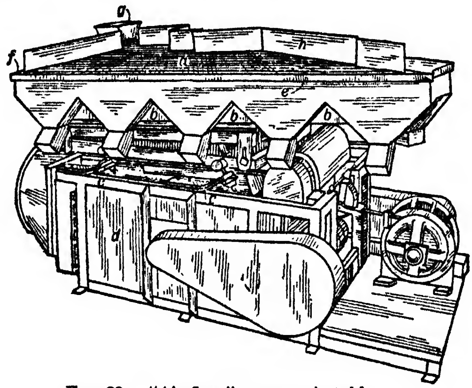

Fig. 89. "Air-float" pneumatic table.

Operation of pneumatic tables involves control of feed, fluidity of bed, and time-factor. The general principles are the same as those already elaborated for jigging with water (Art. 2).

Feed size for minerals of 2.6 sp. gr. and heavier ranges from $^3/_8$-in. to about 65-m.; performances on grains outside this range are not satisfactory. Feeds should be short-range. Practice is not to exceed three $\sqrt{2}$ steps (= 2.8 ratio of diameters) and most work is at one or two such steps. Manufacturers' representatives say that the ratio may equal the ratio of specific gravities of the minerals to be separated (= concentration criterion, air basis), but since the necessary separation is between pure mineral and an allowable middling, calculation of the criterion and allowable size range gives a lower result. The fact is that the greatest practicable uniformity in feed-particle size is necessary as an operating factor. A long feed-size range tends to produce nonuniform resistance to air over short distances on the deck, with the result that blowouts occur at the areas of least resistance and the surrounding areas become dead. Blowouts recurring in a given area can be corrected in the Air-float table by suitable adjustment of under-deck dampers, but this adjustment does not take care of the local blowouts due to unequal distributions of fine particles.

Fluidity of bed depends upon size of feed, air flow, and shake. The best operating condition is one in which the bed is kept so fluid that effective density is low, which may be judged by the distance from the feed corner at which the great bulk of the heaviest particles in the feed have reached the deck. With a concentration criterion of 1.35 to 1.4, this should be a few inches only. Fluidity may be and is lower with coarse feeds than with fine, because of the greater capacity to penetrate possessed by the large particles. On the other hand, the coarse bed becomes nonpenetrable much more suddenly than the fine, and fluidity must be carried further above the operating minimum.

Fluidity is adjustable by changes in air flow, stroke length, speed, longitudinal tilt, and feed rate. Air flow is the easiest operating adjustment. But increase in stroke length and/or speed lighten the bed more cheaply, since air accounts for about 80% of total power consumption. Increase in longitudinal tilt against the load and increase in feed rate both thicken the layer on the table and decrease fluidity, unless concomitant changes are made to maintain it. Too great fluidity throws settled material over its sustaining riffle cleat down-slope.

Time-factor must be sufficient to permit the lightest particle of middling that it is desired to reject to get behind a riffle cleat before the upper layer reaches the discharge edge. Similarly, heavy concentrate must be held back until it has floated out the heaviest piece of reject-grade middling. Time-factor is controlled by feed rate and by the flow rates of the primary (top and bottom) strata. Fluidity affects flow rate of the top stratum, which is also affected by side slope. Flow rate of the bottom stratum is controlled by speed and by longitudinal tilt. A high rate of longitudinal flow with low fluidity tends to drag the top stratum toward the diagonal.

Extensive tests on the effects of operating variables on pneumatic-table operation were made at Columbia University (*87 A 165*). The general findings are summarized above, but the details should be consulted.

Applicability. Manufacturers' representatives assert that the air table will make separations between minerals when the specific gravity difference is 10% (Jarman, *Feb. meeting AIME. 1941*). This

corresponds to a concentration criterion, air base, of 1.1. Assuming quartz as the gangue mineral and percentage base, it would mean that separation could be made from a mineral of 2.91 sp. gr. No data concerning such separations are published, but enrichment of crude fluorspar contaminated with quartz and calcite, with respect to both minerals, as shown in Table 101, is cited by Jarman (*loc. cit.*). This

Table 101. Concentration of 8/20-m. crude fluorite by pneumatic tabling at Big Creek Fluorspar Co. (*After Jarman*)

	Assays, %			
	CaF_2	SiO_2	$CaCO_3$	R_2O_3 *a*
Feed	53.8	17.0	27.6	1.5
Concentrates *b*	89.8–90.5	2.5–5.1	0.3–1.0	3.6–7.4
Tailings *b*	14.5–37.8	24.5–46.3	31.5–36.3	1.4–4.9

a Contains considerable galena and sphalerite.
b Extremes of three analyses.

separation has a concentration criterion, air base, of 1.13 to 1.21 as against quartz, and 1.11 to 1.18 as against calcite. Jarman (*A TP 959*) cites results of an operation on a pneumatic table at Columbia Tungsten Co., Quesnel, B. C., treating 18~30-m. scheelite: Feed assayed 2.9% WO_3; concentrate, 64%; and ratio of concentration was 22.8; from which tailing calculates 0.92% WO_3, and recovery 70%. Concentrate contained pyrite and galena, which were not further separable except by very close sizing and careful treatment. Jarman (*ibid.*) further cites use of the table on rutile-zircon magnetic concentrate, separation of pyrrhotite from actinolite, volcanic ash from obsidian, asbestos from sand, mica from quartz and feldspar, garnet from kyanite, galena from blende, gold and black sands from placer sands, inert from active fuller's earth. He states (*PC*) that sizable commercial operations are recovering cassiterite and mica from pegmatite minerals; pyrrhotite from rocky gangue, pyrite from rutile, ferro-alloys from slags and are grading closely sized abrasive grains by shape. No performance data are available for judging any of these operations. Garnet (almandite) has been separated from hornblende at North River Garnet Co. (*Ed. 1, 117*) for many years; sizes treated were 30~40, 40~52-, and 52~68-m.

Coal separation. There is considerable commercial use of pneumatic tables in coal separation.

Screen table, used for separation of asbestos (Sec. 3, Art. 2) is a shaking screen, about 6 (wide) ×20-ft., covered with about 1/16-in. cloth, with several fantail suction hoods (Fig. 90) or aspirators

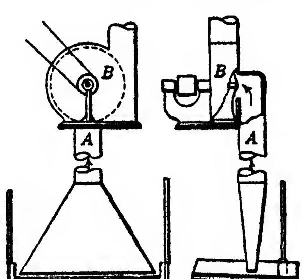

Fig. 90. Aspirator and screen table.

suspended with lips close to the surface of the bed. The screens are shaken about 300 r.p.m. The bed leaves the cloth, owing to Ferraris suspension (Art. 16), and in settling back undergoes reverse classification (Art. 1). The fibrous asbestos, both because of its acicular shape and its lightness, floats to the surface and is picked up as it passes under the aspirators. A 20-ft. screen is normally broken by 1 or 2 drops to turn over the bed and thus uncover buried fiber.

Stratification on this table resembles that on wet shaking tables rather than that of the pneumatic table.

37. PNEUMATIC QUICKSAND

A pneumatic quicksand may be formed by blowing air through a finely porous diaphragm into a relatively deep box of fine sand (*e.g.*, <20-m. siliceous river sand). With such material an air pressure of 1 1/2 to 3 in. Hg, sufficient to cause dilation without boiling, produces a spindle-hydrometer density of 1.45. This corresponds to an interstitial volume of 44%, or 15 to 20% dilation. Such a quicksand floats bituminous coal (*A PreP 1561-F*), and permits slate and pyrite to sink. Flotation of the coal is due to the fact that at this dilation, dry, the effective density of the quicksand is well above the composite density.

38. BLOWING

Blowing (sometimes called DRY PANNING) involves direct impulse of a stream of air across a stream of free-falling particles and across a 1-grain-deep layer of particles supported on a smooth plane surface. Effectiveness is greater the shorter the size range treated and the greater the differences in specific gravity.

Blowing (WINNOWING) was used at the MINERALS RESEARCH LABORATORY, Univ. of Witwatersrand (*40 JCM 212*), to separate vermiculite from rocky gangue minerals. The material was crushed dry and closely sized (about 2 @ $\sqrt{2}$ steps) and then dropped in a sheet across a blast of air from a blower in a box expanding with the run. The material piled on the catching surface varied from tailing to gradually richer middling at increasing distances from the feed point. Middling could be separated by recrushing in rolls or a slow hammer mill and then rescreening or reblowing. Roll crushing reduced the gangue but did not affect the vermiculite greatly; the hammer mill light blows cleaved the vermiculite but did not break the gangue. Uniform feeding was essential to effective blowing. The laboratory estimate was that a flowsheet utilizing such a combination of treatments would recover 85% of the vermiculite in sizes $>1/_{64}$-in.

Dry panning is practiced with two gold pans. The gravel, roughed down as far as possible by screening, is placed in one pan and held chest-high above the other in such a position that a strong current of air will blow across a stream dropped slowly, well-scattered, from upper to lower pan. Deflection of the lighter particles in falling is used to cause them to fall outside the lower pan. This procedure is repeated, with hand picking to aid in removing coarse waste, until a rough concentrate remains. This is further enriched (in gold panning) by magnetic concentration for removal of magnetite. The residue is then spread one grain deep in one pan and, holding the pan chin-high, is blown gently. The larger and lighter pieces tend to roll away from the smaller and heavier.

The operation is slow, laborious, and very uncertain.

SECTION 12

FLOTATION

1. INTRODUCTION

Flotation is a method of concentrating solid minerals in a relatively finely divided state. It is essentially a method of gravity concentration in water in which the effective specific gravity of certain of the ore minerals is substantially decreased by causing air bubbles to attach more or less tenaciously to particles of that particular mineral, whereupon they float on the separating medium while the unaffected minerals sink. The lightening may be insufficient to cause actual buoying to the surface but yet enough to cause differential travel in a gravity separator such as a shaking table or hydraulic classifier. When the selected mineral is separated in the form of a froth the operation is called FROTH FLOTATION. This is the usual method. When the degree of levitation is insufficient to cause the particle-bubble aggregates to float, the method is variously called AGGLOMERATE TABLING, OIL-AIR SEPARATION, and TABLE FLOTATION, which last name will be used herein.

Steps of froth-flotation method. In essential outline the ordinary simple froth-flotation operation comprises the following steps: (1) Grinding the ore in water to a maximum size of 35- or 48-m.; (2) dilution to a pulp consistency of 15 to 35% solids; (3) addition to the pulp of small quantities of one or more various inorganic conditioning agents, which have a

number of functions (Arts. 7, 8, and 9); (4) addition of a collector reagent (Art. 3), which has the function of coating the mineral to be floated with a water-repellent film; (5) addition of a frothing agent (Art. 13), which imparts persistence to bubbles when they reach the surface; (6) aeration either by agitation, or by air injection as through the porous bottom of the containing tank, or through pipes (Art. 11), during which the coated mineral particles become more or less firmly attached to gas bubbles; (7) separation of mineral-bearing froth from a liquid pulp containing residual particles which did not take on collector coatings. These steps frequently follow the sequence stated, but the conditioning agent, and sometimes the collector too, may be added to the grinding mill; dilution is usually effected in the classifier; the frothing agent may be added in the flotation machine where aeration is going on, or it may be added in the classifier or even in the ball mill.

Applicability. It is probably safe to say that if two minerals differ to the extent that one contains a substantial amount of a particular metallic element or acid ion which is [illegible] in the other, the two may be separated by flotation. This is not to imply that the methods for all such separations are already known, but that this is the known essential difference present in all separations now practiced, and that each new separation that is worked out is explicable on this basis. At present any sulphide can be separated from the usual rocky gangues; differential flotation of sulphides has been substantially controlled; the oxidized heavy-metal minerals and the rocky minerals of the non-silicate series can be separated from each other and from the silicate minerals; coal, graphite, and sulphur are readily separable from the rock-forming minerals; quartz and certain other silicates can be floated in the presence of metallic oxides and of mineral salts of the alkaline earths; soluble chlorides can be separated from associated clays and from each other; and new achievements are listed at frequent intervals.

Flotation as a means of separation is also beginning to be widely investigated and somewhat less widely applied in manufacturing, usually for reclamation of the values in fine wastes, but in some cases for purification of manufactured products. The following bibliography on such uses is selected from an article presented by Patek (*AIME, Feb. meeting, 1941*).

1. Flotation as applied to the chemical industry, Cullen and Lavers, *14 ICE 26.*
2. Fundamental properties of textile wastes, IV, Flotation, Clanton, *8 Text. Research 270;* VIII, Flotation of colloidal suspensions, Magoffin and Clanton, *8 Text Research 357.*

4. Behavior of textile fibers toward cationic soaps, Blow, *57 SCI 118.*
5. Wastes problems in the non-ferrous smelting industry, Swain, *31 IEC 1358.*
6. Separating colloids from liquids by flotation, *Brit pat 231, 430/1924.*
7. Chemistry of the Thylox gas-purification process, Gollmar, *26 IEC 130.*
8. A flotation method for treating white water, Anspach, *104 #9 Paper Trade Jour. 40.*
9. Separation of seeds by froth flotation, *U. S. pat. 2,155,219.*
10. Bromine recovery, *U. S. pat. 1,662,305.*
11. Recovery of silver from spent photographic solutions, *U. S. pat. 2,205,792; 2,221,163.*

Size treated. Flotation is practiced in the grain-size range from, say, $^1/_8$- or $^3/_{16}$-in. to colloidal. In froth flotation particles coarser than 65-m., particularly if of high specific gravity, tend to drop from the levitating bubbles, and losses also increase rapidly in the finest size range. Coal and other minerals of low specific gravity and flaky minerals such as graphite, mica, and talc can be froth-floated at sizes up to 10-m. Table flotation will handle granular material up to the maximum size stated above, but fails for fine sizes.

2. HISTORY OF FLOTATION

The fact that water can be displaced preferentially by certain oils at the surfaces of certain mineral particles brought to the interface between the two liquids has been known for many years. Utilization of the fact runs back into antiquity, if we may thus interpret the tales of the Golden Fleece, and of the pitch-daubed feathers in the hands of the Greek virgins. Modern recognition of the phenomenon of selective cling of certain solids at the interface between oil and water is first recorded in a patent to Haynes (*Brit. pat. 488/1860*). The converse phenomenon, *viz.*, selective oil-coating of certain particles in an aqueous ore pulp when relatively minor amounts of oil were stirred in was utilized by the Bessels in 1877. Their patents (*Ger. pat. 42/1877; Ger. pat. 39,369/1887*) for the froth flotation of graphite specify almost all conceivable kinds of oils and a variety of other organic compounds as reagents; they generated gas bubbles in the pulp by boiling and/or by chemical reaction, and floated the graphite as a froth.

Subsequent landmarks in the development of modern flotation practice are Everson (*U. S. pat. 348,157/1886*), who described the use of sulphonated fatty oil as well as hydrocarbons, with inorganic

acids, and introduction of air by agitation to effect levitation of metalliferous sulphides and oxides; Elmore (*Brit. pat. 13,579/1904* and *U. S. pat. 826,411/1906*), who described supplying the gas for bubbles by electrolysis and by vacuum respectively; Sulman and Picard (*U. S. pat. 793,808/1905*), who pumped air into an oiled pulp through a perforated submerged pipe; Sulman, Picard, and Ballot (*U. S. pat. 835,120/1906*), who prescribed beating in air by violent agitation in conjunction with the use of minute quantities of fatty oil; Towne and Flinn (*U. S. pat. 1,295,817/1919*) and Callow (*U. S. pat. 1,141,377/1915*), who described introduction of air through a porous medium underlying the pulp; Martin (1915), working in the laboratory of Utah Copper Co., who discovered the utility of the soluble sulphydrates as collectors for metalliferous minerals, the knowledge being buried in the company archives for nearly 10 yr; Christensen (*U. S. pat. 1,467,354/1923*), who changed the horizon of separation from that of metalliferous minerals from all others to non-silicates from silicates; Perkins and Sayre (*U. S. pat. 1,364,307/1921*), who described generally the use of soluble organic non-frothing reagents for selective modification of the surfaces of the minerals to be floated; Sheridan and Griswold (*U. S. pat. 1,427,235/1922*), who disclosed specifically the use of cyanide to prevent flotation of sphalerite in the presence of galena, and who indirectly pointed the way to understanding of activation and depression; Forrester (*U. S. pat. 1,646,019/1925*), who introduced matless cells into the mills; and several inventors who describe the use of cationic collectors for silicates.

PRINCIPLES OF FLOTATION

A flotation machine and its contents, in continuous operation, comprise a system in a rough sort of dynamic and chemical equilibrium. Into this system ore, water, air, and a variety of chemicals in small quantities are introduced continuously; from it flow continuously two or more streams of products which differ obviously in physical state and somewhat less apparently in chemical composition. The overflow stream is usually a froth carrying a load of solid which is different in mineralogical character from that of the other product streams and of the feed stream; the underflows are suspensions of the residue of the feed solid in the balance of the feed water. Determination of the distribution of the added chemicals in these product streams has been the key to the understanding and control of the process. From such study it has developed that the added reagents have a variety of functions. These have been assigned descriptive names as follows:

COLLECTION is a selective change in the surface of one mineral species or genus present in the ore, as a result of which the changed mineral is rendered water repellent, the other mineral species present remaining unaffected and water-wet. Reagents which effect collection are called COLLECTORS, COLLECTING AGENTS, and, less frequently, PROMOTERS.

CONDITIONING comprises changes in mineral surfaces and in the composition of the aqueous solution. Such changes in surface as aid collection of the changed particle are called ACTIVATION; surface changes that prevent collection are called DEPRESSION; changes in the solution which do not at the same time effect changes in particle surfaces are usually designed to protect other reagents and are, therefore, called PROTECTION. Other treatments of the flotation pulp such as heating, desliming, dewatering, *etc.*, which contribute to the success of flotation, are also usually classed under the head of conditioning.

LEVITATION is the act of lightening collector-coated particles by causing them to become attached to air bubbles. By extension the term is also applied to flotation at the upper surface of the suspending medium, and to attachment to droplets of a liquid lighter than and immiscible with the suspending liquid.

FROTHING is the act of producing a collection of bubbles (FROTH) at the surface of the suspending medium. It is usually implied that the froth carries a load of levitated solid.

COLLECTION

Collection is performed for the purpose of producing selective water-repellent coatings on the mineral particles which are to be separated from the pulp, in order that gas bubbles may cling to these particles. The coatings are of hydrocarbon or hydrocarbonlike nature. In the simplest case all that is necessary to effect collection is to add to the pulp a small amount of one of a certain class of organic chemicals (COLLECTORS), and to agitate the mixture long enough to effect thorough dispersion and permit the desired chemical reaction. If the pulp contains substances that interfere with the reaction, or lacks other substances that facilitate it, remedial treatment is required (see Art. 4).

3. PRINCIPLES OF COLLECTION

Many theories seeking to explain selective coating of mineral particles have been put forward. The following bibliography is representative. The hypothesis followed in this section was implied in the Christensen patent (*U. S. pat. 1,467,354*), was formulated in

definite terms on the basis of work done at Columbia University, and the factual basis therefor has been extensively checked both at Columbia and elsewhere. Much of the recent dissenting theory reduces, on its face, to a question of terminology; none of the basic facts is seriously in dispute.

Understanding of the theory is essential to intelligent design and control of operation. For that reason a considerable part of the experimental foundation is given herein.

20. Chemistry of collection of nonmetallic minerals by amine-type collectors, Taggart and Arbiter, *A TP 1685.*

Chemical theory of collection was first formulated (*87 A 217*) as follows: "*All dissolved reagents which, in flotation pulps, either by action on the to-be-floated or on the not-to-be-floated particles affect their floatability, function by reason of chemical reactions of well recognized types between the reagent and the particle affected.*" This generalization applies not only to the action of the organic collectors themselves, but also to activators and depressants, in so far as the action of these is directly on the particles affected by their presence and not simply on the pulp atmosphere.

Much of the experimental work was done on galena but enough parallel work on other minerals has been done to demonstrate that the behavior of galena is typical and that conclusions founded on the action of this mineral are broadly applicable.

Experimental Basis for Chemical Theory of Collection

Solubility of minerals. Most minerals are appreciably soluble in water.

A distilled-water extract of an ore, representing a leach of only a few minutes' duration, corresponding to the time that an ore is in contact with water prior to flotation in a mill, contains readily determinate concentrations of most of the principal ions present in the ore, or of ions derivable therefrom by oxidation.

Oxidation of sulphides in grinding. When galena is wet ground in a pulp in contact with air the new surface of galena thus produced oxidizes almost immediately and a surface coating of oxidized products, comprising sulphates and lower sulphoxides and carbonates of lead, forms. In part this dissolves, but a part adheres to the particle surfaces.

Equilibrium between dissolved and undissolved is established at lower concentrations in solution than with the corresponding substances in bulk. This indicates that the surface layers are of lower solubility than masses of the same chemical composition and leads to the hypothesis that the retained oxidation films are so thin—probably substantially monomolecular—that they are essentially parts of the original galena lattice, that the oxidized ions are bound to that lattice by forces intermediate between the attraction of the sulphide for the lead ions of the galena mass and that of the oxidized ions

for lead in their respective massive crystalline states. Similar oxidation occurs with other sulphides to such an extent in high-sulphide ores that the oxygen content of flotation-feed water may be as low as 20% of that of the mill water (*87 A 369*).

Ion exchange. Leaching of minerals with collector solutions results invariably in exchange of collector ions with mineral-surface ions, evidenced by diminution in concentration of collector ion in the leach solution and stoichiometric increase in concentration therein of mineral-surface ions of the same charge.

Oleate ion is abstracted from dilute aqueous solutions of alkaline oleates by apatite, phosphate ion appearing in solution, and by calcite, with return of carbonate ion; ethyl xanthate solutions leach sulphate, reduced sulphur-oxygen ions and carbonate from galena, giving up xanthate; soap solutions do the same, losing oleate; pyrite, chalcopyrite, chalcocite, malachite, and metallic copper all remove xanthate ion, the sulphides returning sulphate ion. Other ions and stoichiometric balances have not been determined for these latter minerals. When the mineral is of oxide type, *e.g.*, quartz, activated by a heavy or earth-metal ion, the coating salt appears to be dibasic, *i.e.*, $HSiO_3 \cdot C_{17}H_{33}COO \cdot Ba$ (*153 A 462*).

One implication of the increase in sulphate ion in xanthate-leach solution on copper sulphides is that even the highly soluble sulphate of copper obeys the previously stated hypothesis concerning the low solubility of surface coatings.

Nature of collector films. The film is a reaction compound.

When powdered galena that has been leached with ethyl xanthate solution is thereafter leached with hot ethyl alcohol, lead ethyl xanthate can be crystallized from the alcohol, the conditions of the experiment being such as to preclude the possibility that lead xanthate precipitated by lead ion in the xanthate-leach solution was the source of the lead xanthate recovered in the alcohol.

Orientation. The collector films are oriented in the fashion pictured in Fig. 1.

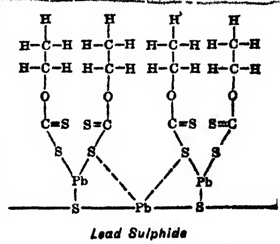

Fig. 1. Lead ethyl xanthate collector film on galena.

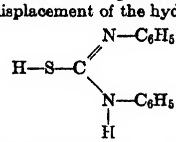
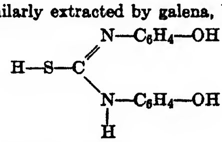
Diphenyl thiourea (thiocarbanilid) is a collector for galena and is abstracted by it from aqueous solution. The reaction probably involves displacement of the hydrogen from the acidic tautomer



Dihydroxy diphenyl thiourea is similarly extracted by galena, but is not a collector. It differs from



thiocarbanilid only in that a hydrogen in *para* position to the urea group on the phenyl has been substituted by hydroxyl. Experience teaches that such substitution tends to induce water solubility, *i.e.*, wetting of the substituted molecule by water (*cf.* the solubility of phenol homologs with the corresponding benzene series). The inference is that the lead thiourea coatings are oriented with the phenyl groups outward. Taylor and Knoll (*112 A 394*) obtained similar results with a glycol xanthate analogous to ethyl xanthate and having, presumably, the formula $HO \cdot C_2H_4O \cdot CS \cdot SNa$. Substantiation is found in the fact that heavily oxidized galena (or cerussite), when treated with xanthate solution to the extent that visible crystalline surfaces of lead xanthate are formed, is not water repellent. The xanthate groupings in crystalline lead xanthate are, presumably, arranged like those in organic crystals generally (see *Wyckoff*), *i.e.*, with the organic group arranged in right hand-left hand order, and not like-oriented as in Fig. 1.

Further confirmation of like-orientation in surface coatings lies in contact-angle studies (Sec. 19, Art. 22). Contact angles at collector-coated surfaces depend, with a given active group, upon the hydrocarbon radical of the collector used, and upon this alone. All minerals capable of collection by ethyl xanthate, with or without activation, show the characteristic angle (60°). The ethyl group in anionic collectors with sulphydric links other than xanthates also gives a 60° angle. Higher xanthates give larger contact angles. Since the behavior of the coated surface is the same with the same hydrocarbon group irrespective of the linking group, and changes with a given linking group when the hydrocarbon part of the coating ion changes; further, since bubble attachment does not occur in the absence of hydrocarbon groups, the clear implication of the evidence is that the interface at which the captive bubble adheres is a hydrocarbon-water interface, in other words that the hydrocarbon end of the coating ion is oriented outward from the mineral surface.

Conversely films which present surfaces with solubilizing groups toward the water (polar groups) are water-avid instead of water-repellent, and cause water wetting rather than gas-bubble attachment.

Coating by oily collectors. *When coating is effected with undissolved neutral oily liquids, the action occurring between the solid surface and the coating agent is one of mutual solution, and the coating formed is a solution of the two substances.*

A limited number of minerals, specifically sulphur, graphite, gilsonite, bituminous coal, anthracite, and certain sulphide minerals with S–S orientation, including molybdenite, orpiment, and stibnite (Bragg, *Atomic structure of minerals*, Cornell Univ. Press), are filmed in water by neutral hydrocarbon liquids and by other neutral oily liquids such as carbon bisulphide and dixanthogen, under circumstances which preclude the likelihood of chemical reaction. When such filming occurs there is, in many cases, visible etching, which can be correlated with solution of the mineral surface in the oily liquid. The film must be thin enough to be substantially rigid; bubbles adhere only where the film is thin enough to show interference colors, or even to be microscopically invisible; adherent contact cannot be established between air bubbles and pure hydrocarbon oils in water either by precipitation (Art. 11) or by pressure.

The neutral oily liquids are not collectors for substances such as sulphides or rock-forming minerals which they do not dissolve. No amount of pressure that can be brought to bear between such an oil droplet and such a mineral surface in water, in the absence of a dissolved collector for the mineral, will cause spreading or filming by the oil. When oleic acid spreads on galena it does so because the surface molecules of oil ionize sufficiently to react with the particle surface and form oriented coatings of lead oleate thereon; spreading of the remainder of the oil is by solution coating of this film. Mixtures of neutral oils with active collectors (the oleic acid-petroleum mixtures, the coal- and wood-tar oils, and the reconstructed oils of early-day flotation) were instances of such a mechanism. (See also Art. 6.)

COLLECTING AGENTS

Chemical collecting agents, so-called, *i.e.*, collectors which function by chemical reaction, are organic compounds, either acids, bases, or salts. They must be soluble in water to at least a small degree. If they are of acid or salt types, they must ionize in aqueous solution. The ion that combines with a component of the mineral surface must be of hydrocarbon structure at the end away from its reactive bond. The reactive bond of the coating ion must be one capable, as modified by the rest of the ion framework, of reacting with an ion present at the mineral surface, to form a compound which is insoluble under the conditions of concentration of reagent and other ions existing in the extremely thin zone of pulp liquor near the mineral-particle surface. Basic-type collecting agents, of which the only ones generally used at present (1943) are the amines and aminium salts, need not necessarily be ionized, but must have the same hydrocarbonlike nature in the part spatially removed from the active group.

Hydrocarbon terminal groups may be of any nature, although they are aliphatic in the majority of commercial collectors and aromatic in most of the remainder. The carbon content of the hydrocarbon part of the reactive ion must be sufficient to overcome the solubilizing effect of the reactive group in this ion when reaction with the mineral is made possible. What this carbon content must be depends, apparently, upon the nature of the reactive group. Thus when the reactive group is carboxyl, at least ten carbon atoms in the chain (*e.g.*, decylic acid) seem to be necessary for collection with low concentrations, while when xanthyl is the reactive group, the hydrocarbon radical may be methyl (CH_3), *e.g.*, potassium methyl xanthate. Aromatic groups such as phenyl and naphthyl are not as effective water repellents per C atom generally as aliphatic groups of the same molecular weights; *e.g.*, phenyl, C_6H_5, is substantially equivalent to ethyl, C_2H_5; their water-repellent character is greatly increased by aliphatic substituents on the ring.

Characteristic contact angles. The effectiveness of collectors with a given reactive group depends upon the contact angle which the hydrocarbon group of the collector will produce. Angles characteristic of various aliphatic groups are: Methyl, 50°; ethyl, 60°; propyl, 68°; butyl, 75°; amyl, 85°, isoamyl, 86°; oleyl, 90°; cetyl, 95°; iso-groups, in general, give angles slightly higher than the corresponding normal configurations. The behavior of aromatic groups is not so simple and no generalization can yet be formulated. Phenyl in monophenyl dithiocarbamate gives an angle that averages 54° while in thiophenol the angle is 70°; it is possible that the presence of the amino configurations in the carbamate has a solubilizing effect; similar effects are shown by the acid soaps. In phenyl-aliphatic salts the angle seems to be that of the aliphatic radical. With mercaptan active groups, phenyl, cresyl, benzyl, and naphthyl all yield the same angle, 70°. See also Table 1.

Recovery vs. contact angle. The recovery obtained with a given quantity of collector increases with increase in contact angle and, conversely, the quantity of reagent required to effect a given degree of recovery decreases with increase in carbon content in any homologous series. This is because the increase in contact angle with increase in molecular weight is more rapid than the increase in molecular weight with increase in carbon content. The essential limitation in the application of contact-angle tests to actual flotation conditions is that conditions in the pulp must be essentially the same as in the test cell; they may actually be and usually are quite different. See Table 3.

Reactive groups may be acid or basic in character. The acid groups are usually carboxylic or sulphydric, typified respectively by the higher fatty acids and their alkaline salts (soaps); and by the mercaptans, the xanthates, and thiophosphoric acids and their salts. Such collectors are designated anionic from the fact that the hydrocarbon group is in the anion. Their reactions with mineral sur-

faces have been discussed in Art. 3. CATIONIC collectors are organic bases, *e.g.*, amines, or salts of such bases. For reactions see Art. 5.

4. ANIONIC COLLECTORS

Anionic collectors are used in the great majority of present-day flotation operations. As described in the literature they constitute a bewildering variety of chemical and trade names. Actually they may be grouped into a small number of classes based on the active, *i.e.*, acidic groups, which determine their capacity to attach to mineral particles; the hydrocarbon loading, which determines solubility and water-repellency of the mineral coating, is what produces the variety and multiplicity of names.

Common effective acidic classes are the carboxylic R·COOH, and the sulphydric, which latter, so far as mechanism of reaction in flotation is concerned, may be looked upon as X—SH, in which X is any one of a great variety of loadings, in all cases containing hydrocarbon groups, but in which the linking to the sulphur, while usually through carbon, may be through phosphorus. A few apparent collectors are of sulphoxy type, $R \cdot SO_3H$ and $R \cdot SO_4H$. In all cases the H of the group formula is acidic; the collector may be used in the form of a salt, usually Na or K.

Vörlander rule. In judging the probability of acidic character of a hydrogen atom the VÖRLANDER RULE (*34 Ber. 1633*) may be applied. It asserts that a hydrogen in organic compounds is acidic when the bond between the third and fourth atoms removed from the hydrogen is double (unsaturated). Thus in carboxylic acids

$$\underset{1}{H}-\underset{2}{O}-\underset{3}{C}=\underset{4}{O}; \quad \text{in xanthic } \underset{1}{H}-\underset{2}{S}-\underset{3}{C}=\underset{4}{S}.$$

Contact angles (Sec. 19, Art. 22) for various anionic collectors are given in Table 1.

Table 1. Contact angles of anionic collectors (*mostly after Wark, PF*)

Hydrocarbon group		Reactive Group				
Name	Formula	Mercaptan R·SH	Carboxyl R·COOH	Xanthyl RO·CS·SH	Thiophosphate $(RO)_2 \cdot PS \cdot SH$	Dithiocarbamate $R_2N \cdot CS \cdot SH$
Methyl	CH_3		0	50		50 *a*

Cresyl	$CH_3 \cdot C_6H_4$	71				
Oleyl	$C_{17}H_{33}$		88			

a "Di"-salt.

Xanthates

Xanthates are the principal collectors of the sulphydric class. They are useful for heavy and precious metals both in sulphide and in oxidized minerals, but not for earth-metal minerals. They are products of reaction between carbon bisulphide, an alcohol, and a strong base, *e.g.*, NaOH, in which water is split out, and the alcohol residue is linked to the disulphide carbon. The general structural formula is

$$RO-\underset{\underset{S}{\|}}{C}-S-H \text{ (or M)}$$

where R is an alkyl group (hydroaromatic and aryl groups linked through aliphatic substituents are possible) and M a metal.

Effectiveness of xanthates as collectors increases with the molecular weight of their alcohol radical (Art. 3). METHYL xanthates, while effective with Cu, Hg, and Ag minerals, are not highly so and are not used commercially. ETHYL and the C_3 to C_5 xanthates are effective in normal concentrations without activators for all heavy-metal sulphides except sphalerite and pyrrhotite. Table 2, after Wark and Cox (*112 A 215*), summarizes contact-angle effectiveness tests of the various alkyl xanthates as collectors at normal concentrations.

Table 2. Effectiveness of alkyl xanthates

Sulphide	Xanthate						
	Methyl	Ethyl	Propyl	Butyl	Amyl	Hexyl	Cetyl
Pyrrhotite			Activation necessary *a*				
Sphalerite							
Pyrite							
Galena							
Chalcopyrite							
Bornite			Activation unnecessary				
Chalcocite							
Hg and Ag							

a May be common-ion control or resurfacing.

The failure to collect pyrrhotite and sphalerite is due to the fact that the ferrous and zinc xanthates of the C_1 to C_5 alcohols are more soluble than any possible concentrations of such xanthates that could be formed with an economic quantity of reagent. On the other hand, cetyl xanthate, from a C_{16} alcohol, yields a relatively insoluble zinc xanthate and is a collector for sphalerite. Hexyl is transitional. The decrease in solubility with increase in molecular weight is characteristic of homologous series. The order of the minerals in Table 2 is roughly the converse of Warren's (*26 Bul CIMM 186*) order of solubilities of the heavy-metal xanthates, *e.g.*, Au > Cu > Pb > Ni > Zn > Fe″. It is probable that Hg and Ag fall between Au and Cu. Pyrite yields enough ferric ion under normal circumstances to form ferric xanthates, which are relatively insoluble. It has been shown, however, by several investigators that the molecular weight of homologous collectors, the quantity added, the time of treatment, and the effectiveness in flotation of a given mineral are interrelated factors—as might be expected in a chemical reaction—and that with increase in quantity and/or time of treatment with the lower homologs, effectiveness of flotation may be made equal to that with a higher homolog. In general the branched chain xanthates make better recoveries than the normal isomers. Tests at Columbia University with relatively concentrated solutions of metal ions and ethyl xanthate showed that in addition to the metal xanthates already described Co″, Sn″, Cd″, Pt″″, and Bi″ all yielded immediate heavy precipitates of the same character as those formed by Pb″, Cu″, etc., which were, therefore, probably the corresponding xanthates. On the other hand, Cr‴, Al‴, U^{+6}, V^{+5}, Mn″, and Fe″ failed to give such precipitates (*112 A 362*).

Anomalous xanthate contact angles are often obtained with copper minerals. When cupric salts react with a xanthate, the end xanthate products of the reaction are cuprous xanthate and dixanthogen. The latter, which is a neutral insoluble oil, spreads on the xanthate film by solubility coating (Art. 3) and gives its own characteristic contact angle which, for ethyl dixanthogen, is upward of 80°. Thus higher angles than the characteristic 60° (Table 1) are frequently reported for ethyl xanthate on copper minerals.

Activation of sphalerite by Ag, Hg, Cu, and Pb ions (Art. 7) renders it readily flotable by C_2 and higher xanthates.

Commercial xanthates. The xanthates commonly used in the mills, their common names, and some common trade names follow.

Potassium ethyl xanthate; potassium xanthate; Z-3.
Sodium ethyl xanthate; sodium xanthate; Z-4.
Sodium isopropyl xanthate; Z-9; AC 343.
Potassium *n*-butyl xanthate; butyl xanthate; Z-7; Raconite (about 70% xanthate and 30% thiocarbonate; *IC 6241*).
Potassium *sec*-butyl xanthate; butyl xanthate; Z-8.
Sodium *sec*-butyl xanthate; AC 301.
Potassium amyl xanthate; amyl xanthate; Z-5.
Pentasol xanthate; Z-6; made from crude (unfractionated) amyl alcohol. PENTASOL contains 6 isomers of C_5H_{11} OH (*128 J 465*).
Potassium hexyl xanthate; hexyl xanthate; Z-10.

Collecting strength. The xanthates are, in general, more powerful collectors than the Aerofloats (see p. 09), pound for pound. They are added, therefore, in smaller quantities, and are frequently used to scavenge in later cells after Aerofloat roughing. The difference in collecting power between the lower and higher xanthates (C_2 *vs.* C_4 or C_5) at low concentrations is tremendous, but becomes much less at higher concentrations.

Buchanan (*TP 18 AC*) gives the laboratory data in Table 3 for flotation of a copper ore

At RAY (*IC 6241*) substitution of higher xanthates permitted marked reduction in the number of flotation machines required to handle mill tonnage, with corresponding saving in power and maintenance. On the other hand, the quantities added are so small that the loss due to precipitation by soluble salts may easily lower collector concentration to such an extent that recovery falls off.

Xanthates of $>C_{12}$ alcohols, with insoluble oils, have been proposed for phosphate flotation (*U. S. pat. 2,162,-495*). Such practice would require activation.

Table 3. Recovery *vs.* concentration for several xanthates

Reagent, lb. per ton........	Recovery, % 0.01	0.02	0.04	0.08
Ethyl xanthate...........	69.8	82.6	90.9	93.6
Isopropyl xanthate.........	76.4	89.8	94.9	96.1
Secondary butyl xanthate...	82.4	91.3	95.3	96.8
Amyl xanthate	86.9	93.5	95.0	96.0

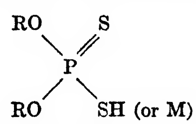
Quantities of xanthates required in sulphide flotation range from 0.2 lb. per ton downward, the necessary amounts being smaller the higher the molecular weight and the smaller the extent of sulphide oxidation. When used for oxidized ores without protection (sulphidizing, solution in organic sulphides) the quantities required may rise to several pounds per ton.

Use. Xanthates are preferably used in weakly alkaline solutions. Bubble-attachment to collector-coated particles is difficult to establish in highly alkaline solutions; in acid solutions the salt goes over to the relatively insoluble acid which decreases dispersion, and requires more reagent and time for coating. In strongly acid solutions the xanthic acid decomposes, yielding CS_2 and the corresponding alcohol.

Xanthomolybdic acid, $MoO_3(RO \cdot CS \cdot SH)_2$, an oily liquid formed by acidifying an aqueous solution of 2 parts xanthate to 1 part of a molybdate, is recommended for floating molybdenite (*U. S. pat. 2,148,475*). It is substantially insoluble in water and should be added in an organic solvent. Since molybdenite is collected by most oils, this seems to be a relatively expensive way of making a collecting oil.

Thiophosphates

Thiophosphates are of the sulphydric class. They are reaction products of phosphorus pentasulphide with various organic compounds such as phenols, alcohols, mercaptans, thioalcohols, amines, and nitriles (*U. S. pats. 2,038,400*, and *2,134,706*). The products with phenols and alcohols are the ones in common use (AEROFLOATS); they have the general structural formula



in which R is an alkyl or aryl radical and M an alkali-metal or ammonium ion. These compounds are water soluble and form relatively insoluble salts with heavy metals, but not with the earth metals. Wark and Cox (*112 A 267*) have found that the heavy-metal dithiophosphates are more soluble than the corresponding xanthates or dithiocarbamates and that, as collectors, they, of the three, are the most easily affected by depressants. Since the iron sulphides are the most easily depressed, the Aerofloats are useful for differential work involving iron depression. On the other hand, in pulps of low alkalinity or slightly acid, they are effective to float iron sulphides.

Aerofloat 15 is a black liquid made by reacting cresol with 15% by weight of P_2S_5. In the type structural formula above R is $CH_3 \cdot C_6H_4$—. The product is the acid. There is also a considerable excess of cresol. Hence the mixture has both collecting and frothing properties, strengthened by a certain amount of neutral oil usually present in the original cresol. Viscosity is slightly higher than that of cresol, making it adaptable to disk-type feeders (Art. 34). It is not a good coating agent for iron sulphides in alkaline circuits but films other common sulphides effectively; hence it is used in differential separation in which iron sulphides are to be depressed. It is frequently used also as a frother in flotation of gold ores. It is best dispersed by adding to the grinding circuit.

Aerofloat 25 is made of the same ingredients as Aerofloat 15, but is compounded with 25% by weight of P_2S_5. It contains, consequently, more of the collector compound, is more powerful, pound for pound, and the differential effect relative to iron minerals is less.

Aerofloat 31 is Aerofloat 25 saturated with (containing 6% of), thiocarbanilid. It is especially adapted to recovery of galena and of silver minerals, and is recommended for oxidized gold ores.

Aerofloat 239 is diamyl dithiophosphoric acid neutralized with ammonia and thinned with 10% of ethyl or isopropyl alcohol. It is largely soluble in neutral or alkaline water and forms a milky suspension in a 10% mixture. It has definite frothing power. It is especially recommended for copper flotation in pulps of high soluble-iron content. It is relatively nonselective as between sulphides. Data on its utility for argentiferous galena are contradictory (*TP 7 AC; 21 #18 MJA 7*).

Aerofloat 241 is Aerofloat 25 neutralized with NH_3, thereby rendered substantially soluble in neutral or alkaline pulp and more readily dispersed. Its collecting and frothing characteristics are practically those of the parent.

Aerofloat 242 is Aerofloat 31 neutralized with NH_3 and thereby rendered more readily dispersed. Its utility is substantially that of the parent except that as a frother one part of Aerofloat 242 is roughly equivalent to 1 1/2 parts of cresylic acid.

Stability. All of the liquid Aerofloats suffer some sedimentation on standing, without, however, noticeable effect on their flotation properties.

Dry Aerofloats (following) are thiophosphoric reaction products neutralized with solid sodium or ammonium carbonates. All are substantially water soluble and nonfrothing. They are commonly fed as dilute aqueous solutions. All exert but little collecting power for pyrite.

Sodium Aerofloat is the diethyl phosphoric salt. It does not collect pyrite strongly in alkaline pulps and is, therefore, used for sphalerite and copper minerals when pyrite is to be depressed. Wark and Cox (*112 A 231*) report necessity for activation by Cu for both galena and sphalerite.

Sodium Aerofloat B is the di-isopropyl salt, similar in flotation properties to the preceding but a stronger collector.

Aerofloat 203 is also the di-isopropyl salt (see the preceding) but more concentrated.

Aerofloat 208 is the sodium-neutralized reaction product of a 50-50 mixture of diethyl and secondary dibutyl phosphoric acid. It is particularly effective for metallic gold, silver, and copper and is used also for the corresponding sulphides.

Aerofloat 213 is the NH_4 analog of Aerofloat B, but more concentrated. It is recommended for gold, silver, zinc, and copper ores but not for lead.

Aerofloat 226 is the di-secondary butyl ammonium dithiophosphate. It is similar to Aerofloat 213 but somewhat more powerful.

Aerofloat 238 is the sodium analog of Aerofloat 226. It has the same collector characteristics as Aerofloat 208, but is more powerful.

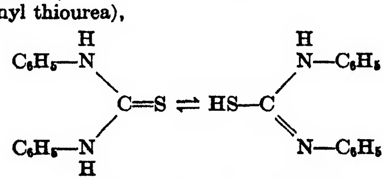
Aerofloat 239 (see *ante*).

Aerofloat 243 is of the same composition as Aerofloat 203, but is even more concentrated.

Quantities of Aerofloat reagents ordinarily necessary range from 0.25 lb. per ton downward.

Mercaptans and thioalcohols are the sulphur analogs of the alcohols and phenols respectively. Their structural formulas are R·SH where R is respectively an alkyl or an aryl group ± hydrocarbon substituents, and the —SH group is acidic. Both classes are relatively slightly soluble in water and acid pulps, but ionize as salts in pulps made alkaline by sodium or potassium compounds. They are collectors for sulphide minerals and are asserted to be selective for copper and zinc minerals over pyrite and to be effective for floating oxidized copper minerals (*U. S. pat. 2,125,337*). Barnac is a mercaptan of a higher alcohol (*21 #13 MJA 7*).

Thiocarbanilid (diphenyl thiourea),



is a white crystalline solid which, in water, assumes equilibrium between the tautomeric forms indicated. The acidic (—SH) form is the one active in flotation, the hydrogen being replaceable by heavy-metal ions to form relatively insoluble coatings on minerals. Since the two forms are in equilibrium, the nonacidic form shifts over as fast as the acidic is taken out of solution by reaction. Thiocarbanilid is very slightly soluble in water, somewhat more soluble in alkaline solutions. It is frequently added in solution in an organic solvent (*e.g.*, T-T mixture = 15% thiocarbanilid and 85% *ortho*-toluidin) but should, nevertheless, be added in the ball mill. It is an excellent collector for galena and is relatively ineffective for iron sulphides. The quantity required is usually less than 0.2 lb. per ton.

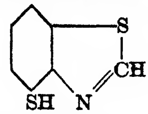
At Mascot (*IC 6397*) the addition of thiocarbanilid either dry or as T-T mixture, together with Barrett 634, increased recovery from 85% to 98%. At Tooele (*128 J 293*) addition of 0.1 lb. per ton to the ball mill increased lead recovery somewhat (zinc unaffected) and stabilized operation in the lead section.

Wettable thiocarbanilid (AC thiocarbanilid 125) comprises thiocarbanilid mixed with a wetting agent, *e.g.*, calcium lignin sulphonate, licorice root, saponin, alcohol slops, soap bark (*U. S. pat. 2,185,-191*). It is recommended to be fed as a 5 to 10% dispersion, using a disk-and-cup type feeder. Dispersion is also said to be effected by dissolving thiocarbanilid in 20 parts strong sulphuric acid (3 or 4 parts 1.84-sp.gr. acid to 1 part H_2O) and pouring the resultant solution in 20 to 400 parts of water (*U. S. pat. 2,052,274*).

Diphenyl thiocarbazid, $(C_6H_5 \cdot NH \cdot NH)_2 \cdot C{=}S$, in which the hydrogen on an amine group adjacent to the central carbon is labile and, on the sulphur, acidic as in thiocar-

banilid, is a specific collector for Co and Ni minerals in the presence of Cu and Fe minerals *(112 A 363)*.

Mercaptobenzothiazole (FLOTAGEN; AC 400 SERIES)



is used for copper and for zinc sulphides. Mixed with soda ash it is marketed as FLOTAGEN S, AC 444, or as SODIUM CAPTAX and is readily soluble in water. In alkaline pulp with Aerofloat 238 or xanthate Z-8 it is used for lead carbonate without sulphidizing, and for stage addition with sodium sulphide for oxidized copper ores. Wark and Cox *(134 A 64)* state that the responses of cerussite and malachite are better with no free alkali present, but that anglesite responds better in an alkaline pulp. It has also been used for oxidized and partially oxidized pyritic gold ores. The critical *p*H value (Art. 10) for galena with this reagent is 7.8 at 40° F and 9.2 at 95° F *(134 A 55)*. It does not collector-coat sphalerite without activation. Pyrite is depressed by hydroxyl and cyanide in its presence more readily than with xanthates. Parsons *(123 J 757)* says that mercaptobenzothiazole can be used with cyanide, sodium sulphite, or sodium thiosulphate; it should be added solid, hence requiring time and agitation to dissolve it before it becomes effective, but the contact time should be minimized; it can be used only in alkaline pulp. The sodium salt goes into solution readily and should not be kept in contact with the pulp for more than one minute before flotation.

Dithiocarbamates are made by treating CS_2 with cold alcoholic ammonia or amines (*vide* xanthates). The general formula is $X_2N \cdot CS \cdot SM$, where X is hydrogen or an alkyl or aryl radical, according to the entering base. The lower alcohols yield powerful collectors; Wark *(PF)* reports that they are more powerful than the xanthates. They are not, however, as cheap because ammonia rather than a caustic alkali is an ingredient.

Trithiocarbonates, $RS \cdot CS \cdot SM$ (or H) form heavy-metal salts of low solubility, the degree depending upon the type and molecular weight of R. None of them is a well-known collector.

Organic sulphides

When sulphydric collectors are subjected to oxidizing conditions, they tend to form organic sulphides and disulphides, many of which are substantially insoluble oily liquids at atmospheric temperatures. When pure they are not collectors of the reactive (chemical) type, but are solution-type collectors (Art. 3) for particles already having hydrocarbonlike coatings. When they contain residual sulphydrates in solution they form excellent spreading-type collectors (Art. 6), yielding higher contact angles than are characteristic of their hydrocarbon groups.

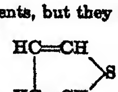
Dixanthogen, $RO{-}\underset{\underset{S}{\|}}{C}{-}S{-}S{-}\underset{\underset{S}{\|}}{C}{-}OR$ is formed by oxidation of xanthates. MINEREC is principally dixanthogen, formed by treating xanthate with ethyl chlorcarbonate, which is a strong oxidiser. It is used, in minute quantities, to supplement the action of true sulphydric collectors, usually with more or less oxidized base-metal minerals. It should be added in the grinding circuit or in a conditioner. Dixanthogens of secondary aliphatic monohydric alcohols, *e.g.*, isopropyl, *sec*-butyl, diethyl carbinol, *sec*-hexyl, *sec*-heptyl are described *(U. S. pat. 2,061,201)*. A similar type of reagent formed by oxidation of dithiophosphates is described *(U. S. pat. 2,060,815)*.

Dixanthogens, when pure, do not coat clean sulphides, *i.e.*, they act like neutral oils in this respect (Art. 6). As ordinarily made, however, they contain residual xanthate in solution and thereby have more or less tendency to collector-coat sulphides according to their xanthate content. Such material exhibits the selective action between sulphides and nonsulphides observed by Wark and Cox *(112 A 316)*.

Gaudin *et al.* *(112 A 346)* assert that both galena and covellite react with dixanthogen to form the corresponding xanthates; the experimental basis comprised grinds of many hours (2 1/2 to 92) in closed containers, and is not to be accepted as in any way representative or indicative of normal operation.

Thiuram disulphides $R_2N{-}\underset{\underset{S}{\|}}{C}{-}S{-}S{-}\underset{\underset{S}{\|}}{C}{-}NR_2$ are the oxidation products of thiocarbamates. Their use as collectors has been suggested in patents, but they have not been used commercially.

Heterocyclic sulphides, *e.g.*, thiophenes,



have been suggested *(U. S. pat. 2,169,313)* as collectors for metallic sulphides. Since, however, they act chemically much like the benzenes, they promise little.

Carboxylic collectors

This group comprises the acids and salts in which the active group is CARBOXYL (—COOX), where X is acidic hydrogen or a base. The only carboxylic collectors which have had other than laboratory use are the fatty and resin acids and their alkali salts (SOAPS). They have been used for both base-metal and earth-metal minerals, but at present have been supplanted in base-metal work by the sulphydric collectors. Flotation with fatty acids and/or soaps is called SOAP FLOTATION.

Fatty acids comprise several homologous series of compounds consisting of chain-type hydrocarbon radicals with a carboxyl group in terminal position. Thus their generalized formula is R·COOH. They are so named because the higher members of the series occur naturally in animal fats. They also constitute, either as the free acid or as ESTERS (R·COO·R′ = reaction products of the acid with an alcohol, R′·OH, thus $R \cdot COOH + R'OH \rightarrow R \cdot COO \cdot R' + H_2O$) the greater part of all animal fats and oils and vegetable oils. When the R group has all of its carbon valences satisfied, the fatty acid is SATURATED, *e.g.*, stearic acid, $C_{17}H_{35}COOH$. If two of the adjacent carbons in the R group have each one carbon valence unsatisfied, the acid is MONO-UNSATURATED, *e.g.*, oleic acid, $C_{17}H_{33} \cdot COOH$. Some fatty acids, notably those in castor oil and in some fish oils, have a number of the carbons in the R chains unsaturated; such acids are said to be highly unsaturated. The common unsaturated acids are liquid at normal atmospheric temperatures; the corresponding saturated acids above C_8 are solids. All of the higher members are relatively insoluble in water, but are sufficiently soluble to ionize at the interface between their dispersed masses and water with which such masses are in contact. Oleic and palmitic acids are the ones commonly used. Keck *et al.* (*134 A 102*) found that in floating hematite the order of effectiveness of the fatty acids tried was oleic > lauric > myristic > palmitic > caprylic for less than 1 lb. per ton of collector, while the more soluble caproic and valeric acids gave substantially no recoveries at 10 lb. per ton.

Soaps are metallic salts of the higher fatty acids (R·COO·M). The sodium soaps are the hard soaps of ordinary domestic and household use; the potassium soaps are softer. Soaps are made by decomposing natural fats and oils with sodium and potassium hydroxides respectively. By an extension of older terminology, the organic salts formed by reaction of a fatty acid with an organic base, *e.g.*, an amine, are also called soaps. Alkali-metal soaps and amine soaps are soluble to a considerable extent in water, and ionize to a somewhat smaller extent than they dissolve. The heavy-metal and earth-metal soaps formed by metathetic reaction between salts of the corresponding metals and an alkali-metal or amine soap are relatively insoluble in water; both classes, however, form in water acid and basic soaps, one or the other predominating according to the *p*H and to the metal of the soap; the neutral soaps of these metals exist alone only within comparatively narrow *p*H bands (*153 A 500*). These acid and basic soaps are ionized in water, are consequently water repellent, and, even though adherent to mineral-particle surfaces, do not have collector action. In general the *p*H of neutral-soap formation is that through which the hydroxide of the metal precipitates.

Crago (*U. S. pat. 2,105,807*) reports flotation experiments which confirm this analysis, showing that when a mixture of nonsulphide minerals all flotable with soap are conditioned together in a deslimed pulp, one floats preferentially with light frothing and that the differential effect is accentuated by repeated cleaning.

Use. Fatty acids and soaps are collectors for all minerals which, in water, free an earth- or heavy-metal ion, or onto the surface of which such an ion can in any way be plated (Art. 7). This fact has the effect of making these collectors largely nonselective, and it is for this reason that they have been supplanted for heavy-metal collection by the sulphydrate collectors, which do not form insoluble salts with the earth metals. But since no such substitute has yet been found for the earth-metal minerals, the fatty compounds constitute the principal collectors for many of these. The carbon content must be C_8 or greater, preferably greater than C_{12}, on account of the relatively high solubility of the earth-metal soaps of the lower acids, and it should not be greater than C_{18} or C_{20}, because of the low solubility of the higher alkali-metal soaps, in which form the collectors are usually dispersed. Some collection can be effected by $<C_7$ fatty acids by adding sufficient quantities to depress ionization of the coating soap by mass action, but recovery is poor and the operation uneconomic. Selectivity between the various earth minerals has to be achieved by control of *p*H, which determines the degree of conversion of the precipitated soap coatings to acid and basic forms, and by control of the solubilities and chemical characters of the surfaces of the minerals that it is desired to depress, so as to prevent the formation of effective soap coatings on them. (See Art. 10, ***Sodium silicate, Phosphates;*** and Arts. 52, 53 under the names of specific minerals.)

Introduction of the collecting ion as the acid is preferable to addition as soap, from the standpoint of froth control, especially if considerable quantities are added at once, since large quantities cause the formation of voluminous, lightly loaded froths. Mineral oils are credited with correcting such over-frothing; what they really do is to smear over the over-coated mineral-particle surfaces and render them collectable, whereupon the solid load on the bubbles breaks down the large ones and adds stability to the small (see Art. 12), so that compact heavily loaded and desirable froths are produced.

Miscellaneous uses. The fatty-acid collectors are frequently depended upon for both collecting and frothing when used in alkaline pulps. The practice is bad, since it does not permit independent

control of the two functions. An independent noncollecting frother will ordinarily improve both grade and recovery, and decrease total reagent cost. Soaps of saturated fatty acids froth much less than their unsaturated analogs.

Since fatty acids are collectors for iron and manganese oxides, they are sometimes used for gold ores in which the values are associated with these oxides. They are also used for some oxidized metalliferous-salt minerals, *e.g.*, copper carbonates at KATANGA, and in some instances for floating iron sulphides after depression in differential sulphide flotation. The water in which they are used should be kept as "soft" as possible (Art. 32), since lime and magnesium soaps precipitated in solution tend to smear all solids indiscriminately and render them all more or less floatable.

Quantities of soaps and fatty acids required vary enormously with pulp conditions and the methods of use. Since the fatty acids are relatively insoluble they must be dispersed mechanically, and the amount needed in a given pulp will vary inversely as the degree of dispersion. In alkaline pulps the alkali-metal soap formed acts as an emulsifying agent, so aiding dispersion; in acid pulps an emulsifier of the sulphated alcohol type, which will ionize in such an environment, should be used. Neutral oils added with the fatty acid will be emulsified with it. The amount of reactive collector required will increase with the fineness of the feed and with the extent of closure of the gangue surfaces (Art. 8). If slime is removed, the *p*H is not too high, and an auxiliary frother is provided, 0.5 lb. or less of oleate soap will suffice unless the feed is very fine sand and substantially all of it must be floated. With good emulsification the amount of fatty acid will not exceed twice the soap requirement. Stage addition (Art. 33), the use of neutral oil, and oiling in a thick pulp may more than halve these figures.

Tall oil (TALLOEL; AC 708) is a mixture of fatty and resin acids extracted from wood pulp in sulphite treatment. It is a cheap source of fatty acid. The resin-acid content adds frothing power, which may become undesirably great if *p*H is permitted to rise above 9. The tanninlike bodies present in the crude sulphite liquor depress frothing somewhat; slime in feed accentuates it. Talloel is used commercially both in phosphate and cement-rock flotation, and has proved effective experimentally for fluorite, barite, manganese oxides, and tungsten minerals.

Talloel soap (AC 608) is made by dissolving tall oil in moderately strong caustic soda solution (about 1 part caustic to 6 parts of oil). This is best added as a dilute solution, *e.g.*, 5%.

See also AMMONIATED TALLOEL, Art. 13.

Naphthenic acids are carboxylic acids of the type R·COOH in which the R is a ring hydrocarbon, usually of 5 or 6 carbon atoms, with two hydrogens or hydrocarbon substituents on most of the carbons, *i.e.*, without unsaturation in the ring. They have been used for phosphate and barite (*RI 3397*).

Use of neutral oils with soaps developed from the fact that unless the *p*H was rigidly controlled at the point of maximum neutral-soap formation—which it never was—the contact angle ranged up and down the legs of the curves of Fig. 2, and flotation was uncertain and frequently poor. But neutral hydrocarbon oils will spread over soap-coated surfaces that contain considerable amounts of acid and basic soaps, whereupon the surface presented for air attachment is the neutral hydrocarbon surface, the contact angle against which is affected little or not at all by wide changes in *p*H. Furthermore, the contact angle against a neutral hydrocarbon surface is 15° to 20° higher than that against a surface monomolecularly coated with a fully neutral C_{17} soap, the difference bringing the angle over into the obtuse range (>90°), which causes a tremendous increase in tenacity of bubble attachment.

Quantity of oil used must be kept down to such an amount that the film is less than about 4 molecules in thickness; below this thickness the layer, on a solid surface, has the characteristics of a solid, above it the characteristics are that of a liquid, and gas bubbles will neither precipitate at nor adhere to a liquid oil-water interface.

Sulphoxy collectors

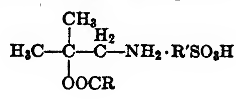
The wetting-agent frothers (Art. 13) are asserted in a number of patents to be collectors for both sulphide and nonsulphide minerals.

Lenher *et al.* (*U. S. pat. 2,074,699*) state that the mixture of organic sulphonates and sulphates resulting from sulphonation of crude lauryl alcohol is a specific collector for sillimanite; will float galena, sphalerite, and the copper sulphides and barite; and generally acts as a collector wherever a fatty acid would serve. One of the oldest of the wetting agents, TURKEY RED OIL, which is largely a sulphuric-acid ester of glyceryl ricinoleate, was described as a collector by Everson (*U. S. pat. 348,157/1886*). Dean *et al.* (*RI 3419*) state that the wetting agents are somewhat less effective collectors for sulphides than the xanthates are and are more sensitive to soluble salts and slimes; that some float sphalerite without activation; that some are as good for nonsulphide flotation as fatty acids are, but that in general larger amounts are required; and that Emulsol X-1 (the sodium salt of the sulphate ester of complex [probably unpurified] higher alcohols) is specific for barite, amblygonite, and beryl. All of these statements are consistent with the conclusion of Dean, Clemmer, and Cooke (*RI 3333*) that the residual fatty acids in some of the cruder wetting agents make them act as anionic collectors, and with the experience of

other investigators that only such recovery as is to be expected from accidental contamination is obtained with these reagents without additional collectors. Some of them as sold are intentional mixtures, thus EMULSOL 238 comprises 7 parts Emulsol X-1, 83 parts corn oil (a mixture of fatty-acids and glycerides) and 10 parts water (*RI 3328*), yet the emulsifier is carelessly given credit for collection. Ralston (*40 CIMM 691*) reports that U. S. POTASH CORP. is using sodium octadecyl sulphate (AVIROL 80) as frother and collector for floating sylvite from halite in saturated brine, but Dean *et al.* (*loc. cit.*) report that Emulsol X-1 will not perform this separation although it can be effected by use of a neutral-oil emulsion made with the X-1 reagent. Dean and Hershberger (*134 A 88*) assert that sulphonation of oleic acid reduces its effectiveness as a collector and that the butyl ester of the sulphonated acid is even less effective. [The ester is probably completely ineffective, such effect as was observed being due to unesterified acid.]

DUPONOL 80 = Na octyl sulphate; DUPONOL WA PASTE = technical Na lauryl sulphate; DUPONOL LS PASTE = technical Na octadecanyl sulphate; DUPONOL D PASTE = higher alcohol sulphate; ULTRA-WET is a sulphonated petroleum product, C_{14} average; EMULSOL X-1 = sulphates of C_8–C_{12} alcohols (*RI 3271*).

Jayne *et al.* (*U. S. pat. 2,278,107*) describe the organic sulphonic-acid salt of an amino alcohol mixed and probably esterified with a fatty acid; a typical example is



5. CATIONIC COLLECTORS

Definition. Cationic collectors, properly speaking, are ionizable organic compounds in which the ion that carries the hydrocarbon and reactive groups is the cation. Such collectors have the general formula R—M—$(R')_n$—Y, where R is a hydrocarbon group, R′ is hydrogen, or the same or a different hydrocarbon group from R, M is pentavalent nitrogen or quadrivalent sulphur, n is a number equal to the valence of M reduced by 2, and Y is hydroxyl or an acid anion, usually halide. They comprise the "-onium" compounds, tetrammonium, pyridinium, quinolinium, and sulphonium.

Amines are derivatives of ammonia in which one or more of the hydrogens of the ammonia is replaced by a hydrocarbon radical. They are primary (MONO-), secondary (DI-) or tertiary (TRI-) amines according to the number of hydrogens replaced. When placed in water they react with it to form the corresponding hydroxides and they react with acids in the same way as ammonia does. The resulting hydroxides and salts in turn react with other salts in aqueous solutions as do the ammonium salts. Amines are classed as cationic collectors. The designation is accurate when the collecting reaction is one of ion exchange with the hydroxide or salt, as is the case with the so-called nonmetalliferous minerals; it is erroneous when the amine acts as a collector for the heavy-metal (METALLIFEROUS) minerals (see p. 15).

Cationic collectors are used principally at present (1943) for flotation of silicate minerals, including quartz. Recent laboratory work (*CU*) indicates their utility for tungstates, molybdates, vanadates, chromates, and arsenates, from which it may be concluded that they should be effective generally for salt-type minerals in which the acid ion contains a metallic atom. They are also broadly useful for nonmetallic minerals, when used with a conditioner comprising an anion common with that of the mineral to be floated (*A TP 1685*).

α-Naphthylamine was used for a number of years for flotation of copper sulphides; there is little or no use of amines in sulphide flotation at present.

Reactions of cationic collectors with nonsulphide minerals is metathesis of the same type as occurs with anionic collectors (Art. 3) except that the cation of the mineral is displaced by the hydrocarbon-bearing cation of the collector.

Abstractions of laurylamine by quartz and by scheelite have been made at Columbia; in the case of the latter mineral it was found that calcium ion was thrown into solution by the reaction. Precipitation tests have shown a precipitate when laurylamine hydrochloride solution was mixed with solutions of silicate ion (*RI 3333; RI 3357; CU*), with all of the metal-acid ions above listed (*CU*), and with carbonate, sulphate, chlorplatinate, and chlorcuprate (probably) (*CU*). In several cases where precipitation occurred, contact angles were obtained with a mineral containing the precipitating ion. Scheelite, barite, and calcite were floated by laurylamine hydrochloride.

Collecting reaction of amines with quartz appears to consist in preliminary formation of a silicic acid film at the particle surfaces according to some such equation as $SiO_2 + H_2O \rightleftharpoons H_2SiO_3$, followed by reaction with the amine hydroxide, thus $RNH_3 \cdot OH + H_2SiO_3 \rightleftharpoons (RNH_3)\ SiO_3 + H_2O$ (equation purposely unbalanced; see p. 05). Existence of the acid coating with the silicate ion adherent, prior to the introduction of amine, is indicated by

the fact that quartz is in Brownian movement in distilled water (Sec. 15, Art. 3). The amine stops the movement and is abstracted from solution.

Solubility of amine salts is not, in general, as low as that of the xanthates or oleates. Hence it is normally necessary in amine flotation to increase the concentration in solution of an ion common to the coating compound in order to effect good collection (Art. 7). The order of solubilities and the general magnitude follow: Molybdate, vanadate < silicate $< 2.5 \cdot 10^{-4}$ mols per liter < carbonate, tungstate, chromate, phosphate < $7.5 \cdot 10^{-4}$ mols per liter < thiosulphate < bicarbonate, sulphite, dibasic arsenate < $12.5 \cdot 10^{-4}$ mols per liter < sulphate $< 25 \cdot 10^{-4}$ mols per liter < fluoride, borate, chloride, sulphide, monobasic phosphate $> 25 \cdot 10^{-4}$ mols per liter (*A TP 1685*).

Collecting reaction of amines with heavy-metal sulphides apparently results (*153 A 517*) in the formation of a metal-amine compound in which the metal and amine constitute an amine-metal complex ion similar to the metal-ammonium ions. Laurylamine is a collector for all of the metallic minerals tested which form water-stable co-ordination complexes with ammonia (Cu, Pt, Ag, Zn, Ni, Cd, Fe″, Sn) and is not a collector for those tested which do not form such water-stable ammonia complexes (Mg, Al, Pb).

The reaction would appear to comprise displacement of "aquo" (or, in some cases, of an "ol" or "oxo" group [A. W. Thomas, *Colloid chemistry*, McGraw-Hill, N. Y., 1934]) from the hydrated ion of a compound of the metal occurring at the surface of the mineral, *e.g.*, $[Cu(H_2O)_4]\ SO_4 + xRNH_2 \rightleftharpoons [Cu(RNH_2)_y(H_2O)_{4-y}]\ SO_4 + yH_2O + (x - y)\ RNH_2$, where y is an integer from 1 to 4 and $x \geqq y$.

Contact angles for laurylamine with heavy metals is 85 to 90°; for nonmetallic minerals the angle with laurylamine hydrochloride is 60° ± 5. The indication is that the metal-amine complex ion contains at least two of the amine groups. Complex metal-ammonia ions may (with the exception of those of H and Ag) contain less than the full complements of NH_3, and, presumably, of RNH_2 (*Hammett*). The magnitude of the contact angle with a given hydrocarbon group in the coating ion is, in general, a measure of the surface concentration of the coating ion (Art. 7). Silver gives an angle in the 85 to 90° range and its ammonia co-ordination number is 2. There is some evidence (Gaudin and Vincent *A TP 1242; CU*) that with nonmetallic minerals the number of amine-ammonium-type ions per acidic ion of the mineral lattice is one. Such an explanation would account for the difference in contact angles cited.

When an amine salt is used as a collector for a sulphide, it functions by reason of the free amine present according to the equilibrium, *e.g.*, $(RNH_3)Cl \rightleftharpoons RNH_2 + HCl$.

Flotation of galena with amine collectors would run counter to the metal-amine-ion hypotheses set down here. Such flotation with commercial amine collectors is possible. Baker (*A TP 1585*) has shown, however, that with pure α-naphthylamine no flotation of galena occurs, although good flotation was effected with the commercial material before purification, and that the extent of flotation decreased as purification progressed. When, therefore, flotation of sulphide minerals containing heavy metals not on the list of those that form water-stable ammonia complexes is effected, as not infrequently occurs, either of two explanations is probable, *viz.*, that the sulphide has become activated (Art. 7) by some metal or acid ion that reacts with amine-bearing ions to form collector coatings (*e.g.*, Cu or Ag, or silicate or carbonate; *112 A 303, 398*), or that the amine reagent contains fatty-acid amine soap. The latter is almost invariably the case with the higher aliphatic amines unless they have been most carefully purified.

Christman *et al.* (*U. S. pat. 2,278,060*) describe collectors comprising the products of reaction between polyalkylene polyamines and fatty acids, such products being amines or esters of the general formula $\underline{Y} \cdot CO \cdot NH \cdot A \cdot Z$, in which A = 2 or more CHR—CHR′—NH— groups in series, $\underline{Y}$ is an aliphatic chain of 9 or more carbon atoms, and Z is H or an acyl radical of an aliphatic acid of 10 or more carbon atoms or the acid salt of such a compound.

Jayne *et al.* (*U. S. pat. 2,336,868*) describe thioureas of the general form HN : CSR·NHR′ in which R′ is hydrogen or an alkyl, aryl, aralkyl, or alicyclic radical or one of the type —CNH_2 : X, where X is NH, O, or S; and R is preferably an alkyl radical of 8 to 32 carbon atoms, *i.e.*, a sufficient loading to prevent tautomeric shift with an amine hydrogen (see ***Thiocarbanilid***, Art. 3). They recommend these for flotation of silicate minerals from nonsulphide nonsilicate salt-type minerals, particularly phosphates.

-Onium collectors are those in which high-valent nitrogen, sulphur, or phosphorus forms the connector between a hydrocarbon-loaded cation and an anion. The nitrogen compounds are either analogs of the inorganic ammonium salts in which the H atoms of the ammonia radical are more or less completely replaced by hydrocarbons, *e.g.*, R_4NA, where the four R groups may be the same or different, and A is usually a halogen; or ring-type compounds in which a part of the carbon loading of the nitrogen is the ring, *e.g.*, pyridinium, . In the sulphonium compounds S is tetravalent, so that the compounds have the general equation R_3SA. In the phosphonium salts the phosphorus is pentavalent, and the salts have the general formula R_4PA. In general, in this class of collectors, at least one of the R's is C_{12} or greater.

Isourea compounds of the type $R{-}O{-}\underset{\overset{|}{NH}}{C}{=}N \cdot HX$, where X is an acid ion, are said to be collectors for silicates when R is a C_{12} to C_{18} aliphatic radical (*U. S. pat. 2,205,503*). The patent further asserts that the compound floats fluorite from silica and sphalerite from its ores.

Aldoximes (R=NOH) are either acidic, *i.e.*, reacting by displacement of H by a base, or basic, reacting by addition, as ammonia, with acids. Heptaldoxime is reported (*ibid.*) as a collector for talc; here the reaction should be typically cationic in acid solutions. Erratic success has been attained at Columbia with cupferron ($ON \cdot C_6H_4 \cdot NH \cdot ONH_4$) as a collector for cassiterite and for hematite, where the collector reaction should be with the cation.

Curiosities. Organic base (tetrammonium, pyridinium, etc.) salts of fatty-acid glycollic esters are described as collectors (*U. S. pat. 2,177,985*). In so far as these are soluble, they will free ions which are collectors, respectively, for silicate, and heavy- and earth-metal ions. They should float the earth itself, if sufficiently subdivided.

Use. Few reliable data are available as to commercial use of cationic collectors. Laboratory work is described in a considerable patent literature and in a number of publications of the U. S. Bureau of Mines. On the basis of these the following generalizations are indicated. (1) The silicate minerals may be grouped, so far as cationic flotation is concerned, as readily floatable, moderately floatable, and difficultly floatable. The readily floatable comprise talc, the secondary micas and sericites, kaolin, silicate-type slimes, and the like highly hydrated forms; the moderately flotable include the primary micas, zircon, kyanite and the related group, and slightly altered granular silicates generally; the difficultly floatable are quartz and the unaltered granular silicates. (2) The collectors may be classified as to floating capacity roughly on the basis of solubility in water, such capacity increasing with decrease in solubility, which, in turn, is in inverse relation to the carbon loading. Increased carbon loading may be effected either by increase in substitution or increase in carbon content of substituents, or both. In general, attainment of a given carbon loading in an unsymmetric amine imparts higher flotative capacity than when the same total carbon loading is effected symmetrically. (3) Collectors of low flotative capacity may be used for the readily floatable silicates; reagents of high capacity must be used for those difficultly floatable. For readily floatable silicates di- and tri-alkyl amines of 8 to 15 carbon atoms are best; for the moderately floatable, amines of 12 to 18 carbon atoms with most of the carbon in one or two substituents should be used; for quartz and the difficult silicates use amines, tetrammonium, or pyridium and like compounds with one substituent at least of 16 to 18 carbon atoms. This classification is not to be accepted as tested and reliable; it is, however, reasonably in accord with the scattered data available (1942). No such information is available as to the salts of metal-acid ions or for the sulphides that are floatable by cationics.

Cole (*U. S. pat. 2,340,580*) describes the use of DP 243, fortified with fuel oil, in a pulp made strongly acid with H_2SO_4, and with pine oil as a frother, to remove iron impurities from a deslimed glass sand; reduction in iron content to $<0.02\%$ is asserted.

Adoption of cationic flotation is largely a question of cost. In many cases of nonsulphide flotation the bulk of siliceous impurity is relatively small and flotation thereof instead of flotation of the large bulk of nonsiliceous mineral is desirable from an operating standpoint. But the relatively large quantity of collector necessary (averaging 1 lb. per ton upward), the relatively high price, and patent royal ties have tended to make anionic flotation the economic choice (1943).

Choice of cationic collectors is first a matter of fitting the general class to the type of mineral to be floated, and thereafter choosing largely on the basis of least unpleasant frothing characteristics and price. All cationic collectors are surface active; in slimy pulps they tend to form voluminous persistent froths that cause difficulty in product thickeners and thus add to operating costs. All of them are relatively expensive, both from the chemical and patent-licensing standpoints. None of them makes the clear-cut selections that prevail in sulphide flotation. All, as manufactured commercially and sold, are likely to contain more or less large residues of the fatty acid starting materials, and this residue will tend to float sulphides as well as heavy-metal and earth-metal nonsilicate minerals over and above those floatable by the cationic reagent itself.

The problem is further complicated from all angles by the present practice of marketing the reagents under trade names and keeping identities secret. Many of the different trade names describe the same substance as prepared by different manufacturers or the same substance in different degrees of impurity as made by the same manufacturer. The sooner buyers refuse to purchase on the trade-name basis, and demand warranties as to content of cationic chemical and anionic contaminants, the more quickly cationic flotation will get onto a stable operating basis.

Trade names. The following data, compiled from various sources, are of some aid in interpreting otherwise unintelligible Reports of Investigations.

AM, followed by a 4-digit number, indicates and describes an *AM*ine, manufactured by Armour & Co. (*PC*). The first digit is 1, 2, or 3, denoting respectively a primary, secondary, or tertiary amine. Digits two and three together denote the number of carbon atoms in the substituent, *e.g.*, 18 (eighteen), 08 (eight). The fourth digit, 0, 1, 2, etc., denotes the character of the substituent as regards degree of unsaturation, *e.g.*, 0 = no double bonds, *i.e.*, saturated; 1 = one double bond; 2 = two double bonds. Letters in place of the four digits indicate a mixture of the fatty acid chains naturally occurring in the oil indicated, *e.g.*, Coco = coconut oil. If no letter follows the four digits, a C.P. (chemically pure) product is indicated; an A appended indicates technically pure; B denotes a mixture of C.P. amines, one of which has the character indicated by the digits; C indicates a similar mixture of technically pure amines. Thus AM 1180 is C.P. *n*-octadecenyl amine; AM 1181-A is T.P. *n*-octadecenyl amine; AM Coco-C is a mixture of technically pure amines corresponding to the fatty acids normally occurring in coconut oil.

DP, followed by a letter or number, denotes a DuPont product. The following are the principal cationic collector types (*PC*).

DP 243 is a 50% aqueous paste of Lorolamine (see below) hydrochloride.

DPQ is lauryl trimethyl ammonium bromide.

DPQB is DPQ of technical grade.

DPC is cetyl linked to a carbon of a betaine (*18 Bul A Cer S 286*).

DPN is stearyl linked to a nitrogen of a betaine (*ibid.*).

DPLA (Duponol retarder La) is technical stearyl trimethyl ammonium bromide.

Lorol is a mixture of primary straight-chain alcohols, about 18% C_8, 10% C_{10}, 55% C_{12}, and 17% C_{14}.

Lorolamine is the mixture of amines produced from Lorol; it contains less than 5% combined secondary and tertiary amines.

DLT series numbered as below are condensation products of ethanol amine and higher fatty acids: 100, 101, 466, 521, 555, 652, 653, 655, 672, 683, 692, 693–696, 698, 698-B, 699, 907, 958, 1001–1006, 1008, 1009, 1041, 1042 (W. Kritchevsky, 1401 W. Jackson Boulevard, Chicago).

Emulsol: Wetting agents by Emulsol Corporation, New York. K-1249, 1339, 1340 are quaternary ammonium compounds with aliphatic substituents. 660-B, 660-C, S-831, 903, 903 L, 1336 are pyridinium salts. 1950-A is a cationic of unknown class.

Ninol 517, 521, 57A are condensation products of alkylol amines and higher fatty acids (*18 Bul A Cer S 286; U. S. pat. 2,173,909*).

Sapamine MS. Cationic; class unknown.

Quantity of cationic collectors necessary is usually of the same order as that of the soaps, except in the case of -onium reagents with a long alkyl group. The reason is that the solubilities of the surface reaction products are relatively high and that the concentration of the coating ion (or of the acidic mineral ion) in solution must be raised sufficiently to cause precipitation. The law of mass action governs the coating precipitation. In general, in metathetic coating, it will be cheaper to add the acidic ion common with the mineral surface, *e.g.*, $SO_4^{=}$ for barite, silicate for silicate minerals, and the like (*A TP 1685*). Failing this, surface coating with smaller quantities is partial only and contact angles are lower than the maximum for the particular collector. Excess tends to cause depression.

Wark and Wark (*143 N 856*) report that cetyl trimethyl ammonium bromide becomes micellar at higher concentrations and that its collecting power thereupon ceases. Their contact-angle tests (*39 JPC 1021*) indicate that the depression is due to an effect on the bubble, probably the formation of a solid skin such as is formed by excess soap (Art. 4), which resists the displacement necessary in order to permit the coated solid surface to break through to the air. Depression is accompanied by excessive frothing, as is also the case with soap.

Conditioning for cationic flotation. So far as collection itself is concerned, it is controllable within limits by changes in concentration of the reacting ions according to mass-action concepts. Whether mass-action laws prevail in the reaction zone at the particle surface is not known, but evidence points to this conclusion (*CU*), and for the purpose of practical control under mass-action considerations the pulp liquor itself may be taken as the reaction zone.

In general, results are better, and a given collector is more effective on the acid side (talc results, *U. S. pat. 2,195,724*), but this is, in many cases, due to the low solubility of the free base. Acid pulps are frequently used to depress nonsilicates in cleaning; the effect is often due to the higher solubility of such salts in acid solutions. Alkali should aid in floating readily floatable from difficultly floatable silicates by lowering the concentration of amine ions. The quaternary ammonium compounds are not affected by hard water (*RI 3333*), but *RI 3419* states of cationics generally that they are sensitive to soluble salts and to slimes. Emulsol 660-B is not affected by moderate amounts of $CuSO_4$, $ZnSO_4$, $Pb(NO_3)_2$(*RI 3333*). An inorganic salt of a polybasic acid is recommended in flotation of quartz with tetrammonium and sulphonium salts. Aluminum salts are reported to aid cleaning (*RI 3558*). Quartz is reported to float best at pH 7.5 to 7.8 with tristearyl ammonium bromide; lead acetate and NH_4OH are the best modifiers (*18 Bul A Cer S 286*).

Oil aids in collection with cationic reagents when weak (low-C) reagents are used. The action, as is discussed in Art. 3, is solution-coating of hydrocarbon-coated surfaces

which have low water-repellent property but sufficient oil-water selectivity to cause oil to spread on them. The surface presented for bubble attachment is a neutral hydrocarbon surface which does not require orientation, if sufficiently thin to have lost its liquid character.

Frother used with cationic collectors is frequently important. Pine oil, with the tendency to make brittle froths, will usually correct, more or less, an overfrothing tendency on the part of the collector, but tends to float nonsilicates, if any fatty acid is present in the system. The higher alcohols have less corrective tendency as to overfrothing, but they float accidentally oiled material less readily. Cresol may carry more or less carboxylic acids and neutral oils, which tend to float nonsilicates.

6. OILY COLLECTORS

Definition. The phrase OILY COLLECTORS is used herein to designate oily liquids which are good solvents for hydrocarbons; which are substantially insoluble in water; which, when spread out thinly at solid surfaces, will cause bubble attachment thereto in the presence of water; and which do not, of necessity, contain ingredients capable of effecting reaction coating of minerals, although such materials may be contained. Oil such as this is best typified by the neutral hydrocarbon liquids of petroleum and of wood and coal tars, with boiling points upward of 350° to 450° F, and viscosities low enough, at ordinary atmospheric and pulp temperatures, to permit uniform feeding and ready dispersion in the pulp. It is desirable, also, that such an oil lack frothing power.

Oils normally employed are the lighter fuels, *i.e.*, kerosenes, gas oils, and cut-back cracking-still tars; and the wood- and coal-tar creosotes. The latter are available with varying quantities of tar acid, *e.g.*, BARRETT #4 contains 25% tar acid, BARRETT #410 slightly less, and BARRETT #634 is substantially all neutral oil. Frothing capacity increases, of course, with the tar-acid content. Specific viscosity should not be greater than 2.5 at the temperature of use, or dispersion will be difficult and the oil will tend to film too thickly. A pale neutral dewaxed distillate (26 A.P.I.) from a paraffin-base crude, with a viscosity of 100 to 115 sec. Saybolt Universal, is used at CLIMAX (*A TP 1675*). This is equivalent in action to the refined white oils of the Nujol class.

Use. Oils are invariably used as auxiliary collectors in table flotation, the reason being that the frosting of small bubbles attached in the thick-pulp conditioning and subsequent cascading onto the table must survive handling that tends to brush them off. Such bubbles should, therefore, make large contact angles with the particles. Contact angles with surfaces thinly oiled with neutral hydrocarbons are upward of 90°; these tend to spread further rather than to be peeled off when they are pushed around at surfaces.

Oils are also used in froth flotation with carboxylic collectors in order to escape the necessity for accurate control of *p*H. With cationic collectors, particularly those with small carbon loadings, oil is a marked aid, since it makes a much larger contact angle with the chemically coated surfaces than air does, and, thereafter, aids air-bubble attachment, as above described. Oil should not be used, however, when differential flotation is sought between two or more minerals all more or less reaction-coated by the same collector.

Oil is used in flotation of oxidized metalliferous ores to intensify floatability of the oxidized minerals. It has the further effect of conserving chemical collector by closing off lightly coated surfaces against continued deeper reaction. It is also used in flotation of oxidized gold ores, where intensification of levitation to the maximum possible is the desideratum.

Quantity of oily collector necessary depends upon the conditions affecting dispersion. If an oil is reasonably mobile, or is used in a machine employing strong agitation, or oiling is done in a thick pulp, and the pulp is, in each case, relatively free of slime (Art. 7), 0.5 to 1 lb. of oil per ton of feed is the maximum that will be needed; under unfavorable converse conditions several pounds per ton may be necessary and selectivity will be poor.

Reconstructed oils are oils that have been refluxed with sulphur at temperatures sufficient to cause reaction therewith. Mercaptans are always formed, whereupon the oily mixture takes on collecting power for heavy-metal minerals because of the coating reaction with the mercaptan.

CONDITIONING

The essential prerequisite to separation by flotation is selective collector-coating. The necessary implication is that one mineral species shall be subject to such coating while all other species present are not. It is the function of conditioning either to insure this state of affairs or to take such steps as will compensate for departure therefrom.

Necessity for conditioning becomes apparent quickly when it is considered that collection, in the case of all but the inert minerals (Art. 54), involves selective chemical reaction between a minute amount of the highly reactive collector and the surface material of particular solid particles in a pulp which comprises a highly complex aqueous solution, a suspension of solids more or less closely related chemically to the solid with which reaction is desired, and a miscellany of extraneous solids of highly varied character. The solutes are those present in the original water supply, others derived from the ore with which this water is in present contact, possibly others retained from prior contacts with ore undergoing flotation or other treatment (*e.g.*, cyanidation), extracts from extraneous vegetable and animal matter, etc. The suspended matter, other than the ore minerals, comprises inorganic precipitates formed by reaction between dissolved ore-mineral ingredients, and undissolved organic residues, of which the most important usually is lubricant picked up by the ore in its travels to the cell, but occasionally is humic matter from decayed and decaying plant life. Many of these ingredients are capable of chemical and physical reactions and interactions between themselves and with the collector; interparticle reactions modify the original particle surfaces; collector reactions may result in collector consumption without any coating being effected, or may cause it to coat in the wrong places, or both. Control of this locale is one of the most important operations in the flotation process from the standpoint of economics. Given a suitable collector in unlimited quantities, plenty of time, and no limitations on recovery and grade of concentrate, it is almost impossible to prevent concentration of a sort whenever a pulp is subjected to suitable levitation and frothing conditions. But collectors are expensive, collection time and machine capacity vary inversely, low recovery means that money which has been expended for mining, crushing, and grinding is thrown on the tailing pile, entirely apart from possible profits lost, and low-grade concentrate means money gifts to the railroad and the smelter. Conditioning determines the state of the particle surfaces and the ion content of the pulp water, and is so regulated as to bring about the maximum of desirable selectivity at minimum expenditure of time and money. Its importance may be judged from the fact that 0.1 mg. per li. of copper ion will activate sphalerite (*87 A 417*), grinding in an iron mill activates quartz, and a minute amount of fatty acid, such as is picked up in the mine lubricants, will hinder and may prevent depression of sphalerite by cyanide.

Definitions. The steps taken in practice to cope with the difficulties outlined above are almost as varied as the difficulties stated and implied. Some grouping is, however, possible. Thus treatments directed specifically toward procurement and maintenance of an effective collector-coating on the desired mineral are called collectively ACTIVATION. Those directed toward prevention of entry of undesired minerals into the overflow are grouped under the name DEPRESSION. Further classification has not yet been effected; the various further operations, which include protection of collector from chemical destruction; maintenance of pulp conditions most favorable to the reactions of collectors, activators, and depressants; maintenance of good frothing conditions, etc., are referred to specifically in the art by naming either the operation, the function, or the reagent, and this practice is followed herein.

It should be noted that perhaps the most informative reading for the flotation experimenter, and for the operator treating complex ores, is the literature of chemical analysis, particularly that which deals with the use of organic precipitants and specific indicators.

Conditioning time. Since conditioning comprises chemical reactions in solutions of very low concentration, and relatively close approach to equilibrium is necessary in many cases, sufficient time must be allowed. Conditioning times in the plants, which, on the average, represent the result of reasonably thorough investigation, vary from a fraction of a minute (reagents added in the cell or feed launder) in easy single-mineral flotations with soluble reagents to 5 or 10 hr. for difficult operations (secondary zinc at MIDVALE; *IC 6492*). The usual times in zinc-lead work are ±5 min. in the lead-circuit conditioner and 15 to 30 min. in the zinc conditioner. Both recovery and reagent consumption are unfavorably affected by less than optimum times. Order of addition of conditioning reagents may have important effects on necessary time and reagent consumption; the probable reactions should be postulated and additions made in the order that will favor them.

On the contrary, conditioning time may be too long, resulting in deterioration of recovery and/or grade of concentrate; for this reason, once the optimum time has been determined arrangements should be made to hold time as nearly constant as possible.

Conditioning tanks are designed to give conditioning time-factor and to disperse reagents, at the same time maintaining pulp solids in suspension. If time-factor is short, an agitation-type flotation cell is probably the cheapest and most satisfactory machine. Otherwise a round tank with means for causing circulatory flow of sufficient velocity to prevent sedimentation is best. For coarse pulps the tank should be relatively small, on account of the vigorous agitation necessary to maintain suspension, and long time-factor

must be attained by repetition of treatment in successive tanks. Successive tanks are also necessary when order of addition of reagents is important. With fine pulps large tanks and slow circulation, as by slow sweeps, will serve, the principal consideration in this case being dispersion of reagent. The grinding circuit is an excellent place for conditioning when circumstances permit, but addition of frothers and even of collectors here will result in discharge of considerable tramp sulphide from the classifier which may not float under the more vigorous agitation in the flotation cells.

Conditioning in thick pulps decreases time-factor because of the greater reagent concentration; reagent consumption may also be less, particularly with oily reagents.

Devereaux agitator (Fig. 1*a*, item *A*) is satisfactory for pulps that are not too quick settling. Propeller is upthrust type.

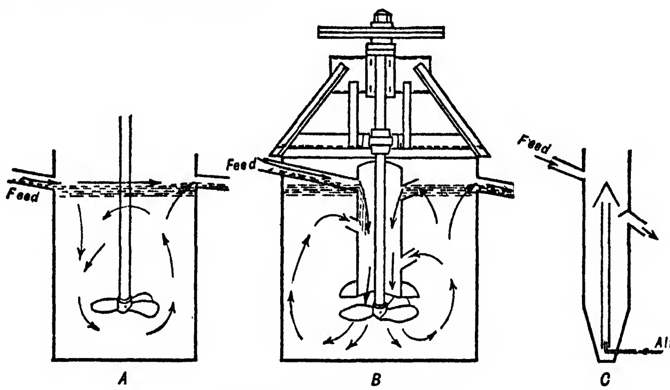


FIG. 1*a*. Conditioning tanks.

At PECOS (*IC 6605*). 8(diam.) × 12-ft. Devereaux tanks had 30-in. impellers at about 3 ft. from the bottom, driven 148 r.p.m. Tendency to sand-up was overcome by bolting an 8 × 8-in. riser to the inside wall, with bottom about level with the agitator and discharge through the tank wall at 11 ft. above the tank floor. The sand that tends to stratify at and below agitator level is thus trapped off and lifted by the accelerated current caused by rising flow of the entire pulp stream through the small conduit.

Denver conditioner (Fig. 1*a*, item *B*) has a central column above a downthrust impeller. The inlets in the wall of the column are to accommodate coarser sands that might otherwise not circulate, or would circulate slowly.

Coarse pulps must be thick or some positive means of circulation must be provided. The usual method is to cone the bottom of the tank and then use an air lift (Pachuca-type tank, Fig. 1*a*, item *C*), or discharge the pulp from the tip of the cone through a spigot and thence to a sump supplying gravity feed to the suction of a sand pump.

At ENGELS (*IC 6550*) a tank-and-pump circuit served both for surge and conditioning. The tank was 20(diam.) × 10-ft. with a 2-ft. central cylinder, the bottom 2 ft. above the bottom of the tank. A 6-in. centrifugal pump took suction on the bottom of the tank and discharged to a launder feeding the top of the well. Working range of pulp in the tank (surge) was about 3 1/2-ft. depth of pulp. Change in level changed conditioning time and was controlled by a splitter in the feed launder, which varied the proportion of return to the tank. Pump elevated 20 ft. and consumed 11 1/2 kw., chargeable against a feed of 1,000 t.p.d.

7. ACTIVATION

General principles. The hindrances to effective collector-coating are both physical and chemical in their nature. It has been found that for a coating to be useful to cause bubble attachment it must be like-oriented, hydrocarbon-end-out from the particle surface (Art. 3). For coatings caused by chemical reaction this implies a monomolecular film (MONO-COATING). If reaction proceeds beyond this, by penetration of the primary film by collector ions, the original lattice arrangement of the coated solid, which held the collector film in the desired position (Fig. 1), is changed, and the components of the film rearrange themselves into a multimolecular film (MULTI-FILM) in which their own crystalline conformation prevails. This normally results in a surface in which polar and nonpolar elements alternate. Air bubbles do not attach to such surfaces. Such multi-films occur in coating relatively soluble mineral surfaces, particularly with small collector ions. The

remedies are either to reduce surface solubility of the mineral prior to coating (see ***Sodium sulphide***, Art. 10), to rub the thick coating down to a monomolecular film before attempting levitation (see ***Attrition mixing***), or to stop the formation of the multi-coating by covering the early mono-film with oil as fast as it forms (Art. 6).

Surfaces that are adequately collector-coated frequently do not attach bubbles. Under such conditions examination usually reveals the surfaces covered with a layer of fine discrete solid particles. The difficulty is a matter of accessibility. It is as though attempt were made to bring a monster balloon (the bubble) into contact with blades of grass (the collector coating) carpeting the floor (the mineral surface) of a forest of tall trees (the small solid particles). Remedies are to prevent the slime coating or to remove it by attrition.

The COLLECTOR-COATING SALTS (reaction products of the collector ion and a mineral ion) of different minerals vary considerably in solubility. The zinc salts of the sulphydric acids are outstanding examples of high solubilities. It is frequently possible to resurface such minerals with ions which yield collector-coatings of low solubility, thus activating the underlying minerals for collection by reagents otherwise ineffective for them (see ***Resurfacing***).

Slimes in an ore pulp are loosely defined as the fine fraction that overflows a desanding separator. Such material, however, contains a major percentage of fine granular material which constitutes ideal flotation feed. It is only the small percentage, fine enough to remain suspended more or less indefinitely in a suitable pulp solution, which ever causes difficulty in flotation. This material, frequently characterized COLLOIDAL SLIME, may be either sulphide or nonsulphide, but is usually of talcy, clayey, or limonitic nature. Its principal offenses are: consumption of reagent, overfrothing, contamination of concentrate, reduction in recovery.

Consumption of reagent by slimes is not serious in extent in sulphide flotation, although a few plants report the necessity for more frother or collector or both when colloidal slimes are present. But in nonsulphide flotation, whether with soap, or with cationic collectors, with or without fortification by oil, colloidal slimes usually consume excessive quantities of such collectors, amounting in some cases to many pounds per ton. Consumption of the reactive collectors is, of course, by chemical reaction and collector coating, as a result of which the slime goes into the froth. The action with oil is coating of the droplets, which are thus stably emulsified, and armored, not only against coalescence with each other, but against their proper functions of smearing the granular material to be floated (Art. 6), or forming selecting interfaces in the bubble column (Art. 19). At EAGLE PICHER it was found (*Q*) that when talcy slimes appeared, more soda ash was required, while increase in limonitic slime increased frothing-agent requirements.

Overfrothing. See Art. 12.

Contamination of concentrate by slimes occurs primarily in nonsulphide flotation when the slime, flocculated and more or less collector-coated, floats. There is minor contamination, both in sulphide and nonsulphide flotation, by dispersed slime carried in suspension in the water, and by reason of slime coating of granular material that is floated despite the coating (see *post*).

Reduction in recovery by slimes occurs in a number of ways. Slime coating (*post*) of granular material otherwise floatable may occur to such an extent as to prevent bubble attachment. Handy (*PC*) states that almost any primary slime in ordinary mill water consists of gelatinous floccules, which when dispersed, as by sodium silicate, drop out very fine sandy material that is readily treated by flotation after removal of the dispersed colloidal material. He recommends such treatment, particularly for oxidized metallic ores. Gaudin and Malozemoff (*112 A 303*) have found that pure sulphide minerals ground excessively fine will not float under the same conditions that are effective to float the same sulphides in granular form. They state that the remedy is to add collector in the grinding circuit, but this is not generally effective in the mills; the only known palliative is to reduce the amount of overgrinding. Prevention of oiling and loss of selecting interface, discussed *ante*, also reduce recovery. Slime is very slow floating.

Slime-coating is caused, on the basis of the available evidence, by at least two different mechanisms.

Cementing hypothesis. Del Giudice showed (*112 A 398*) that certain cases of coating, *e.g.*, calcite slime on galena, were accompanied by an exchange of ions in solution in the pulp, carbonate ion leaving and sulphate ion appearing. This indicates reaction at the galena surface resulting in the formation of lead carbonate, which del Giudice postulated to act as a binding cement between the calcite particles and the galena mass. This postulate was strengthened by the showing that reagents which tended to CLOSE (render less soluble) THE SURFACES of either or both of the minerals, *e.g.*, silicate, sulphide, carbonate, or ethyl-xanthate ions, decreased or prevented coating.

Flocculation hypothesis. Bankoff (*153 A 473*) observed that when conditions in a pulp favor complete flocculation, the granular particles become slime-coated. It had already been shown (*87 A 217*) that when pulp solids are dispersed they are in Brownian movement and that the conditions in the pulp are such as to produce at the particle surface a compound having a bulk solubility of 0.5 to 15 or 20 mg. per li. Fitt *et al.* (*153 A 493*) have shown that under such conditions the dispersed particles, with one of the ions of the postulated coating, will, in an electrical field, migrate to one pole while the other ion migrates to the other pole, and that removal of the ion that travels with the particle, as by filtra-

tion through a collodion sac surrounding the pole, results in flocculation. Dispersion never occurs without such charging. Hence the condition for dispersion is the combination of anchored and free-swimming ions. Surface compounds too soluble to permit anchorage produce flocculation, as do also coatings too slightly soluble to permit a suitable atmosphere of surrounding free-swimming ions. Observation of slime pulps under a microscope, under conditions that permit control of the chemical atmosphere, show that the particles in a thoroughly dispersed pulp never make contact with each other, despite their continuous darting movements, but that when Brownian movement is stopped, either by oversolubilising or closing the particle surfaces, the particles, moving along in liquid currents, contact and adhere, *i.e.*, flocculate. Conditions in Bankoff's experiments, in so far as they were traced out, showed that slime coating corresponded to failure of Brownian movement which occurred in pulp atmospheres that produced relatively soluble or highly insoluble particle surfaces.

Ionic hypothesis. Sun (*153 A 479*) revives Ince's hypothesis (*87 A 261*) and, on the basis of cataphoretic estimates of ionic zeta potentials, concludes that slime coating is heavy when the potentials of granular particle and slime are high and of opposite sign, and/or when the potential of the slime is low; that the coating is light when the potential of the slime is high and that of the particle low, or when both potentials are high but alike in sign.

Reagents used to prevent slime coating are acids, alkalis, alkaline silicates and phosphates, and the organic colloidal dispersants. Their various reactions are discussed sufficiently under the specific reagent headings to indicate the line of attack in particular cases.

Remedies for slime difficulties, other than those already discussed, are separate sand-slime treatment (Art. 35) of the pulp to effect dispersion of the slime particles, and desliming. The last, with discard of the slime, is solely a question of economics; it is frequently advisable in nonsulphide flotation and almost never so in sulphide treatment, except, perhaps, very light desliming of the kind practiced at BUNKER HILL & SULLIVAN (Sec. 2, Fig. 108).

Attrition mixing is mechanical treatment of a pulp designed to rub particle surfaces with sufficient vigor to detach slimes and other relatively gross loosely adherent coatings such as films of mineral-alteration products and collector-coating multi-layers. The essence of the procedure is thick pulp (>60° solids) and vigorous mechanical agitation as in a lightly loaded tumbling mill or the beater box of an agitation-froth machine. Power consumption and maintenance are relatively high, but in many cases the alternative chemical treatment is even more costly. The action is aided by addition of a dispersant.

An alternative to attrition mixing, particularly if the slime coating is selective, is to treat the coated mineral as though it were of the composition of the coating, and collect with a suitable chemical collector fortified by a neutral oil.

Attrition mixing aided separation of talc (*140 #12 J 39*) and spodumene (*148 A 347*) from other nonmetallic minerals. It is asserted (*U. S. pat. 2,216,040*) that a sequence of steps comprising desliming, mechanical polishing, as in an agitation-froth beater box, and thorough secondary desliming in a hydraulic classifier aids flotation of quartz from pebble phosphate.

Resurfacing comprises production at the surfaces of specific classes of minerals of surfaces of a different nature. It may be intentional, and directed either toward activation or depression, or it may be the concomitant of accidental presence of some ingredient in the ore or water supply.

Resurfacing for activation is a common practice. The best known example is, perhaps, the addition of copper sulphate to resurface sphalerite. Copper ion exchanges with zinc and produces a surface of copper sulphide which, if the reaction is permitted to proceed, assumes the nature of covellite (*87 A 417*). In general any ion will resurface any mineral if it forms with an ion available at the mineral surface a compound less soluble than the original surface. The solubility difference must, however, be relatively large for resurfacing to occur in the short time usually available in a flotation operation and with the relatively low ion concentrations prevailing. Possibilities for sulphide resurfacing may be estimated from the following list of increasing sulphide solubilities: Hg, As; Ag, Sb; Cu; Pb, Sn, Bi; Zn; Fe, Co, Ni; Mn.

Precipitation resurfacing is, of course, aided by increasing concentration of the resurfacing ion in solution. Hence, when minerals are close together in the above list, the normal resurfacing may be reversed by using a high concentration of the ion yielding the more soluble sulphide. Thus Sutherland (*153 A 453*) reports resurfacing of chalcocite by lead. Activation of this character occurs whenever mixed sulphide ores are ground. Sutherland also reports that the effectiveness of activants for sulphides is dependent to a degree on the mineral and is chalcopyrite > sphalerite > pyrite with Cu, while with Ag it is sphalerite > chalcopyrite > pyrite. He reports further that Pb as a sulphide resurfacer produces galenalike surfaces which are not depressed by cyanide.

Oxidation and reduction. Less well recognized, because they occur as necessary sequelae of the processes of preparation, are oxidation and reduction reactions effected by other ingredients of the pulp, and secondary effects which flow from reagents added primarily for other purposes. Examples are developed in the consideration of the actions of specific reagents.

General principle in intentional resurfacing for activation is to anchor at the surface of the particle to be floated an ion which will be open to collector reaction and will form with the collector ion an effective collector coating less soluble and hence more susceptible to levitation than would have been formed with the unaltered mineral. Hence the collector to be used determines the nature of the resurfacing, or the kind of resurfacing possible sets the kind of collector that must be used.

Resurfacing agents for use with anionic collectors are the salts of heavy and earth metals; silicate ion and the metal-acid ions are used with cationic collectors.

Excess of resurfacing ion in the pulp precipitates more or less of the collector ion, according to the solubility product of the two ions. Wark and Cox (*112 A 214*) have shown that excess of Ag and Hg ions prevents bubble attachment at sphalerite surfaces with ethyl xanthate collector. Excess of Cu or Pb ion does not have this effect, although it does increase the time required for collector coating.

Copper sulphate is not effective to resurface Zn metal (*112 A 230*).

Resurfacing of nonsulphide minerals by heavy-metal and earth-metal ions is well established (*TP 1UU; 112 A 373; 134 A 180; 153 A 462*). It is a definite hindrance to the making of clean concentrate in soap flotation, but does not cause difficulty in sulphide flotation with sulphydric collectors. Examples are the use of Pb or Fe'' for calcite, Ba for gypsum, Pb for chromite and for scheelite; Fe, Ca, Ba, or Al for quartz. It has also been proposed to depress earth carbonates by resurfacing them with Fe'' or Ni and then using sodium metaphosphate to depress the resulting metallic soaps in fatty-acid flotation (*U. S. pat. 2,040,187*).

Common-ion activation. The aqueous solution film surrounding a sulphide particle to be collector-coated, and the solid surface itself are, prior to the addition of collector, in a state of near equilibrium, yet the concentration of oxidation-product ions in the region is far higher than exists in the body of the solution. This is proved by the fact that while leaching of a copper- or lead-sulphide suspension with water for a period of, say, 30 min. produces a low concentration, only, of sulphate ion in the bulk solution, addition of xanthate ion, which will form with the metal ions a precipitate of relatively low solubility, increases the concentration of sulphate ion. This additional sulphate can have come only from the particle surface and from the solution zone directly contiguous thereto. It follows, if the bulk of the solution was below the metal-sulphate saturation point before the addition of xanthate ion, that the metal sulphate at the particle surface must be of lower solubility than the same metal sulphate in bulk. This is readily understandable, since the sulphate ion at the sulphide surface is held to the lattice by forces approximating those that hold the sulphide ions. It follows further, from the solubility-product principle, that addition of a common ion will tend to load up the particle surface with that ion. If the metal ion is added, the surface will tend to become more completely metallic, whereupon, according to the same solubility-product principle, precipitation of the collector coating can be effected with a lower concentration of collector ion than otherwise.

Thus Wark and Cox (*112 A 212*) found that while a contact angle could not be developed on sphalerite in amyl xanthate solution of 25-mg. per li. concentration, addition of 9 mg. per li. of zinc sulphate caused bubble attachment. Similarly added copper ion is necessary to cause collector coating of chalcopyrite with methyl xanthate.

When the solid is relatively soluble, *e.g.*, cerussite, the same principle applies, but the amount of lead ion that must be added to give a preponderantly metal-ion surface is so large that more collector is consumed by precipitation in the solution than is otherwise required. In such cases it is usual to add first an ion that forms with the lead a relatively insoluble salt, *e.g.*, a phosphate, chromate, or arsenate. This forms a film of the corresponding lead salt over the surface of the cerussite and is held there by an excess of the common-acid ion in the solution. The bulk solution now being substantially freed of lead ion, a relatively small amount of a collector anion, which forms with the lead a salt less soluble than that formed with the conditioning ion, is sufficient for collector coating. See also ***Sulphide ion,*** Art. 10.

8. DEPRESSION

Depression is the converse of activation; it comprises steps taken to prevent flotation of a particular mineral or group of minerals. It is practiced both to hold down gangue and low-assay middling in one-mineral flotation and to hold back one or more of the minerals normally floatable by a given collector in differential flotation.

The methods of depression are manifold, but they may be grouped according to purpose into a small number of classes. (1) Prevention of activation resurfacing by soluble salts present in the pulp; (2) closure of surfaces against collector reaction; (3) destruction or nullification of collector coatings; (4) dispersion; (5) resurfacing to produce water-avidity.

Prevention of resurfacing by soluble salts is ordinarily accomplished by precipitating or complexing the activating ion or ions (*e.g.*, $3CN^- + Cu^{++} = [Cu(CN)_3]^{-}$). The usual

precipitants for heavy metals are hydroxyl, carbonate, silicate, and sulphide ions; the earth metals require high concentrations of hydroxyl for precipitation as hydroxides, but their basic carbonates, and their phosphates, silicates, and fluorides as well as their metal-acid salts (tungstates, molybdates, etc.) are relatively insoluble. Complexing ions are cyanide, fluoride, fluosilicide, silicate. The weak-acid anions generally form relatively insoluble salts with the alkaline-earth metals. Since the alkaline-earth ions tend to activate quartz and the alkaline silicates in alkaline solutions, their precipitation tends to depress these gangue minerals when fatty-acid or other collectors for alkaline-earth minerals are present. Such collectors are almost invariably present in ores, owing to the lubricants used in mining and crushing, hence this type of depression serves to raise grade of sulphide concentrate even though sulphydrate collectors are the only ones intentionally added.

Usual procedure in the attempt to prevent accidental activation is to try one after the other of the reagents carrying the above-mentioned precipitating or complexing ions; this is the quickest procedure in preliminary testing. If it fails, the cationic composition of the pulp water and the mineralogical character of the unwanted float should be determined. The nature of the activation can then be deduced, and a remedy devised. The problem is usually straightforward ionic chemistry, guided by a table of solubilities (Seidell, *Solubilities of Inorganic and Organic Substances*, D. Van Nostrand Co., N. Y.; *Handbook of Chemistry and Physics*, Chemical Rubber Publishing Co., Cleveland, Ohio).

Closure of surfaces against collector reaction is best typified by the action of SODIUM SULPHIDE in flotation of heavy-metal minerals. With sulphides, if the concentration of sulphide ion is held high enough so that oxidation of surfaces is reversed by resulphidization as fast as it occurs, no collection will take place, because the sulphide is less soluble than any known collector-heavy mineral reaction products. Similarly the iron-cyanide complex and the iron iron-cyanides formed when CYANIDE ION attacks the surface of pyrite keep the concentration of available iron ions at pyrite surfaces so low that reaction with collector is too meager for effective levitation. Added SILICATE ION drives back surface ionization of silicate minerals, thus closing these surfaces against both anionic and cationic collectors. SULPHURIC ACID acts similarly with quartz.

Destruction or nullification of collector coatings occurs, *e.g.*, when mixed copper-molybdenum concentrates made with sulphydric collectors are heated, the reaction in this case being destruction of the sulphydrate-coating compound and probably, also, steam distillation of oily contaminants which had acted as accessory collector (Art. 6). Adsorption of organic colloids at surfaces coated with collector, which occurs (*153 A 473*), covers over the collector coating and renders the particle water-avid and unsusceptible to levitation. Acid and alkali in soap flotation form acid and basic soaps at coated particle surfaces; these ionize and thus decrease the tendency to levitation. See also critical pH, under ***Hydrogen and hydroxyl,*** Art. 10.

Dispersion is essentially a means of insuring that all of the particles in the pulp are free to act as individuals in response to any subsequent treatment. The mechanism of producing it has already been discussed (***Slime coating,*** Art. 7). It is, in general, a sign that particles are not collector-coated, but the acid and basic soaps formed both sides of the pH of maximum contact angle with soap collectors cause the coated particles to disperse. Collector coating with sulphydric reagents and production of neutral-soap coatings with carboxylic collectors cause flocculation of the coated particles, leaving those uncoated still dispersed. This is the condition sought by flotation operators in cell feeds, as it usually foretells good flotation, in which neither will granular values be entrained in slime and carried into tailing nor will slime gangue be carried with collector-coated material into overflow.

Resurfacing with hydrophilic coatings anchored by collector groups has been mentioned (Art. 3). This use of collector groups with hydrophilic substituents has not been employed commercially, principally for the reason that no field for its use has presented itself in operation. Depression of pyrite by cyanide makes use, in a way, of the same principle by anchoring the water-avid ferrocyanide at the pyrite surface; depression of galena by chromate and of barite by acid dichromate are other instances. These, however, also involve surface closure and are usually so classed.

Use of organic colloids to depress involves hydrophilic coating. When the amount of colloid added is small, the coating is usually selective, and unless the pH is that of the isoelectric point of the coating colloid, dispersion is effected. At the isoelectric point the coated particles flocculate. Large quantities of colloid coat all ore constituents and usually produce flocculation.

Duration of conditioning is important, especially when, as with the organic colloids, the action is not ionic.

At ALASKA JUNEAU, using soluble starch as a depressant, air supply and starch feeders are activated electrically on a predetermined automatic schedule which cuts off air supply and pulp discharge to a

large subaeration machine for, say, 30 min., during which time feed and conditioning agent are being introduced. A heavy matted froth is formed during this time; the timer then cuts off starch feed, opens tailing discharge, and turns on air for, say, 10 to 15 min. (*U. S. pat. 2,184,115*).

9. PROTECTION

Protection is necessary both for collectors and for weak-acid salts used as conditioners. Protection for collectors usually involves precipitation of soluble salts of metals; the methods have been discussed (Art. 7). Weak-acid salts, both the soap collectors and the silicate, sulphide, cyanide, and similar conditioners, should be used in pulps that are at least not more than slightly acid, or they are thrown over into the acid form and ionization is largely suppressed by the excess of hydrogen ion present.

10. CONDITIONING AGENTS

Functions have already been discussed generally. In the following discussion of individual reagents, arranged alphabetically according to the principal active part, these functions are dismissed in many cases simply by naming them, and reference should be made to the functional description.

Acids are normally added for the purpose of controlling hydrogen-ion concentration; hydrofluoric acid is an exception (see ***Fluoride***). SULPHURIC ACID is ordinarily used, on account of its low price. It depresses quartz—and probably other silicates—in soap flotation by repressing ionization of silicic acid at the particle surfaces by mass-action effect, thus preventing both activation by metals and/or collector coating. It also represses ionization of the fatty-acid collectors, decreasing availability of collector ion.

Sulphuric acid depresses granular silicates while permitting flotation of mica with amines (*RI 3558*). Short-chain organic acids are said to be as good depressants for silicate gangue as sodium silicate in nonsilicate nonsulphide flotation. On the other hand, sulphuric acid may be used to reactivate nonsulphides after depression by sodium silicate (*RI 3239*), copper sulphides after depression by cyanide and $FeSO_4$ or other reducing agents (*U. S. pat. 2,105,901*); and cationic collectors after tie-ups by sodium silicate.

Acids convert metal soap coatings to acid soap substantially completely at pH values dependent upon the soaps (Fig. 2). Particles so affected are unfloatable unless auxiliary oily collector is used. Fig. 2 shows that the neutral soaps of the heavy metals exist at pH 7 and below while in this range the earth-metal soaps are largely in acid form; this explains, in part at least, the effectiveness of sulphuric acid in early-day fatty-acid flotation of sulphides.

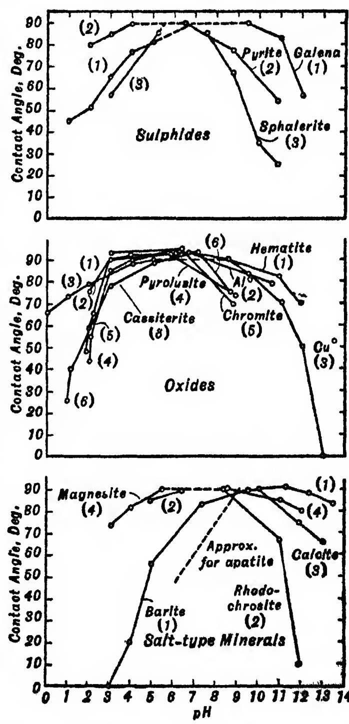

FIG. 2. Effect of pH on contact angle with fatty-acid collectors.

Quantity of acid necessary varies according to both the base and acid ions in nonsilicate salt-type minerals. Dean and Hershberger (*134 A 84*) report that with oleic acid as a collector the amounts of sulphuric acid required to depress rhodochrosite was 4 lb. per ton; calcite, 3 lb.; scheelite, 0.6 lb. and apatite, 0.4 lb. (See also Fig. 2.) As between the carbonates, manganese required more than calcium because of the greater basicity of the latter. As between the calcium minerals, the carbonate required by far the most because of loss of hydrogen ion by formation of carbonic acid.

Depression occurs on the acid side with many of the sulphydrate collectors. This is due, in most cases, to a decrease in dispersion of the collector by reason of precipitation of the corresponding acid, and, with higher concentrations of hydrogen ion, to actual destruction of collector ion by decomposition.

Acids usually coagulate ore pulps.

Aluminum salts (nitrate and sulphate) are said to activate quartz over a wide pH range (*U. S. pat. 2,185,224*); feldspar is also activated in the range 7 to 8, but depressed (as is spodumene) at pH <7 (*40 CIMM 691*). See also ***Metallic ions.***

Hahn (*123 J 449*) showed that in flotation of a chalcopyrite ore with xanthate the addition of aluminum sulphate raised the tailing from 0.07% Cu at zero addition of Al salt to 0.12% at 4 lb. and 0.42% at 10 lb. The addition of lime was no help at sulphate additions up to 4 lb., but above this quantity lime in quantities substantially equal to the Al salt additions kept the tailing in the range 0.09 to 0.12% Cu. $Al_2(SO_4)_3$ was used at RIVERMINES to activate sphalerite (S. J. Swainson, *PC*).

Carbonate ion is used as a precipitant for heavy and earth metals in prevention of resurfacing and in protection. Its effectiveness for heavy metals is increased by hydroxyl because of the tendency to form basic carbonates. Co-addition of lime is recommended for Ca ion (*RI 3328*). Carbonate ion is useful in steel-mill grinding of nonsulphide ores, where iron acts as an activator, to prevent solution of abraded iron (*RI 3328*).

The usual carrier employed is sodium carbonate, which contributes both $CO_3^{=}$ and OH^-. It is usually employed in lead circuits (see Art. 46, *Galena*), for pyrite flotation, and in bulk floats because of the specific depressing effect of lime on iron sulphides. It prevents activation of sphalerite by lead salts, if present in stoichiometric excess (*112 A 230*). Quantity normally added in lead circuits is from 1 to 2 lb. per ton, but may run up to 5 lb. (*128 J 293*). If the soluble salt content of the ore is too great, consumption becomes prohibitive, *e.g.* BRITANNIA slimes (*IC 6619*). Excess usually increases frothing, and causes a watery froth and a drop in recovery; in sulphide flotation this may be accompanied by increased flotation of quartz (*RI 3328*). It is reported (*RI 3247*) that sodium carbonate tends to prevent oiling of quartz in thick-pulp conditioning of table-flotation feed, even with heavy overoiling.

Cement has been used to depress pyrite and pyrrhotite. It carries unstable complex silicate and so-called aluminate ions which are made available in water and form insoluble iron compounds. Hence the function is surface closure.

Chromate and dichromate have been used for surface closure of galena in lead-zinc differential work, the reaction producing a multi-coating of the lead-chromate salt on the galena particles. Two to 5 lb. per ton of bulk concentrate is ordinarily required for depressing the galena content; about half as much is required on raw ore. Reactivation is asserted by use of ferrous sulphate, hydrochloric acid alone or with sodium chloride, or sulphuric acid with sodium hydrosulphite or bisulphite (*U. S. pat. 2,150,114*).

Gaudin (*TP 1 UU*) reports depression of pyrite with relatively low concentrations of $Na_2Cr_2O_7$, with ethyl xanthate collector, while at the same time K_2CrO_4 had no effect at concentrations up to 2 lb. per ton of solid. Since the dichromate of iron is soluble, this should not be a surface closure. But the dichromate is a strong oxidizer, while ferric xanthate is particularly susceptible to decomposition by oxidation; the chromate, on the other hand, is much less powerful in its oxidizing effect. The postulate that oxidation is responsible for the dichromate effect is confirmed by the fact that potassium permanganate has an almost equal depressing effect.

Wark and Cox (*112 A 225*) report that prolonged treatment of sphalerite (30 min.) with 100 mg. per li. of dichromate, followed by 30 min. in 10-mg. per li. copper sulphate solution resulted in failure to collector-coat with ethyl xanthate. This represents a residual effect, not explicable on the basis of chromate coating, because of the relatively high solubility of zinc dichromate, nor on the ground of decomposition of the xanthate by oxidation. It is not consistent with the differential flotation of zinc with chromate as the lead depressant.

Dichromate, preferably in acid solution, is reported as a depressant in soap flotation for cleaning calcite from a rough barite concentrate made with metal salt-silicate depressant (*post*) in the rougher (*40 CIMM 691*). This is probably depression of a silicate surface. The dichromate is asserted to be generally a better depressant for silicate gangue in soap flotation than sodium silicate is; it is reported to depress both magnesite and sulphide minerals in talc flotation (*RI 3239*).

Copper ion. Copper sulphate is the cheapest form. Its principal use is to resurface sphalerite, in either acid or alkaline pulps. Precipitation as hydroxide is insufficient to prevent activation, although it slows it down; with both hydroxyl and carbonate ions present (soda ash) even more time is required.

Mortensen (*25 ChA 3281*) reports that the time required to activate blende with copper sulphate increases with the iron content of the blende, and increases with rise in temperature and in H-ion concentration. Cu^{++} is effective similarly to activate galena, pyrite, arsenopyrite, stibnite (*RI 3328*), and chalcopyrite, but not pyrrhotite (*112 A 254*). Sulphide activation is probably the useful effect gained in grinding in the presence of $CuSO_4$ in gold flotation, since there is no known reaction between the salt and gold itself, and clean native gold does not require resurfacing. Fahrenwald (*139 #2 J 80*) reports that Cu^{++} depresses stibnite at pH 4 to 7.4. It complexes cyanide ion. It is used (0.3 lb. per ton) at WRIGHT-HARGREAVES to resurface pyrite before gold flotation after leaching with cyanide and lime (*140 #4 J 42*). Wark and Cox (*112 A 301*) report that copper ion in conjunction with cyanide and alkali can prevent bubble attachment to pyrite with thiophosphates, xanthates, and dithiocarbamates, and that less cyanide is necessary than otherwise; they believe the copper-cyanide ion to be the effective depressant. The action may well be surface closure by an iron cuprocyanide which is less soluble than

the iron iron-cyanides. Cu^{++} also has some resurfacing action on carbonate, phosphate (*U. S. pat. 2,105,826*), silicate, and other nonsulphide minerals whose anions form compounds of low solubility with copper; this action is, in general, more pronounced in alkaline medium. Wark and Cox (*134 A 61*) report that when copper ion is used with cyanide ion in chalcopyrite-pyrite or sphalerite-pyrite differential work, copper acetate gives better results than copper sulphate.

Feeding is best done as a dilute solution, say 5%. The actual feeder must have wood or copper parts in contact with solution. Usual quantity range is 0.5 to 1.5 lb. per ton. At PECOS (*IC 6605*) addition to the feed launder entering the zinc conditioner rather than entering the conditioner where lime is also added decreased the quantity of copper salt required by about 0.3 lb. per ton. At POTOSI (*IC 6706*) the amount of copper sulphate necessary after 0.05 lb. of sodium cyanide had been used in the lead circuit was 0.42 lb.; at BALMAT (*IC 6574*) the corresponding quantities were 0.09 and 2.3; at BASE METALS (*Tref 5/42*), 0.31 and 1.24, $ZnSO_4$ (1.1 lb. per ton) having been used with cyanide. Consumption of the copper salt is definitely less when $ZnSO_4$ alone is used as depressant for zinc.

Cyanide ion, as the Na or K salt, is used commercially to depress sphalerite, the iron sulphides, and arsenopyrite in the presence of sulphydric collectors. The action with iron minerals is improved by lime and by copper sulphate (*q.v.*); that against sphalerite by zinc sulphate. It is reported (*112 A 267*) that the combined action of cyanide and copper on pyrite is decreased by rise in temperature. Cyanide also has some depressing effect on the copper-iron minerals (*31[1] Bul CIMM 75; PF 196*), enargite, and stibnite (*139 #2 J 80*), but has none on galena, chalcocite, or covellite. The depression of both pyrite and the copper-iron minerals is greatest in a reducing atmosphere, *e.g.*, $FeSO_4$ or SO_2.

It is proposed to combat the Cu-Fe depression by resurfacing with Pb^{++} (*U. S. pat. 2,048,370*) or with Ni^{++} in neutral or slightly acid pulp (*U. S. pat. 2,035,458*). In soap flotation cyanide is reported to have improved separation of manganese oxides from iron oxides (*RI 3600*), and is recommended as a depressant for quartz and silicate minerals (*U. S. pat. 2,106,800*). It is also proposed as a dispersant in cationic flotation (*U. S. pat. 2,195,724*).

The mechanism of depression differs with different minerals. With sphalerite it involves prevention of resurfacing by metal ions of low sulphide solubility (Art. 7) by complexing them with cyanide, and depends upon the fact that the complexes are so stable that they either will not yield the metal to sulphide ion (*e.g.*, Cu) or, by mass-action effect the equilibrium between $[Me(CN)_x]$ and MeS is shifted so far toward the complex ion that resurfacing is inappreciable (Ag, Hg). Pb^{++} from oxidized galena resurfaces sphalerite slowly and is not complexed by cyanide, but concentration of Pb^{++} can be kept down in relatively unaltered ores by adding collector in the grinding circuit. With collectors that coat sphalerite without resurfacing, *e.g.*, potassium di-*n*-amyl dithiocarbamate, cyanide has relatively slight depressing effect (*112 A 267; PF 197*); it is not unlikely that the small effect reported is due to contained iron (see below).

The mechanism of depression of pyrite has not been established. Since the mineral does not need resurfacing for coating with the lower xanthates, depression cannot be ascribed to prevention of this phenomenon. Cyanide forms with ferrous ion the very stable ferrocyanide $[Fe(CN)_6]^{≡}$, which, in turn, forms with either ferrous or ferric ion the very slightly soluble $Fe_7C_{18}N_{18}$, probably $Fe_4[Fe(CN)_6]_3$. Precipitation of this salt, with excess of cyanide present, would close the surface against oxidation of the iron, which is essential to collection of iron sulphide by xanthate (Art. 4), and, since the formation of the ferric compound from ferrous ion involves oxidation, reducing conditions are maintained at the surface of the pyrite. The latter possibly correlates with the fact that ferrocyanide ion itself is not a depressant for pyrite (*TP 1 UU*). The usual amount of cyanide required to keep down sphalerite and pyrite in the lead circuit is 0.1 to 0.25 lb. per ton.

Depression of the copper-iron minerals by cyanide would appear to be due to surface closure by copper ferrocyanide, the ferrocyanide ion being formed by the reaction of CN^- and Fe^{++} at the particle surface and immediately precipitating with copper ion in the lattice. This postulate is consistent with the fact, above cited, that Cu^{++}, which resurfaces pyrite, aids in the depression thereof by cyanide, that ferro- and ferricyanides are depressants for chalcocite (*F 164*), and that xanthates are not abstracted from solution by copper-iron minerals when the cyanide-ion concentration is sufficient to prevent bubble attachment (*134 A 41*).

Despite depression of the copper-iron minerals by cyanide, the concentration of cyanide ion required is sufficiently higher than that required for pyrite (while the conditions at the copper-mineral surface are such as to keep down CN^- concentration by the $[CuCN_3]$-$Cu_2[Fe(CN)_6]$ equilibrium struggle) that differential depression of pyrite is possible, if the amount of cyanide added is kept low.

The depressing effect of the cyanide ion on pyrite and on chalcopyrite is less the more active the reactive group of the collector and the higher the molecular weight of the collector ion in homologous series (*PF 200*).

The effectiveness of alkaline cyanides as a source of cyanide ion is increased by increase in *p*H. The increase in effectiveness has been shown to be substantially in direct proportion to the increase in ionisation of the cyanide salt with increase in *p*H, *i.e.*, the effect is

simply one of making cyanide ion available. Accepting the value $4.7 \cdot 10^{-10}$ as the dissociation constant of hydrocyanic acid, Wark and Cox (*112 A 245*) have calculated the following concentrations of cyanide ion in mg. per 100 mg. of NaCN added to an aqueous pulp at the corresponding pH values:

pH	6	6.5	7	7.5	8	8.5	9	9.5	10	11	12	13
CN^-	0.025	0.079	0.25	0.78	2.4	6.9	17	32	44	52	53	53.1

Taking these figures with contact-angle tests, Wark and Cox (*112 A 245*) report that the concentration of cyanide ion necessary to prevent bubble attachment with ethyl xanthate as collector ranges from 101 to 228 mg. per li., averaging 177, for chalcocite; 21 to 40, aver. 34, for covellite; 6.3 to 7.4, aver. 6.8, for bornite; 0.34 to 0.52, aver. 0.44, for chalcopyrite; and 0.08 to 0.16, aver. 0.10, for pyrite. Wark (*PF 204*) calls this the CRITICAL CYANIDE-ION CONCENTRATION for the mineral. It is to be noted that only in exceptional cases will all of the cyanide ion added be available to build up the requisite cyanide-ion concentration, owing to loss in complexing metal ions in solution, and further that the mineral to be depressed may have been resurfaced, which will call for a different critical cyanide-ion concentration.

Wark and Cox (*112 A 230*) report that 1 mg. per li. of NaCN lowers the critical pH of pyrite from 10.5 to 8.5 and 100 mg. per li. lowers it to 7. Wark (*PF 182*) states that cyanide is not a depressant for sphalerite and pyrite against a cationic collector such as cetyl trimethyl ammonium bromide.

Brighton *et al.* (*133 J 276*) report parallel abstraction and pure-mineral flotation tests with cyanide, using xanthates as collectors. Their tests indicate that complete depression of PYRITE occurs when the thiocyanate test for iron in the pulp is very faint and there is still free cyanide ion present; that the depression parallels the concentration of cyanide complex, whether with iron or copper, and is probably due to resurfacing with the iron-metal cyanide salt. The SPHALERITE that they tested contained some copper, and they found it necessary to add much more cyanide than was required to complex the copper sulphate added, in order to effect depression. GALENA did not abstract cyanide, and its flotation was not affected by concentrations up to 1 lb. per ton. CHALCOPYRITE consumed cyanide, but its flotation was substantially unaffected thereby in concentrations up to 1 lb. per ton; the paper records, however, that the chalcopyrite floated with terpineol alone so that it was already collector-coated when added to the machine, and the test is to be interpreted as indicating that the amount of cyanide added was insufficient to displace the copper-soap coating. SPHALERITE activated by lead was not depressed by 1 lb. per ton of cyanide.

When cyanide is used as a depressant for sphalerite and/or pyrite in gold ores it dissolves appreciable quantities of gold and carries them into tailing. At GOLDEN CYCLE (*136 J 381*) where cyanide had to be used to depress pyrite on account of the flocculating effect of high lime, the amount was 20 to 40¢ ($35 gold) per ton of water. Precipitation by activated charcoal and flotation thereof (Art. 49) might serve to decrease the loss; at GOLDEN CYCLE the solution was worked back into the cyanide plant; the same procedure prevails at DEMONSTRATION (*134 A 241*).

Wark and Cox (*112 A 301*) state that cyanide prevents activation of sphalerite by copper in lower concentrations and/or less time than it deactivates copper-resurfaced sphalerite and that this latter operation is easier than depression of the resurfaced mineral after collector coating. On this basis it is, of course, advisable to add cyanide to the grinding circuit when sphalerite depression is sought.

Parsons (*123 J 759*) points out that TIME-FACTOR is important in conditioning with cyanide; he states that optimum time may range from a few minutes to an hour.

Dextrine. See ***Organic colloids.***

Dyes comprise a tremendous variety of compounds. Many of them are hydrocarbons with two or more solubilizing substituents. Induline blue, Congo red, aniline blue, eosin bluish, eosin yellowish, picric acid, methylene blue, Erie black G*x*00, Wool green S, acid green, acid orange, Hoffman violet, acid blue, acid orange A, and indigotine have been recommended for depression of molybdenite from copper sulphides with xanthate collectors (*U. S. pat. 2,095,967*). Others, especially acid dyes containing carboxyl or sulphonic substituents or both, *e.g.*, sulphonated nigrosine, sun yellow, and alizarin saphirol B, have been proposed for dispersion of both siliceous and carbonate gangues (*U. S. pat. 2,211,686*). Nothing is definitely known as to mechanism, but the recommendation of poly-substituents suggests that one of the substituents acts as the anchoring group while the other ionizes and both produces Brownian movement and prevents bubble attachment.

Earth-metal ions have little or no effect in sulphide flotation with sulphydric collectors except in concentrations far exceeding any met other than in flotation with sea water (*79 A 50*). With fatty-acid collectors, however, they consume reagent by precipitating

insoluble soaps; these, having gummy characteristics, smear all particles indiscriminately and tend to carry them into froths. Ca and Mg salts are asserted to retard sulphidization with Na_2S (*RI 3333*).

See also ***Resurfacing*** (Art. 7).

Fluoride ion is used as a precipitant for ferrous, ferric, aluminum, and the earth-metal ions; it therefore serves to prevent resurfacing of quartz by these ions and thus permits soap flotation of other silicates from quartz (*RI 3419*). Fluoride forms relatively stable complexes with the small positive ions, *e.g.*, $SiF_6^{=}$ (fluosilicate) and $AlF_6^{\equiv}$, the alkali and earth salts of which are only slightly soluble; it thus acts as a dispersant for clays and other alteration products of feldspars, even in acid solutions. The fluosilicate ion is asserted to complex aluminum (*134 A 76*). Solutions of multivalent metal oxides in hydrofluoric acid are recommended (*U. S. pat. 2,297,689*) as aids in floating aluminous silicate minerals with cationic collectors.

Glue. See ***Organic colloids.***

Hydrogen and hydroxyl ions are present in all aqueous solutions; the quantities are equal in pure water; H^+ predominates in acid solutions and OH^- in alkaline.

***p*H.** The product of the ionic concentrations in mols per liter $[H^+]$ $[OH^-]$ is always constant and equal to 10^{-14}. pH is the common logarithm of the reciprocal of hydrogen-ion concentration in an aqueous solution. Since $[H^+] = [OH^-]$ in pure water, $(H^+) = 10^{-7}$, hence pH of pure water = 7. In acid solutions $[H^+] > [OH^-]$ and is, therefore, $>10^{-7}$, whence $p\text{H} < 7$. Conversely in alkaline solutions $p\text{H} > 7$.

Hydrogen-ion concentration affects the concentrations of collector ions and consequently their reaction rates and the equilibrium points for the collector-mineral coating reaction; it affects the extent to which the mineral-particle surface ionizes, and may determine the nature of the ions; and it similarly affects the ions in solution in the pulp, whether they be brought there in the mill water, leached from the ore, or added as reagents.

Acid pulps are rarely used today in sulphide flotation, but they are not uncommon in nonsulphide work. Dispersion of anionic collectors is usually hindered by an acid pulp because the acid forms of most of them are relatively insoluble; on the other hand dispersion of cationic collectors in the highly ionized salt form is aided by acidification. The weak-acid types of conditioning agents, *e.g.*, silicates, cyanides, sulphides, are similarly hindered in their actions in acid pulp. Acidification tends to clean oxide crusts from sulphides and thus frequently aids flotation of the easily oxidized iron sulphides; this is true whether the collector is of sulphydric or fatty-acid type, because the neutral-soap peak for iron falls well on the acid side (see Fig. 2). In general acid flocculates nonsulphide slimes without, at the same time, dispersing the sulphides, hence it aids slime coating of the latter. Acid minimizes or prevents resurfacing of quartz by metal ions, probably by suppression of ionization of the silicic acid at the quartz surface. Froth in acid pulps tends to be heavily loaded and correspondingly meager; such pulps are not, therefore, well suited to the vigorous aeration of pneumatic cells. The usual reagent for producing acidification is sulphuric acid, on account of cheapness. Hydrofluoric and fluosilicic acids are occasionally used in nonsulphide flotation because of specific properties of the anion, *q.v.*

Alkaline pulps. Hydroxyl ion is used for a number of purposes. It is an effective precipitant for heavy-metal ions; it complexes the readily amphoteric metals at low pH values and even some of the heavy metals in the middle alkaline range. It thus serves to prevent resurfacing by the less vigorous activators, to protect more vigorous activators such as Cu^{++} from consumption by collector (and conversely to protect collector), and it protects weak-acid ions such as silicate and sulphide. It increases the ionization and consequent availability of weak-acid collectors and conditioners. It is a depressant in its own right for pyrite and the other iron sulphides, probably owing to surface closure by the gelatinous hydroxide, and to mass-action effects with ferrous and ferric ions at the pyrite surface; it is most effective in this service when introduced as lime; it depresses all minerals with all collectors at sufficiently high concentration. It acts as a dispersant for many minerals, particularly the nonsulphides, at low concentrations (0.001 to 0.01 molar), but is a flocculant at higher concentrations; hence it has a controlling effect on slime coating. At high concentrations produced by alkaline (not earth-metal) carriers it removes oil coatings from minerals and emulsifies the oil in the water so that it can be separated from the solids by decantation. Excess always has a bad effect on frothing, producing watery, lightly loaded froths. This effect is most pronounced with fatty-acid collectors. It is probably secondary, however, reflecting prior sequential effects on collector coating and levitation. Metal work in contact with alkaline pulps wears more slowly than in acid, owing, of course, to the low concentration of hydrogen ion.

Range in pH is generally from a value between 7 and 8 for sulphide flotation in which pyrite is sought to be floated to 10 or more when lime is depended upon for pyrite depression. The pH for pulps in which cyanide is used as a depressant depends upon the mineral

to be depressed, the minerals to be floated, the collector used, the resurfacing salts present, and the other demands on hydroxyl ion. Maximum alkalinity with sulphydric collectors is fixed by the CRITICAL pH VALUE, which is defined by Wark (*PF 186*) as that value of pH above which bubble attachment to a mineral cannot be effected with a given quantity of a given collector. Table 4 gives values under a variety of conditions. The quantities of

R = Resurfaced with Cu^{++}.

collector used in the tabulated tests were molar equivalents. The failure of attachment at the critical point is due to lack of collector film, owing to complexing of the metallic ions of the surface with hydroxyl as anions of the form $[\text{Me}\,(\text{OH})_x]^{-y}$ (*Hammett*). If conditioning is attempted in a solution, at or above the critical point, no collector coating forms because of unavailability of metallic ion; if a collector coating is formed at lower pH and the pH is raised to the critical, the film dissolves and cannot re-form. At higher concentrations of collector the critical pH value is higher, and *vice versa* (*153 A 453*). Barsky (*112 A 236*) points out that for any given collector the product of hydrogen-ion and collector-ion concentrations at critical pH is roughly constant.

Wark (*PF 189*) postulates that the relationship $[A]/[OH] = K$ holds for the critical point, where [A] is concentration of the collector ion, [OH] concentration of hydroxyl ion, and K an experimental constant, and that depression will occur when the value of the ratio exceeds the constant. The critical pH for a given collector is higher the greater the collector concentration (Table 5); as between homologous

Table 5. Effect of concentration of collector on critical pH value (*After Wark and Cox, 112 A 267*)

collectors it is higher the higher the molecular weight; it falls somewhat with increase in temperature; it is different for different sulphydrate collector groups with the same hydrocarbon groups, *e.g.*, dithiophosphate < xanthate < dithiocarbamate; and, with most such collectors maintains the order sphalerite < galena < pyrite < chalcopyrite < chalcocite (*PF 187*).

Below the critical pH value, pH and cyanide-ion addition should be so proportioned as to reach critical cyanide-ion concentration for the mineral to be depressed with the least cost.

The fact that for each collector or collector class there is an optimum hydrogen-ion concentration was pointed out by Gaudin (*10 MMt 19*) and has been confirmed by a number of other investigators. The optimum band averages wider for some collectors than others, *e.g.*, xanthates have a relatively wide band while the range for the dithiophosphates is much narrower.

With fatty-acid collectors maximum pH depends certainly on the mineral to be floated, and possibly on the fatty acid used. Without fortification by oil it is probable that the floating range with oleate collectors is that above about 60° contact angles for the various minerals in Fig. 2.

Carriers of hydroxyl ion differ according to the operation. Lime is usual in copper flotation and in lead-zinc differential work when pyrite is not desired in concentrate, but if the pyrite carries precious-metal values, soda ash is used for pH values below 10 and sodium hydroxide for higher pH. Cyanide, water glass, sodium sulphide, and the alkaline phosphates produce hydroxyl ion by hydrolysis, but this is not usually their primary function.

Point of addition depends upon the end sought. Normally the effect is wanted prior to collector coating, wherefore the addition is made before collector is added. The usual point is the grinding mill or its equivalent in the circuit. Occasionally lime is added as far back as the mill bins, and frequently there is addition subsequent to a part of the flotation, as in differential work where pH is an essential part of the control.

Buffering. The weak-acid carriers are all buffers. (See under the specific carriers for ranges.) The ores contribute buffering effect also, probably due to reactions of mineral constituents, some of which consume or contribute H^+, others OH^-, and reach equilibrium at particular concentrations of these reactants. Certain minerals, *e.g.*, quartz, the earth-metal phosphates, and sphalerite, consume either H^+ or OH^-, according to which predominates in the solution.

Iron salts are both activants and depressants, their role depending upon the mineral in question. In either role they hinder the flotation operation. The usual source is iron sulphides, but in nonmetallic flotation they may come from machines used in comminution.

Activation occurs by resurfacing of earth-metal salts by metathesis, *e.g.*, $CaCO_3 + FeSO_4 \rightarrow FeCO_3 + CaSO_4$, and of quartz either by metathesis with a soluble silicate formed at the quartz-particle surfaces in alkaline solutions or by a flocculation coating of iron hydroxide. Resurfacing is most active in alkaline solutions. When the mineral resurfaced is one that it is desired to float, *e.g.*, calcium phosphate, no harm is usually done, since the iron soaps are sufficiently insoluble to precipitate as collector coatings. Such reactions also have the effect of lowering the concentration of iron ion to a point where resurfacing of quartz and silicates does not occur.

Ferrous sulphate has been recommended (*U. S. pat. 2,150,114*) to reactivate galena that has been depressed by chromate.

It has been proposed (*U. S. pat. 2,040,117*) to utilize the resurfacing of earth carbonates by iron, and the further fact that the neutral-soap maximum for iron occurs well into the acid range (Fig. 2), to make the iron a specific depressant in certain nonsulphide flotations. Thus in separation of fluorite or scheelite from calcite, condition with ferrous sulphate to resurface the calcite with iron carbonate, which will float reluctantly or not at all at pH @ 7 to 8. Sodium ortho-, pyro-, or metaphosphate, it is said, aids depression of the resurfaced carbonate. Similar separation of barite from witherite is suggested.

Depression by iron salts is a well-recognized phenomenon in sulphide flotation. The effect on copper minerals (principally chalcopyrite in the ore tested) is shown in Table 6 (*after Hahn, 123 J 449*).

Table 6. Effect of iron salts on flotation of chalcopyrite ore

Ferrous sulphate		Ferric sulphate	
Lb. $FeSO_4$ per ton of ore [a]	Tailing, % Cu	Lb. $Fe_2(SO_4)_3$ per ton of ore	Tailing, % Cu
0.0	0.07	0.0	0.07
1.5	0.19	2.0	0.21
3.0	0.16	4.0	0.19
4.5	0.22	6.0	0.46
6.0	0.79	8.0	0.44
7.5	0.73	10.0	0.32

[a] Reagents: 4 lb. CaO, 0.2 lb. xanthate, 0.5 lb. Cleveland Cliffs No. 2, per ton of ore.

These tests indicate that the ferrous and ferric salts have equally bad effects up to 4 or 5 lb. per ton of ore. The effect of ferrous sulphate on flotation of copper-activated sphalerite with ethyl xanthate or Aerofloat is particularly bad (*RI 3149*). Ferrous sulphate has been used in conjunction with cyanide as a specific depressant for pyrite at MATAHAMBRE (*128 J 921*), and alone as a depressant for arsenopyrite (*RI 3370*).

Remedy for dissolved iron salts is, usually, to remove them by precipitation, but washing out and complexing, as by CN ion, have also been proposed. The usual precipitants are hydroxyl ion and carbonate ion; phosphate has also been added, and is present naturally in the phosphate ores. Table 7, after Hahn, shows the advantage of lime in chalcopyrite flotation.

In light of the fact that lime produced the greater improvement in the presence of the ferric salt (Table 7) Hahn proposed that when the iron salts were ferrous an oxidizing agent be added with the lime. He found that both bleaching powder and oxygen gas were highly effective, but that excesses were harmful, probably owing to decomposition of collector.

Table 7. Effect of lime in flotation of chalcopyrite ores containing iron salts

a Reagents: X lb. CaO, 0.2 lb. xanthate, 0.5 lb. Cleveland Cliffs No. 2, per ton of ore.

Lactic acid, which is named as typical of short-chain dihydroxy organic acids in its action, is asserted to be a powerful depressant in iron-sulphide flotation (*RI 3293*). It has been used commercially as a specific depressant for mica in floating platinum-bearing iron sulphides.

Lead acts as a resurfacing activant for sphalerite, chalcopyrite, pyrite (at $pH > 7$), and for stibnite in sulphydric flotation, but not for covellite or pyrrhotite (*153 A 453*). It also resurfaces quartz, feldspars, and nonsilicate earth minerals in soap flotation; and barite with the fatty alcohol ester salts. It is suggested as an aid to copper flotation in a pulp treated with starch to depress molybdenite (*U. S. pat. 2,070,076*), and to aid flotation of halite from sylvite (*U. S. pat. 2,188,933*). (See also ***Phosphates.***)

Lignin sulphonates, particularly the calcium salt (Goulac), are recommended for depression of carbonaceous gangues with fatty-acid, sulphydric, and cationic collectors (*U. S. pat. 2,130,574*). The amount recommended for cement rock is about 2 lb. per ton (*32 IEC 645*).

Lime is used as a carrier of hydroxyl ion (*q.v.*), and as a specific conditioner. Since it is the cheapest hydroxyl carrier, it is used for this purpose unless its specific action, as against pyrite, is undesirable, or unless the action of an anion such as silicate, sulphide, carbonate, and the like is desired additionally, when hydroxyl carriers such as the alkali salts of these ions are used. (See also Art. 46, ***Galena,*** and Art. 49, ***Gold.***) Lime is stated to be a specific depressant for quartz or talcy slimes in the flotation of silver minerals (*RI 3436*), using sulphydric collectors. Under the same conditions it depresses pyrite and, to a lesser extent, sphalerite. The action with pyrite is attributed by Gaudin (*F*) to the formation of sulphites. When present in excess in sulphide flotation it prevents galena from floating, has a definite depressant effect on the copper sulphides other than chalcopyrite (*123 J 758*), and produces tough slimy froths and low-grade concentrates (*RI 3328*). The effect of lime on dispersion of gangue varies with the ore; some experimenters (*RI 3328*) assert that low lime causes flocculation and high lime deflocculates; others that high lime flocculates gangue to an extent that separation is poor (*123 J 931*).

At Potosi (*IC 6706*), where it was desired to increase contact time of lime with the pulp for depression of pyrite in zinc flotation, it was found that if the collector and frother (butyl xanthate and cresol) were added in the ball mill, lime could be used to replace soda ash in lead flotation up to pH 8 without bad effect on flotation of galena.

For methods of feeding see Art. 34.

Lime for use in producing alkalinity or for precipitation of soluble salts should be calcium lime; dolomitic lime is undesirable for the reason that the contained $Mg(OH)_2$ is substantially inert in the circuit on account of its relatively slight solubility. On the other hand, the magnesium hydroxide is available for neutralization.

Milk of lime for flotation use should be slaked with more than ten times the theoretical quantity of water, since such milk is substantially slower settling than lime added directly and almost twice as rapid in reaction (*120 J 1016*).

Tests at Utah (S. E. Stein, *PC*) indicated that of 6 lb. of lime per ton added to the pulp, 0.8 lb. was consumed by the new water, 3.1 lb. by some nonmetallic solid in the ore, and about 0.1 lb. by Cu and Fe salts leached from the ore. Much of the remainder was leachable with time from tailing.

Mercury or a mercury salt with a sulphide, in relatively large quantities, with sulphydric collector ± oil is recommended for flotation of gold (*U. S. pat. 2,097,608–9*).

Metallic ions naturally present in ore pulps are the bane of the flotation operator's existence. In large excess any one of them may be expected to prevent flotation of any mineral with any anionic collector, the most acid (Zr, Th, Al, Fe, Cr) being the worst offenders (*79 A 50*). The heavy-metal ions are activators generally for nonsulphide minerals, the effect being more marked with the nonsilicates, and greatest on the alkaline side. For the effects of those metals most common in ore pulps or added in operation as activators or depressants, see under the specific ions.

Oxidation is a form of activation for sulphide minerals in that it is a necessary preliminary to flotation when using known collectors and known methods of effecting collector coating (Art. 3). The fact that it normally takes place spontaneously during grinding, classification, and in the flotation cell has led to its being generally overlooked. But with heavy sulphide ores the oxygen dissolved in the mill water is used up so rapidly that oxidation is incomplete in the usual grinding treatment and special aerators must be used to complete such conditioning.

In actual milling at NORANDA (*Q*) no method or reagent combination yielded satisfactory differentiation between chalcopyrite, pyrite, and pyrrhotite without adequate aeration of the pulp in the grinding circuits or at least prior to flotation. Laboratory flotation of some types of NORANDA ores is satisfactory without aeration, but duplication has not been possible. On average NORANDA ores 20 min. aeration is usually sufficient; occasionally 40 min. is necessary, particularly when the pyrrhotite content is above 55%. Optimum times are determined by laboratory tests. In controlling mill work there, the amount of thiosulphate found present in the pulp is used as a measure of the requisite aeration. The thiosulphate has no effect on flotation. The aerator used at Noranda is shown in Fig. 3. It comprises a circular tank about 9 × 15 ft. with 4 rubber air-lift pipes *a*, a plurality of radial air-inlet pipes *b* of different inward extension, and a slow-moving rake mechanism at the bottom. Feed, introduced at the top, overflows into annular launder *c*.

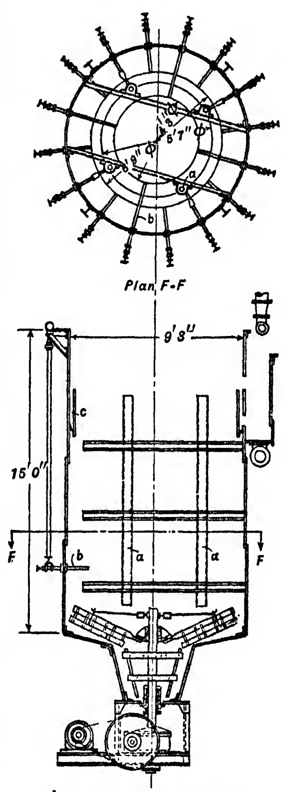

FIG. 3. Noranda aerator.

Parsons (*123 J 757*) warns against excessive oxidation of complex ores. He recommends a quick journey from the face to the flotation machine and, if necessary, high circulating loads or thinner pulps than usual in the grinding circuit, or the addition of suitable reagents in the circuit to minimize either the oxidation or its results.

At ALDERMAC, with ore similar to that at Noranda, it was found that aeration to oxidize prior to chalcopyrite-pyrite flotation increased xanthate consumption and decreased copper recovery. This is consistent with general experience with high $FeSO_4$ concentration. Oxidation by blowing was, however, necessary for flotation of pyrrhotite, using amyl xanthate. At PECOS (*IC 6605*) oxidation in stopes activates pyrite; if it is excessive, the amounts of lime and cyanide required to depress the pyrite lower the recoveries of Au and Cu considerably and even Pb recovery is decreased somewhat.

Arsenopyrite similarly needs more oxidation than is normally effected in preparation for flotation. Heavy-metal pulps to which sulphide ion is added must be freed of excess before good flotation can be effected. Dichromates, permanganates, or bromine water have been used experimentally with some benefit for oxidation in sulphide pulps, but such use is rare in operation; they must be used sparingly and should be exhausted before reducing-type collectors are added to the pulp.

Organic colloids are depressants. Some, such as glue, gelatin, albumin, dried blood, casein, and whey, are of protein character, comprising aggregates of large molecules, each molecule having a plurality of hydrophilic groups of both basic and acid nature, *i.e.*, amine and carboxyl. Others are complex polyhydroxy carboxylic acids and glucosides of high molecular weight, such as tannin (also called TANNIC ACID) licorice, saponin, and quebracho extract. Yet others are carbohydrates, *e.g.*, the dextrines and starch. These substances all form multimolecular aggregates (MICELLES) when dispersed in water. The micelles have the property of precipitating upon solid surfaces, probably either forming

definite compounds with some ingredient, as is the case with tannin and iron, or static neutralization complexes or floccules between charged ionized solid surfaces and ionized groups at their own surfaces. Whatever the mechanism, the fact of coating is well established and the coated surfaces resist collector coating and levitation. The protein substances accelerate slime coating. If added in large quantities, the colloidal depressants generally prevent flotation completely; in restricted quantities the depression is selective, possibly not due to selectivity in the coating, but to different levitation tendencies equally diminished.

Uses. GLUE and STARCH have been used to depress graphite (*U. S. pat. 1,906,029; RI 3397*), mica, and talc. They are recommended (*U. S. pat. 2,019,306*) in amounts of about 0.3 lb. per ton for depressing sulphides in lightly deslimed pulps. It is reported (*PF 108*) that a limited amount of GLUE permits flotation of blende from galena. STARCH was used successfully in laboratory flotation of cerargyrite with xanthate to depress an iron oxide-talc slime (*RI 3436*). It is reported (*40 CIMM 691*) as a depressant for fusain in flotation of coal with cresol. STARCH in so-called soluble form (prepared by making a thick paste of starch and cold water, adding one part caustic soda for each 4 parts starch, diluting to 20 volumes with water, heating to boiling and then cooling) is recommended in small quantities (<2 lb.) for depressing molybdenite in xanthate flotation of copper sulphides (*U. S pat. 2,070,076*); excess depresses the copper minerals also. Pulp made alkaline with lime is preferred for the separation. At RAUB AUSTRALIAN mill (*141 #6 J 35*) CAUSTIC STARCH was used to help settle flotation concentrate. Gardner and Ray (*134 A 146*) show that it is an effective flocculant for bituminous coal slurries and for various ores. TANNIC ACID is reported better than QUEBRACHO EXTRACT for depression of calcite and dolomite in soap flotation of nonsulphides (*RI 3437*). It is also said to aid selectivity with both anionic and cationic collectors (*U. S. pat. 2,205,923*). Clemmer *et al.* (*153 A 547*) state that it has mild flocculating properties; that in the flotation of silica from magnesite it reduced the amount of anionic collector required as did several inorganic flocculants such as alum and lime. The DEXTRINES are recommended for depression of carbonaceous gangues in gold flotation (*e.g.*, MOTHER LODE ores), the YELLOW CORN DEXTRINE, in amounts of 4 to 6 lb. per ton, being reported superior to white corn and yellow- and white-potato dextrines (*U. S. pat. 2,145,206*). Average consumption is <0.5 lb. per ton. Cost is about 7¢ per lb. (1940). The DEXTRINES should be fed as dilute (2 to 5%) aqueous solutions, which should be prepared daily. They have some frothing power, which is not, however, pronounced when the quantity added is less than 0.5 lb. per ton. They have some depressing effect on secondary silicates such as talc and sericites. Quick conditioning, as in a pump, and stage addition are recommended.

QUEBRACHO is recommended as a depressant for sphalerite and carbonaceous gangue in floating galena with sulphydric collectors and for calcite in floating fluorite with fatty acids (*U. S. pat. 2,168,762*); it is reported to depress sulphides more strongly than fluorite in such flotation, and to depress fluorite less than TANNIC ACID does (*RI 3437*). It is a highly effective dispersant for slime gangue in soap flotation. It is recommended as more dependable and less difficult to handle than metal salt-silicate (*vide*) in depressing calcite from barite or scheelite (*RI 3419*). The experimenters warn that excess depresses all minerals; that the optimum quantity varies with the collector, the pulp density and the *p*H; and that heavy-metal salts must be precipitated or complexed before addition of quebracho, since the reaction products (characterized as heavy-metal tannates) are powerful depressants of fluorite as well as of calcite and silicates.

It was found at IDAHO-MARYLAND (*133 J 344*) that SOLUBLE STARCH raised the grade of gold concentrate from about 1.0 to >6.0 oz. per ton by depressing talc and mica; excess tended to depress the gold-bearing sulphides, but this effect was overcome by adding copper sulphate.

Phosphates of both the heavy metals and of Ca and Mg are relatively insoluble, hence phosphate ion is used both to precipitate these metals and also to close the surfaces of and depress their nonsilicate salts in soap flotation.

The *ortho* tribasic salt is ordinarily used for precipitation; the *meta* is most effective in depression, the *pyro* definitely less effective, while the *ortho* salts are substantially worthless (*U. S. pat. 2,040,187*). Rose and MacDonald (*ibid.*) assert that the *meta* salt depresses calcite, apatite, barite, witherite, fluorite, chromite, bauxite, and cassiterite, the effectiveness being roughly proportional to the concentration, which differs, for a given degree of depression, with the mineral. Sodium hexametaphosphate (CALGON) is reported as a depressant of iron oxides in soap flotation of kyanite (*RI 3473*); of calcite and pyrite in cationic flotation of talc (*RI 3484*); and of clay and grit in cationic flotation of mica (*RI 3427*); it is said to have activated chromite and depressed calcite with soap, the action having been aided by either $FeSO_4$ or $Pb(NO_3)_2$ (*RI 3397*), and to have been useful in preventing activation of silicates by Fe and Al in floating bauxite (*RI 3586*). Tetrasodium pyrophosphate has been used to complex iron (*134 A 76*). Wark and Cox (*134 A 7*) report that phosphate ion activates oxidized lead minerals; the phosphate of lead is very slightly soluble, hence this is probably surface closure to an extent that prevents the formation of an unlike-oriented collector multi-coat. Sodium hydrogen phosphate activates anglesite for ethyl xanthate; considerable excess can be tolerated by galena, but very little by anglesite (*134 A 18*). AMMO-PHOS (crude mono-ammonium phosphate) is recommended for use with mercaptobenzothiazole for oxidized lead ores.

Quebracho. See *Organic colloids*.

Reduction has not been practiced as a conditioning operation in commercial flotation. Wark (*PF 117*) reports use of PYROGALLOL as necessary to effect contact with pyrite, chalcopyrite, and bornite with certain dithiocarbamate collectors. Callow (*CU*) used

acetylene and illuminating-gas atmospheres in the grinding mill to condition manganese oxide ores. It is not improbable that suitable reducing conditioning of metallic oxides such as cassiterite and hematite would improve their flotation by permitting the use of sulphydric collectors. See also *Chromate.*

Silicate ion is added to pulps in the form of a sirupy liquid, comprising an aqueous solution containing many hydrates of salts which may be considered integral compounds of Na_2O and SiO_2 with a silica-to-soda ratio varying between 1 and 4. Ratios of 2 or 3 are preferred. The mixture goes by the names SODIUM SILICATE and WATER GLASS. It carries a certain amount of free alkali, but with ores that are acid or contain much soluble salt, soda ash is usually added as a protective to prevent gel formation.

The cheapest form in which to purchase is dry, making up the liquid reagent with steam; this yields a product containing about 40% of sodium silicates, to be further diluted as desired.

SOLUBLE SILICATE is the reagent most used to depress quartz and silicate minerals and to disperse siliceous and iron-oxide slimes. The probable mechanism in depression is surface closure by mass-action effect, while dispersion, which requires the smaller amount of reagent, produces silicate surfaces, ionization of which, however, is not so completely suppressed. Excess of reagent causes weak, brittle froths and depression of all minerals. Sodium silicate tends to prevent precipitation of calcium soaps from hard waters.

Metal salt-silicate treatment comprises co-addition of sodium silicate and a heavy-metal salt, *e.g.*, $Pb(NO_3)_2$, $CuSO_4$, $FeSO_4$, $Al(NO_3)_3$, $Cr(NO_3)_3$. The result is a much stronger depressant effect than that obtained with alkaline silicate alone, and one that is effective for nonsilicate nonsulphides. By judicious use calcite is depressed and fluorite floated (*RI 3437*); calcite and fluorite depressed and scheelite floated (*40 CIMM 691*); and quartz depressed and cassiterite floated (*135 J 125; RI 3397*). Conditioning time as well as concentration is vital (*RI 3419*). The mechanism postulated (*RI 3239*) is resurfacing of the depressed mineral by the metal ion, formation of the metal silicate by reaction with the metal ion, and depression of the silicate by the mass-action effect of excess silicate ion in solution.

Silicate ion precipitates cationic collectors. Rose (*32*[2] *CIMM 535*) states that it may be used to suppress iron ions at pyrite surfaces in lieu of or in conjunction with lime.

Feeding should be as a dilute (5 to 10%) aqueous solution. Dilution to this strength is aided by heat.

Soda ash, sodium carbonate. See *Carbonate ion; Hydroxyl.*

Sodium sulphide. See *Sulphide ion.*

Starch. See *Organic colloids.*

Sulphide ion, normally added in the form of sodium sulphide, is used principally in flotation of oxidized metalliferous ores. Its function in such service is to prevent wasteful and ineffective multi-coating by collectors; it does this by first producing a sulphide coating and then retarding reoxidation sufficiently so that the subsequent collector-coating is substantially a mono-film, like-oriented and effective (Art. 3). Rey (*134 A 24*) postulates that the function of sulphide ion in flotation of cerussite and anglesite is to decrease the concentration of metallic ion in an ionic cloud surrounding the relatively soluble surfaces, this cloud otherwise precipitating diffusing collector ions and thus preventing access to the metallic ions anchored in the solid. Allen (*A TP 371*) states that when using oil with sulphydrate collectors, sulphide ion tends to raise pyrite. EXCESS of sulphide ion prevents collector coating by maintaining the relatively insoluble sulphide films at the particle surfaces; it is indicated by barren watery froths. Excess also causes penetration of the sulphidizing reaction, forming a sulphide multi-coating which is fragile and easily removed by the agitation necessary to produce subsequent oxidation. Higher excess can be tolerated by cerussite than by galena (*139 A 18*). It follows that the best procedure is to make a number of limited additions of sulphide ion (STAGE ADDITION), preferably alternating with similar stage addition of collector, but the latter practice is not necessary if the reducing atmosphere of the pulp is closely controlled so as to prevent more than monomolecular reversion at any time.

Commercial use of sulphidizing is limited to flotation of cerussite (Sec. 2, Art. 29) and attempts at bulk sweep-up of oxidized sulphides in gold flotation (Sec. 2, Art. 22). Na_2S has been used at MIDVALE (*IC 6492*) and BALMAT (*IC 6574*) to reactivate pyrite after differential flotation of galena and sphalerite, and experimental reactivation of pyrite and arsenopyrite after depression with $FeSO_4$ in acid solution is reported (*RI 3370*). In general oils are used as supplementary collectors when sulphidizing is practiced. Oxidized copper ores are floated with soap (Art. 51). Anglesite and the lead oxides, the oxidized zinc minerals, chrysocolla, gold, and the oxides of iron, tin, manganese, and chromium cannot be sulphidized satisfactorily. Cerargyrite does not require sulphidization (Art. 51).

At SAN FRANCISCO MINES OF MEXICO (*A TP 371*) sodium sulphide was necessary in galena flotation whenever the amount of soda ash required to maintain alkalinity in the lead circuit increased, indicating oxidized ore.

Sulphide ion has marked depressant effect on flotation of sulphide and of free gold when using anionic collectors. The mechanism is a combination of surface closure by sulphide films more insoluble than collector-coating films and resistance to reoxidation. Sphalerite, which is much more soluble than the other sulphides, is depressed as against the lower xanthates but not against cetyl xanthate; the others are closed also against cetyl. Wark and Cox (*134 A 7*) give critical concentrations of hydrosulphide ion necessary to prevent bubble attachment with ethyl xanthate in normal concentration as 0.01 mg. per li. for galena; chalcopyrite, 0.30; bornite, 1.3; covellite, 1.7; pyrite, 2.5; chalcocite, 6.4. The silver sulphides are also depressed at very low concentrations. The order is roughly that of decreasing resistance of the minerals to oxidation under atmospheric and pulp conditions. With mixed sulphide-oxide ores practice is to float the sulphides before starting sulphidizing. Excess of $S^{=}$ is readily removable by Pb^{++} or Cu^{++}; use of MnO_2 is also reported (*RI 3419*).

Because of the depressing action of EXCESS sulphide, close control of addition is necessary. Periodic tests of filtrate from pulp samples taken at critical points in the circuit should be made with lead acetate solution. If other than a faint dark coloration is observed on addition of the acetate, sulphide addition should be adjusted to this test color.

Sodium sulphide is also used as a self-buffered source of hydroxyl ion for dispersion of slimes in nonsulphide flotation. It is reported (*RI 3328*), however, that with some slimes, even within the buffered range, complete flocculation occurs at some concentrations of the reagent and good dispersion at others.

Fused sodium sulphide contains about 30% Na_2S. To dissolve in the mill, circulate the required amount of water to make a given strength over the solid supported on a screen. It should be prepared immediately before use. Dewatering before addition will reduce the quantity required by removing precipitating ions and increasing concentration of sulphide ion.

Thiocarbonates have been recommended as a source of sulphide ion. They have the advantage of keeping the concentration down, but are expensive. Barium sulphide has been suggested as a possible cheaper source (*23 #13 MJA 7*).

Wark (*PF 182*) reports that sulphide ion is not a depressant for sulphides when cetyl trimethyl ammonium bromide (cationic) is used as collector. The report covers conditions, however, in which relatively tremendous quantities of collector were used and is to be weighted accordingly.

Sulphite ion, added either as the sodium salt or formed following introduction of SO_2, will depress sphalerite and permit galena to float with sulphydric collectors. The action is accentuated by co-addition of $ZnSO_4$. The operation requires close control and is not as effective as that with cyanide, but does not have the disadvantage of gold dissolution and loss.

Christman (*TP 17 AC*) postulates the formation of metal-sulphite complex anions similar to those formed with cyanides, quoting Ephriam (*Anorganische Chemie, p. 429*) to the effect that such ions form with Fe, Co, Ni, As, Cu, Zn, Ag, Cd, Au, and Hg but not with Pb. Other sulphoxy ions less oxidized than sulphate, *e.g.*, thiosulphuric and the various polythionic acid ions are recommended for the same service. Excess of the lower sulphoxy reagents tends to depress all sulphides.

At St. Joseph Lead Co., Hughesville (*IC 6447*), use of sodium sulphite instead of $ZnSO_4$ and NaCN lowered the zinc in lead concentrate from 6.5 or 7% Zn to 4 or 4.5%; excess had no effect on lead recovery.

Sulphuric acid. See ***Hydrogen ion.***

Tannic acid. See ***Organic colloids.***

Wetting agents have been used as dispersants. Those which contain sodium silicate, sodium phosphate, or free sodium carbonate undoubtedly function largely because of these ingredients. But with respect to the great majority of them no generalization as to suitable chemical structures can be made as yet. The most that can be said is that the characterization "Detergent" in tables such as those presented at *31 IEC 66* and *33 IEC 16* may be taken as a pointer, whereupon, if the chemical type does not clearly mark unsuitability, the substance is worthy of trial for cases that cannot be handled by better known reagents. Many of the reagents are violent frothers, which is likely to be a disadvantage, in that it divides froth control.

Zinc ion, added as zinc sulphate, is used together with cyanide ion and with sulphite ion to increase their depressant effects on sphalerite. The action with cyanide is reported to be better if the two salts are added in stoichiometric proportions to make $Zn(CN)_2$ and this salt is precipitated before addition. The instability constants of the Cu, Ag, and Hg cyanide complexes are lower than the solubility product of zinc cyanide, so that cyanide ion thus added is available for preventing activation. At the same time the concentration of cyanide ion is thus held low, which tends to conserve the supply against consumption by other reactants, such as iron, which are not activators for sphalerite. It is also true that in the presence of excess zinc cyanide, zinc cyanide should precipitate at the sphalerite surface and tend to reduce the availability of zinc ions there for coating reaction with

fatty-acid ions introduced into the pulp by lubricants. Any excess of zinc ion in solution would tend to react with and precipitate such accidental fatty-acid ions before they reached the sphalerite-particle surfaces. Zinc sulphate alone is reported to have a depressant effect on sphalerite in differential flotation; the reason for such action is obscure, barring the presence of more than the usual amount of lower sulphoxy ions from oxidation of large amounts of iron sulphides co-present.

Wark and Cox (*112 A 225*) show that high concentrations do not affect bubble attachment to sphalerite in the presence of copper ion when using ethyl xanthate as collector. Sutherland (*153 A 453*) reports that it also has a depressant effect on chalcopyrite in the presence of cyanide, but that it has no substantial effect on the amount of cyanide required to depress pyrite.

LEVITATION

The attachment of air bubbles to collector-coated mineral particles, and the subsequent separation of the air-mineral aggregates from nonbubble-bearing particles by differential sedimentation and skimming of the float is called LEVITATION.

11. BUBBLE ATTACHMENT

A BUBBLE is a gas- or vapor-filled hole in a liquid. The mechanism underlying cling of a bubble to a solid surface is completely unknown today except in so far as explanation is comprised in the statement, based on the second law of thermodynamics, that when a bubble clings to a particle in water in static equilibrium the system has reached a level of minimum potential energy for the conditions prevailing. This is, of course, sound, but not particularly informative as to the forces acting.

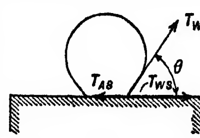

FIG. 4. Diagram for Young equation.

Attempted explanation usually proceeds along the following lines (*PF; 18 MMt 282; 17 MMt 339*). The Young equation expresses the equilibrium relationship between the forces involved in spreading, as shown in Fig. 4.

$$T_{WS} + T_{WA} \cos \theta = T_{AS} \quad [1]$$

T_{AS}, T_{WA}, and T_{WS} are the surface tensions of the air-solid, water-air, and water-solid interfaces respectively, and θ is the contact angle through the water. T_{AS} and T_{WS} cannot be measured. But from the second law of thermodynamics, the work per unit area done in peeling off such a bubble is

$$W = E_{WA} + E_{WS} - E_{AS} \quad [2]$$

where E is interfacial energy per unit area. But E_{WA} is numerically equal to T_{WA}, etc. Hence, combining equations 1 and 2,

$$W = T_{WA} - T_{WA} \cos \theta = T_{WA} (1 - \cos \theta) \quad [3]$$

Total work is, of course, WS, where S is the area of air-solid contact at equilibrium. This equation tells nothing, of course, about the force required to pull a bubble away. Observation teaches, however, that the greater the value of θ, the greater the adhesive force.

Lifting by bubbles has usually been accounted for by a force diagram such as that shown in Fig. 5, item *a*, equilibrium conditions being stated by the equation $W = \sigma l \cos (90 - \theta)$, where $W = V(\delta - \rho)$, when W = weight supported by the surface forces, V = volume of the solid (shaded) body, δ = specific gravity of solid, ρ = specific gravity of liquid, σ = surface tension, l = length of 3-phase contact line, and θ = angle of contact measured through the liquid phase. Wark (*PF*) reports, however, having loaded a hydrocarbon-coated zinc plate thus floating to an extent many times greater than could be supported according to this equation; and at Columbia University such loading has been carried to the point that W = approx. $10 \sigma l \cos (90 - \theta)$, when the loading of the plate was far from shockproof.

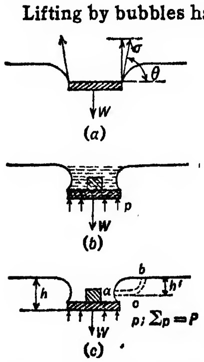

FIG. 5. Floating plates.

Experimental work at Columbia indicates that the supporting force is equal to the weight of liquid displaced by the floating system, according to the principle of Archimedes. A circular paraffin-coated disk, loaded to the limit and floating in water, shows in a diametral vertical section a configuration such as that indicated in Fig. 5, item *b*, and $\Sigma p = vp = W$ where v = the volume indicated by horizontal dotted hatching, to within less than 1%.

The analysis of the mechanism of capillary rise (see *Adam*) shows that the pressure on the liquid side of a convex liquid surface, as at *a*, Fig. 5, item *c*, is greater than that under a plane surface, as at *b*. Hence if *acb* is considered to be any liquid-filled theoretical

tube in the mass of liquid, liquid must stand higher than a therein, *i.e.*, at b, according to the relation $a - b = h'(p - \alpha)g$, where α = sp. gr. of the gas (H_2O = 1), and g = gravity constant. The total upward pressure on the under side of the plate is, of course, by the ordinary methods of hydraulics, $P = Ah\rho g$, where A is the mean horizontal cross-sectional area of the displaced fluid (neglecting the additional pressure due to the substituted gas).

When particles, small in comparison to bubble diameter, cling to bubbles, they normally arrange themselves with their largest flat surfaces in the gas-liquid interface. This corresponds to the equilibrium position for the disk pictured in Fig. 5, and is in accord with minimum-energy requirements.

Contact angles are a measure of the adhesion between bubbles and particles. This follows from the fact that spreading is spontaneous once contact is established, which means that an energy reduction is occurring; the greater the spread before equilibrium is reached, the greater the energy reduction. But large spread corresponds to large contact angle, whence the larger the contact angle the more work must be done to dislodge the bubble. This conclusion is confirmed by experiments with bubbles generated electrolytically on surfaces variously coated, which showed that bubble volume at the time of release (maximum upward pull) increased with contact angle as in Fig. 6.

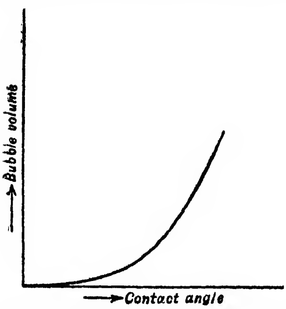

FIG. 6. Bubble adhesion *vs.* contact angle.

Rapidity of establishing contact between bubbles and coated particles varies greatly in contact-angle tests with different collectors, and with different solution environments with the same collector. Under favorable conditions the captive bubble on near approach to the particle surface appears to jump thereat; under other circumstances the bubble must be pressed so hard against the surface that it is compressed vertically to two-thirds to one-half its original diameter and may then not make contact for many seconds. It is probable that the variable rates of flotation in practice are due, in part at least, to the same phenomenon.

It has been established (*CU*) that maximum contact angles and maximum rapidity of contact are obtained with galena, chalcocite, calcite, and barite, using sodium oleate as the collector, at pH's ranging from 6.5 to 10.5 for the different minerals, and that these points correspond to the pH conditions for maximum neutral soap production. The experimental results are shown in Fig. 2. The oleate film is not removed at the points of zero contact, as is evidenced by the fact that there is immediate return to the water angle, *i.e.*, that corresponding to pH 6 to 7, when the particle is transferred (with precautions against drying) to water. The varying resistance to drying is attributed to the presence of H and OH ions introduced reversibly into the surface-reaction soaps in the acid and basic ranges respectively, these, probably (*153 A 500*), causing the affected soap molecules to loosen from the solid surface and re-orient, reactive water-avid end outward, thus decreasing the drying tendency of the hydrocarbon surface.

The curves of Fig. 2 probably point the explanation for the barren froths made with fatty-acid collectors in the presence of excess of alkali, *i.e.*, the alkali prevents bubble attachment although it does not prevent frothing. On the acid side frothing is also prevented or greatly depressed.

It is certain that the foregoing explanation of flotation time and maximum angle does not apply in the case of all collectors. Destruction of angle by excess of hydrogen and of hydroxyl ions with ethyl xanthate on galena has already been discussed (Art. 10). Flotation time is parallel and there is no return of angle in plain water; the coating is progressively removed.

Frothing agents affect contact. Wark (*PF 55*) asserts, on the basis of tests with bubbles aged in certain collector solutions, that oriented films of frothing agent at bubble surfaces (Art. 12) will increase the time to effect bubble attachment, because the bubble film presents water-avid groups to the particle surface, and that contact cannot be established until these are squeezed out. Actually, however, contact is established with extreme rapidity in operating bubble columns under very light pressures (the individual weights in water of the falling mineral particles) and the bubbles in these columns are heavily loaded with frothing agent by transfer from the bubbles that break at the top of the column. Furthermore a captive drop of oleic acid, at the surface of which the molecules are oriented with polar ends toward the water, makes immediate contact with surfaces coated with xanthate or fatty-acid soaps, or with solid hydrocarbon surfaces such as paraffin wax, gilsonite, or bituminous coal.

Certain frothing agents such as SAPONIN, however, destroy bubble adhesion to collector-coated minerals. This may be due, as has been postulated, to the fact that such substances tend to ADSORB (concentrate) at air-water interfaces so strongly that they form solid layers which cannot be displaced by

mineral particles. The same exclusion of mineral would occur if these substances, although not actually solidified, maintained their positions with water-avid groups presented to the coated surfaces, thus holding water against these surfaces and preventing drying. On the other hand saponin, like glue, gelatin, tannin, and the like, forms colloidal solutions in water and some of these, at least, adsorb at mineral surfaces and prevent contact.

Undissolved oils, whether of frothing type (oleic acid) or nonfrothing (neutral hydrocarbon) will, in the presence of soluble frothing agents and particles already attached to air bubbles, intrude between the bubble and the particle, leaving the particle attached at the oil-water interface. Since the surface-tension of this interface is less than that of an air-water or air-solution interface, the firmness of contact is thereby decreased.

Surface required for bubble attachment. Air bubbles will not attach themselves in water to solid surfaces which are not of hydrocarbon character. Even if the surface is hydrocarbonlike in part, as, for example, a surface of crystalline lead xanthate, no attachment can be effected, although ready attachment is obtained if the lead xanthate molecules are like-oriented with hydrocarbon ends out, as is the case with a monomolecular lead xanthate film on a particle of galena (Fig. 1).

Attachment of preformed bubbles. Air (or other neutral gas) bubbles in water will attach themselves to hydrocarbonlike surfaces under a number of different conditions. Captive bubbles (Sec. 19, Art. 22) adhere when pressed against such surfaces; more time and more force are required in some cases than in others. Under exceptional circumstances sufficient force and time to effect attachment may conjoin in an ore pulp undergoing agitation, and a preformed bubble adhere to a collector-coated mineral particle, but the occurrence is rare. The reason is that adjacent bubbles and particles are swept along by the same mass of water in the same directions, by substantially parallel forces of substantially equal magnitudes; only gravity tends to drive them in different directions; gravitational forces are not sufficient to squeeze out the water between them in a short time, while their relative velocity is too great to permit light contact of sufficient duration.

Gas precipitates from solution selectively onto collector-coated mineral surfaces under the influence of heat, reduced pressure, chemical generation of gas, or electrochemical reaction. Thus if a pair of particles, one collector-coated (*e.g.*, galena) and one uncoated (*e.g.*, quartz), is placed in a dish of clean tap water and the latter is heated slowly, gas bubbles precipitate on the galena but not on the quartz. If a similar system is placed under a vacuum or, having been subjected to super-atmospheric pressure, is removed to atmospheric pressure, again gas precipitates selectively on the galena. If a calcite particle is introduced into such a system, spaced well away from the galena, and sufficient acid is added to induce evolution of CO_2 at the calcite surface, gas bubbles will shortly thereafter appear on the galena, despite that close observation shows that no bubbles generating at the calcite surface have moved through the water to the galena. Finally, if the mineral-particle members of the system are made individually a pole of an electrolytic cell, gas precipitates on the galena but not on the quartz.

Selective gas precipitation is explicable (*36 JPC 130*) on the basis that vapor pressure is inversely proportional to surface tension. The interfacial tension between two liquids immiscible in each other lies between their individual surface tensions against air. Assuming that the interfacial tension of a solid hydrocarbon against air is not greatly different from that of a liquid hydrocarbon against air, which is of the general order of 20 to 30 dynes per cm., the interfacial tension between water and a hydrocarbon surface should be somewhere between 30 and 72 dynes per cm. The surface tension of a flotation pulp against air is of the general order of 60 to 65 dynes per cm. The surface tension of water against a natural salt is higher than that of water against air, since the surface tension of molten salts against air is higher than that of water against air, and surface tension increases with fall in temperature. Hence the surface tension of solution against hydrocarbon-coated mineral is the lowest tension of any of the pairs involved, and vapor pressure should, therefore, be the highest at this interface. Hence when the aqueous solution becomes subject to conditions that cause evaporation (heat, pressure reduction) the vapor releases at the surface of highest vapor pressure, which is the hydrocarbon surface.

Bubble removal at breaking of bubble-particle contact occurs by PEELING, *i.e.*, by sliding of the 3-phase line along the solid surface, when the contact angle is less than 90°. Such peeling is the more difficult the more minutely jagged the solid surface is. This is because of an edge effect, noted by Coghill and Anderson (*22 JPC 237*).

These authors accredit to this phenomenon the fact that the ordinary tumbler (which is greasy) can be superfilled. Fig. 7 shows the application in flotation. In item *a* three positions of one wall of a peeling bubble are represented. At 1 the equilibrium position with contact angle θ is shown on a plane surface of the solid. At 2 the equilibrium position with the edge is shown. In order to swing around the edge into position 3 the water must be bulged as indicated. This involves setting up excess surface pressure in the concave surface of the liquid in the region of x, to do which additional force must be applied. This is, in part, supplied by the tendency of the overhanging liquid to slump down under the in-

fluence of gravity. Advance across a depression in the surface and across a depressed edge is shown in items *b* and *c*. As in item *a*, the advancing edge of water across the plane bottom of a trough is shown in item *b*, position 1. The position at the depressed edge is shown by 2. In order for the water to reach position 3 in item *c*, water must be pushed away from the surface into a position as at *x*, item *a*, against the gravitational pull, or else water must distil from the surfaces of low curvature adjacent to *y* in item *b* into space *y*. Additional energy is needed to effect the displacement and time to effect the distillation; either slows down the progress of the water. In item *d*, in order for the advancing liquid to surmount

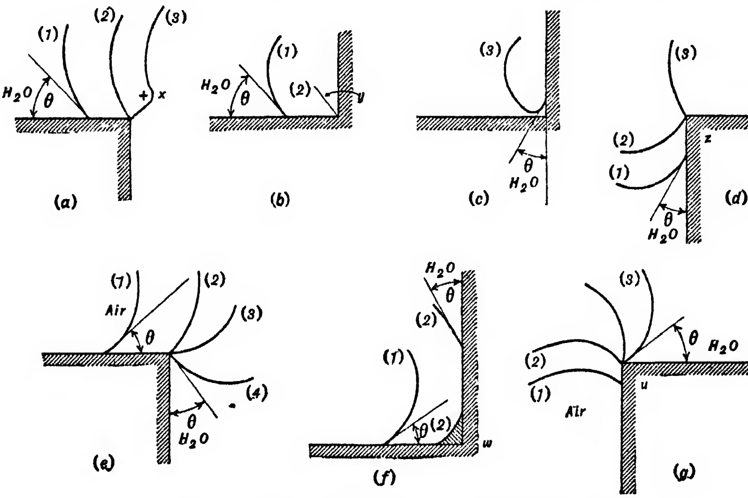

FIG. 7. Edge effects in bubble spreading and removal.

the edge *z* from position 2 to position 3 enough work must be done to raise liquid above the level of the face 4 without any appreciable movement of the 3-phase contact line. This is equivalent to the heaping up of water in a tumbler.

Spreading of bubbles is hindered on rough surfaces by the converse of the phenomena discussed in bubble removal, but this hindrance is not normally so great as the hindrance to removal.

In item *e*, Fig. 7, the bubble wall advancing from position 2 to position 4 must flatten the bubble, thus increasing its area and surface energy and also lowering its center of gravity and increasing potential energy. Since such energy increases require work to be done they tend to hinder bubble spreading. In item *f*, when the advancing bubble reaches 2 it bridges across the depressed corner *w*, leaving a body of liquid in the corner, as indicated by hatching. This tends to hasten spreading, although liquid islands are thus left behind within the confines of the bubble as the 3-phase contact line moves on. In moving around the corner buoyancy aids the rise of the bubble wall, and since there is no appreciable tendency to increase concavity on the liquid side of the air-water interface, in rounding the corner, there is no energy increase at this interface and no additional work need be done on this score.

Hysteresis of contact angle. The difference in the forces required for bubble spreading and bubble removal is the cause of the so-called hysteresis of contact angle, much discussed by early writers on flotation. Their contact-angle measurements were made on rough and contaminated surfaces to which water was applied and over which it was caused to flow by gravity. All such particles showed contact angles because of their contamination. The advancing angles were always larger than the receding. Since the extent of contamination was always greater on the minerals which reacted with fatty acids (Art. 3), the hysteresis was greatest with these. Thus arose Sulman's theory (*29 IMM 44*) that the magnitude of hysteresis, which he attributed to inherent floatability, was an indicator of floatability.

Flocculation. See Art. 42.

Flotation machines. The ways in which the principles of levitation are employed in separation of collector-coated particles from pulps is described in Art. 19.

12. FROTHING

The term FROTHING, in flotation, means the maintenance of a body of bubbles at and above the upper surface of the flotation pulp. The liquid walls of these bubbles contain

ore particles either at rest or in motion or in both states. The functions of the froth differ according to the process of bubble attachment employed but, including all processes for the minute, froth changes the effective density of the minerals included in it to an extent that permits them to rise instead of fall in a quiescent pulp; it permits differential draining back of gangue minerals into the body of pulp; it maintains a body of ore particles above the pulp long enough to permit such draining to effect more or less concentration; and it transports floated material horizontally to the concentrate discharge point.

A FROTH is simply a collection of bubbles. Prolongation of bubble life is, therefore, an essential element in frothing. Sufficiently long life is necessary to give time for the desired draining and horizontal transport. Beyond such time, however, further life is a nuisance, since froth is difficult to transport and dewater. The draining function is best served by a relatively large bubble froth, comparatively thick walled, with plenty but not an excessive amount of internal movement.

Theory of frothing

Pure water does not froth, and the more or less contaminated waters of mill pulps froth very little. Under the same external conditions, however, the addition of minute quantities of certain reagents, such as cresol, pine oil, etc., produces frothing, *i.e.*, increases the effective resistance of the bubble walls to external strain.

Adsorption of frothing agent. The properties of liquids that cause them to exist in film form are viscosity and surface tension. Frothing agents, when added in the minute quantities effective in flotation, do not affect the viscosity of water measurably; but they lower the surface tension, and they concentrate (adsorb) at the interface between the water and bodies of gas in contact therewith. The extent of surface-tension lowering is proportional to the extent of such surface concentration according to the Gibbs equation $\frac{d\sigma}{dc} = -RT\frac{U}{c}$, in which σ is surface tension, c concentration, U the amount adsorbed, R the gas constant, and T the absolute temperature (J. W. Gibbs, *Collected Works, Vol. I*, Longmans, Green & Co., N. Y.). The underlying bulk solution is correspondingly impoverished. Experimental confirmation of the relationship for frothing agents is reported (*36 JPC 300*). Inspection of the equation shows that when concentration is away from the surface (negative), as is the case generally with ionized compounds, surface tension will increase with increase in concentration of solute.

Variable resistance to strain. When a bubble is strained by external forces the covering film stretches; the result is that some of the underlying bulk liquid of the film is brought to the surface. Being lower in content of frothing agent, its surface tension is higher than that of the film before stretching. It offers greater resistance to the external strain. Time is required for sufficient contaminant molecules to diffuse to the surface to raise the surface concentration to the original level and correspondingly lower the surface tension. Until this happens, the increased resistance persists. The different tensions are manifestations of the familiar difference between dynamic and static surface tensions of solutions. If the original strain was not sufficient to break the strengthened film, and if the strain does not last too long, the bubble will remain unbroken. Hence the essential function of the frothing agent is to impart to the film capacity to adjust its internal stresses, temporarily at least, to increases in external strain, thereby increasing the life of individual bubbles, and so making it possible for them to collect into a froth.

Viscosity of mineral-froth films. When solid particles adhere to bubbles they assume positions such that one of the particle faces is either in the air-water (solution) interface or in the interface between the dilute solution of the bulk of the film and an oily film surrounding the gas of the bubble ~~(see Art. 11)~~. Other solid particles are usually present in suspension in the bulk solution in the bubble walls. When deformation of the bubble wall occurs, these particles interfere with and are forced to slide past each other. This is a phenomenon with the characteristics of fluid viscosity, *i.e.*, resistance to flow, or resistance to deformation; it is, consequently, an aid to bubble-wall persistence and, therethrough, to frothing.

If there is insufficient mineral present in the pulp to stiffen the froth, as in quartz-gold ores with little or no sulphide, or the reclaimed native copper tailing at CALUMET & HECLA, and slime gangue is also lacking, it is usually necessary to add a froth stiffener. Oils, such as destructively distilled pine oils or the coal- or wood-tar creosotes, are normally used. At ENGELS (*IC 6550*) two pine oils, one making a brittle froth and one a tough froth, were used, the proportions varied as necessary.

Coalescence interferes with froth building. Bubbles in pure water coalesce immediately on contact. Frothing agents and solids in the bubble interfaces decrease coalescence markedly. This decreases activity and hence strain within the froth, and keeps the bubbles small and structurally more resistant to strain.

Characteristics of a mineral-bearing froth. A good froth should carry the mineral load without collapse or excessive showering, but should not be so tight that gangue is carried in it, nor so tough that it persists unduly after leaving the machine. From the standpoint of workability on the machine, the froth should be lively, which is to say in active coalescence in its upper portion, but sufficiently small bubbled to support a fairly heavy load of solid, and not so tough that large bubbles (several inches to a foot or more in diameter) build at the top. Coalescence transfers solid load to underlying bubbles and affords opportunity to shake out gangue and mineral. If it occurs too low down, mineral showers back into the pulp. If bubbles are too fine and too much crowded (froth too dry), and coalescence infrequent, coarse gangue is carried over mechanically as on a screen. This difficulty is sometimes overcome by spraying clean water in a fine spray onto the surface of the froth. Tough films are usually the sign of too much neutral oil filming the bubbles and holding solid tenaciously. Overvoluminous lightly loaded froths are characteristic of excess of soapy frothing agent, and usually, also, of poor collection. Brittle froths, marked by spitting at the surface, are usually poor load carriers and permit excessive showering; they are used, however, for difficult differential work. When they are not the result of starvation, they can usually be stiffened by adding a small amount of neutral oil, which has the effect of producing heavier and more tenacious solid loading, with consequent increase in viscosity. Tough soapy froths can be embrittled by addition of pine oil in small quantities (5 parts per million of water, upward); too large amounts of pine oil prevent soap frothing.

Overfrothing is a term applied to any condition of a froth which involves an uncontrollable amount thereof; which can, in general, be corrected by a reduction in quantity of frothing agent; or which resembles in appearance and general behavior a condition thus correctible. Overfrothing in the absence of considerable quantities of undissolved oil is usually marked by a fluffy, large-bubble froth of large volume, carrying little or no ore solids. With sulphide ores the solid carried is frequently predominantly gangue. Such overfrothing is usually due to the formation of a skin of solid or semisolid character around the bubbles, ordinarily formed of colloidal materials present in the pulp. Soap is the usual offender, but glue, gelatin, saponin, and the like act similarly. The evil effect increases with increase in surface activity of the colloid. The films apparently exclude granular material mechanically from the interfaces that they occupy. Overfrothing of this type is induced in soap flotation by excess of soap or by excess of alkali; both conditions produce the same result of an excess of micellar (solid) soap in the pulp. When there is insoluble oil present, ORE COLLOIDS (gangue slimes) may similarly occupy the interfaces; this is particularly likely when a collector for these minerals is present.

At BENGUET CONSOLIDATED (*134 A 224*) a soft clayey gold ore requires treatment in a slightly acid pulp since in alkaline pulp large, slimy bubbles are formed and recovery falls off rapidly as pH increases. Variations in amount of slime are smoothed out by use of a 50-ft. thickener run as a surge tank preceding flotation.

Overoiling produces an overfrothing condition in which the froth is small-bubble and highly fluid and carries a heavy solid load with little or no selectivity. This condition was common in the days of oil flotation, but is rarely, if ever, met with now except in cases of accidental oil spills which find their way into the pulp stream. Another overfrothing condition which flows from overoiling is the formation of tough thin-walled froths by wood tars and creosotes when these are used as subsidiary collectors. Concentrate made by such froths is low-grade and hard to clean because of the inactivity in the froth (lack of coalescence and consequent inner disturbance), and the hindrance to bubble-column action ~~(Art. 10)~~ incident upon the narrow interbubble channels.

Temperature. The effect of heat on frothing is substantially negligible within the temperature range normally prevailing. In general, persistence decreases as temperature increases. On the other hand, because of the effect of temperature on the viscosity and consequent ease of dispersion of pine oil and of crude cresylic acid, it is usual experience that more frothing agent is required in winter than in summer in climates where winter temperatures are low and seasonal changes large.

Electrolytes in solution have various effects on frothing according to their character. ACID decreases frothing with fatty-acid collectors by decreasing dispersion of the collector and its contribution to the frothing effect. In general, also, acid tends to decrease froth volume, probably because it tends to flocculate slime gangue and thus decrease its stabilizing effect. ALKALI almost invariably increases frothing, but with excess the froth is usually underloaded, gangue-bearing, and generally undesirable. NEUTRAL ELECTROLYTES, when present in any concentrations normally present in mill waters, have no marked effects on frothing unless they react with and destroy the frothing agent (*e.g.*, earth-metal salts with fatty acids and soaps).

FROTHING AGENTS

Surface-tension characteristics. Frothing agents are substances which dissolve in the liquid to be frothed and which, when in solution, change the gas-solution interfacial ten-

sion. If they lower the surface tension of the solvent, the slope of the surface tension-concentration curve is negative and adsorption is positive, *i.e.*, the reagent concentrates at bubble surfaces; if they raise the surface tension, they concentrate away from the interface. Typical surface tension-concentration curves for aqueous solutions are shown in Fig. 8. Curve *C* is the type yielded by most inorganic compounds; curves *A* and *B* are typical of organic solutes. Compounds that yield type *A* curves are good frothers at low concentrations because the degree of adsorption is high and consequently the change in surface tension is large for relatively small changes in concentration. Traube (~~*87 KB 110*~~) states that in any homologous series of aliphatic surface-active substances the reduction in surface tension with a given weight increases as $1 : 3 : 3^2 : 3^3$, etc., for each additional CH_2 group. A good flotation frother should give a surface tension-concentration curve with an average slope of 1 to 2 dynes per cm. per 10 parts per million of water in the first part of the curve.

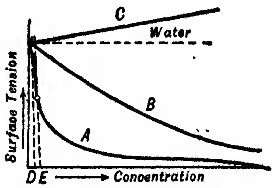

FIG. 8. Surface tension-concentration curves.

Chemical structure of frothing agents. Study of frothing agents shows (*87 A 285*) that type *B* reagents are polar organic compounds of the general structural character RA, where R is a hydrocarbon radical of any type, but normally having upward of 6 carbon atoms, and A is a polar solubilizing group such as hydroxyl (OH), carboxyl (COOH), carbonyl (CO), amine (NH_2), and the like. In alkyl compounds the solubilizing effect of the principal polar groups is COOH > NH_2 > OH > CO; in aryl compounds the order is OH > NH_2 > CO > COOH. In general the compound containing the more powerful solubilizing group is the better frother, provided both compounds are close together in solubility. Solubility for good frothers ranges normally from 0.001% to 3 or 4%. In homologous series throughout this solubility range the frothing power increases with molecular weight, *i.e.*, with the bulk of the hydrocarbon group in the molecule, up to a maximum and then falls. Bartsch (*20 KB 1*) states that amyl is the maximum in the alcohol group and butyl in the acid group.

By using yet stronger solubilizing groups such as in the strong inorganic acid esters and their salts, the salts of the tetrammonium compounds and their analogs, substituted polybasic acids, betaine salts, salts of mixed esters of polyalcohols, etc., Harris found (*134 A 88*) that the compounds of hydrocarbon groups of much higher molecular weight than otherwise could be used as frothers. Thus while cetyl alcohol ($C_{16}H_{33}\cdot OH$) is too insoluble for satisfactory frothing, cetyl hydrogen sulphate $C_{16}H_{33}\cdot SO_4H$ is an excellent frother. Others within the above classification are: sodium salt of stearyl glyceryl sulphate, $C_{17}H_{35}\cdot COO\cdot CH_2\cdot CH(OH)\cdot CH_2\cdot SO_4Na$; carbopalmitoxy methyl pyridinium bromide, $C_{15}H_{31}\cdot COO\cdot CH_2\cdot C_5H_5N\cdot Br$; stearyl malic acid, $C_{17}H_{35}\cdot COO\cdot CH\ (COOH)\cdot CH_2\cdot COOH$; cetyl ester of betaine hydrochloride, $CH_3\cdot NCH_2CO_2\cdot C_{16}H_{33}\cdot HCl$.

On the other hand, multiplication of solubilizing groups, holding hydrocarbon content constant, decreases frothing capacity. Thus lactic acid, $CH_3\cdot CH(OH)\cdot COOH$, is a poorer frother than propionic acid, and glycerine, $CH_2(OH)\cdot CH(OH)\cdot CH_2OH$, is less effective than propyl alcohol.

Orientation of surface films. The adsorbed surface films of frothing agents are like-oriented, with the hydrocarbon groups turned toward the gas phase (~~*22 ACS 1846, PCS*~~). A pseudo-kinetic explanation for this fact lies in the resistance of the hydrocarbon part of the molecule to wetting and the corresponding tendency of the polar groups to surround themselves by water. Negative adsorption of ionized compounds is similarly accreditable to the hydration tendencies of ions. Insoluble substances, having no attraction for water in any part of the molecule, are not broken up into molecular or ionic individuals by the water and do not adsorb; they consequently do not affect surface tension and do not cause frothing. The good frothers are those of sufficiently high proportion of hydrocarbon bulk to resist being pulled into the water body by the tendency of the polar radical to surround itself by water, but not containing such a high proportion of hydrocarbon that its solubility is too low to permit ready molecular dispersion.

Mixtures of surface-active materials may increase or decrease frothing above that obtainable by either singly according to the effect that each has on the solubility of the other. If there is no substantial solubility effect, the results are additive, *i.e.*, the addition of the second produces the same result as addition of a further equivalent amount of the first. If the second decreases the solubility of the first to the point of precipitation of some of it, without in itself adding equivalent frothing effect, the combined action will be less than that of the first alone, *e.g.*, benzyl alcohol added to amyl alcohol solution or to *m*-cresol (*20 KB 1*). If the second increases the solubility of the first and thus results in dissolving more of it, frothing increases, *e.g.*, ethyl alcohol added with nonylic acid (*ibid.*).

Ideal frothing agent should have no collecting property, in order that frothing may be controllable independently of collection; it should be intensely surface active, so that it produces frothing in low concentrations; it should be independent of kind and quantity of

solutes present in the pulp; it should produce a copious, lively, nonpersistent but nonbrittle froth; and it should not adsorb soaps or other organic colloids to the exclusion of solids (~~*Dean, 186 J 880*~~). It should be liquid, cheap, and stable against storage (time) and high atmospheric temperatures. When used with ores not mined and crushed so as to contain the usual complement of lubricating oil, it should, if used in bubble-column flotation, adsorb to the extent of a second liquid layer at the bubble surfaces, or some oil must be added.

Quantity of frothing agent required varies with both the agent and the ore, but lies, in general, between 0.05 and 0.20 lb. per ton for good frothers. Bartsch (*ante*) found that with any frother in aqueous solutions there is maximum frothing at some intermediate concentration; that the surface tension at this point ranges from 54 to 70 dynes per cm. for the representative alcohols, acids, phenols, and amines that he tested; that optimum frothing for the majority occurred when the surface tension was within 4 dynes of the average for the 19 agents tested, *viz.*, 62.5 dynes per cm.; and that persistence was greater the lower the surface tension at optimum frothing.

Common frothing agents used in operating plants are pine oil, eucalyptus oil, cresylic acid, soaps, the liquid Aerofloats, mixtures of aliphatic alcohols, and sulphates and sulphonates of long-chain alcohols, the alcohol products being, in general, marketed under various trade names.

Pine oils are of several varieties. The oil obtained by steam distillation of dead pine stumps and redistilled to a close-cut fraction with an initial boiling point of about 290° to 350° F. and an end point at from 370° to 430° F. is the one most used in flotation (G.N.S. No. 5; Yarmor F). The specific gravity of these oils is about 0.92 to 0.95, refractive index about 1.48, specific viscosity about 2.5 at 70° F., color a deep straw to sulphur yellow. RISOR PINE is a lower grade with a boiling range of 420° I.B.P. to 80% at 465°, and with a slightly lower alcohol content than the preceding (*PC*, Hercules Powder Co., 1/27/38). The principal frothing compound in these oils is TERPINEOL, a hydroaromatic alcohol. There are minor amounts of FENCHYL ALCOHOL and BORNEOL. Hydrocarbons of the terpene class comprise the remaining 30 to 40%. Abnormally low specific gravities indicate adulteration with petroleum fractions; such adulteration may be determined by a polymerization test (Allen, *Commercial Organic Analysis*, Blakiston, N. Y.).

The hydroaromatic alcohols are extremely effective in emulsifying the hydrocarbons, so that with even gentle agitation the oil forms a very fine emulsion, much of the alcohol content is extracted by the water, the alcohol remaining in the undissolved hydrocarbon renders it highly surface active, so that extremely small quantities are effective (0.05 to 0.1 lb. per ton of ore), and the froth has no oily characteristics even when very deep bubble columns are carried. Ray (*U. S. pat. 2,286,374*) described emulsions of a blend of pine oil and hydrocarbons of the naphtha range together with an emulsifying agent; he named sulphonated pinene-cresol or phenol condensate, sulphated dehydroabietyl alcohol, sulphonated higher fatty-acid esters, *e.g.*, sulphonated castor oil, or the mixture resulting from heating together an ethanolamine and a vegetable oil. Such mixtures are highly surface active and yield more, and more definite, oil-water selecting interface in bubble columns (Art. 19) than is obtainable with an equal amount of pine oil.

Other steam-distilled pine oils are derived from pine needles (PINE-NEEDLE OIL), from fresh pine wood with bark on, and from pine gum (TURPENTINES).

Flotal is a synthetic mixture of alcohols and terpene-type hydrocarbons with frothing properties similar to those of pine oil. TAROLS are mixtures of steam-distilled pine oil with rosin oil. Creosote-pine oil mixtures are often used as frothers; the coal-tar creosotes stiffen froth slightly, the wood creosotes make froths that are tough and hard to clean, and tend also to carry up much middling.

Destructively distilled pine oils are obtained by redistillation of the overhead (CREOSOTES) and tars obtained in destructive distillation of live pine wood. Specific gravities and viscosities of the fractions depend upon the boiling range. Low-temperature cuts have low specific gravities (0.91 to 0.95) and low specific viscosities (@ 1.5 at 70° F.) while the corresponding values for high-temperature cuts are 0.95 to 1.04 and 3.5 to 5.0 at 185° F. Long-range cuts have lower viscosities and somewhat lower specific gravities, of course.

Destructively distilled pine oils contain aromatic hydroxy compounds and carboxylic acids in addition to alcohols. The percentage of insoluble hydrocarbons is higher than in the steam-distilled oils, and the high viscosity of these hydrocarbons makes dispersion difficult. As a result, more oil must be used to effect frothing and there is more oil in the froth. This tends to make the froth tough and the concentrate hard to clean. These oils are useful, however, in small quantities, in conjunction with more active oils, to prevent excessive froth breakage and SHOWERING (dropping of mineral from froth) when machines are being run with a restricted air supply.

Eucalyptus oil is similar in composition and frothing characteristics to steam-distilled pine oil, differing principally in that the predominating alcohol is CINEOL, which has the

same composition as, but a somewhat different structure than, TERPINEOL. It was much used in Australia in the early days of flotation in place of pine oil, on account of local availability, and is still used to some extent.

Cresylic acid ($CH_3 \cdot C_6H_4 \cdot OH$), also called CRESOL, is obtained from coal tar by distillation of the crude tar to obtain a light fraction (COAL-TAR CREOSOTE), extraction of the creosote with aqueous alkali, acidification of the aqueous extract to precipitate the mixed tar acids (homologs of phenol), and fractional distillation of the mixed acids. Crude cresylic acid, which is the usual plant reagent, normally contains considerable neutral hydrocarbon as well as some phenol and a considerable proportion of higher homologs (toluol and xylol), in which hydrocarbons are substituted on the benzene ring.

High-grade cresylic acid forms a relatively fragile froth that is easy to clean, but which tends to shower unless used with a powerful collector (one giving a high contact angle). Crude acid is a more powerful frother, if the impurities are largely toluol and xylol (indicated by higher distillation end point and low insoluble content); if the impurity is largely phenol, however, the frothing ability of the crude is lower than that of the refined acid. Insoluble oil content in the crude adds stiffness to the froth but tends to lower the grade of concentrate.

Refined acid is normally added in amounts ranging from 0.05 to 0.15 lb. per ton of ore.

Christman (*U. S. pat. 2,250,190*) asserts that isobutyl or isopropyl alkylated phenols are superior to cresol as frothers. Landolt *et al.* (*129 J 351*) state, on the other hand, that normal substituents are superior to *iso*. They also report that metacresol is superior to the other isomers, and that a refined acid containing a high percentage of this isomer is desirable.

Soaps. The soaps of the alkali metals are vigorous but otherwise highly unsatisfactory frothers. Their froths have but little carrying power, tend to load with slime, and in the presence of excess of alkali-carried hydroxyl become over voluminous and almost completely solid-exclusive. (See ***Overfrothing***, Art. 12.) Earth-metal soaps are too insoluble to froth, hence water in which soaps are depended upon for frothing must be soft.

Solution of Ca or Mg soap in gas oil is described as a froth modifier (*U. S. pat. 2,208,143*). This is essentially a thinned cup grease. It has definite but sluggish surface-active capacity, which is enhanced by the presence of an active frother. It should aid collection somewhat in bubble-column machines and to that extent load down and stiffen froth.

Ammoniated talloel (AC 712) is recommended for making tough froths to aid in pulling middling when recovery is more important than grade of concentrate. It is an inflammable liquid. It should be added as a dilute aqueous solution (5 to 10%) which should be freshly prepared daily.

Aerofloats. The liquid Aerofloats (Art. 4) contain considerable residual cresylic acid, and to that extent are frothing agents.

Aliphatic alcohols of carbon content ranging from C_7 to C_{10} are powerful frothers. They are marketed under the names DUPONT ALCOHOLS, AMERICAN CYANAMID FROTHING AGENTS, NINOLS, with numbers indicative of compositions.

The DuPont series are the higher-boiling by-product fractions of the residue from the manufacture of butyl alcohols. They are identified by number as follows:

B-22: approximately 60 to 65% primary alcohols, principally 2-methyl pentanol-1; 15 to 20% secondary alcohols, principally di-isopropyl carbinol; 18 to 20% ketones, principally 2-4 dimethyl hexanone-3; 2% unidentified esters. Approximate average molecular weight, 105. Boiling range, 271 to 302° F. Specific gravity, 0.836.

B-22H is an upper shorter-range fraction of B-22 with an approximate boiling range of 284 to 302° F.; sp. gr., 0.838.

B-23: approximately 40 to 45% primary alcohols, principally 2-4 dimethyl pentanol-1; 40 to 50% secondary alcohols, principally 2-4 dimethyl hexanol-3; 8 to 12% unidentified ketones. Approx. aver. mol. wt., 123; sp. gr., 0.844; boiling range, 302 to 320° F.

B-24: approximately 43 to 47% of a mixture of primary alcohols, principally 4-methyl hexanol-1, 2-4 dimethyl hexanol-1, and 4-methyl heptanol-1; 32 to 36% secondary alcohols; 17 to 19% ketones, and 1 to 4% esters, all unidentified.

B-25 is the final residue above 382° F. from the above distillation. End point before tar is about 600° F.; sp. gr., 0.89 to 0.93. Less than 1% water soluble. When vacuum distilled the overhead product (**B-30**) is approximately 65 to 70% primary alcohols; 12 to 17% ketones; 10 to 15% phenols, principally mesitol with some 2–6 xylenol; and 2 to 6% of hydrocarbons.

B-21 is the unfractionated mixture of the above, comprising about 40% B-22, 20% B-23, 22% B-24, and 18% B-25; sp. gr., 0.86.

Amyl Alcohols is the fraction of the aforementioned by-product residue boiling between 250 and 271° F. The approximate composition is 60% 2-methyl butanol-1, 35% 2-methyl pentanol-3, and 2 to 3% ketones.

Use. Of the above alcohols, B-22, B-22H, and B-23 are used alone, the frothing power increasing generally with the molecular weight. B-24 and B-25 are not active frothers alone, but are used to add stiffness. B-21 and the Amyl Alcohols are not in commercial use (*PC, 3/20/41*) but have utility where

a fragile froth is desirable. It is reported (*21 #13 MJA 7*) that high lime causes the alcohol froths to become brittle and evanescent.

American Cyanamid Co. numbered frothers (*U. S. pat. 2,065,053*) are blends of the DuPont alcohols as follows:

AC-52 is a mixture of B-23, No. 2 domestic fuel oil, and pine oil.
AC-60 is a mixture of B-23 and No. 2 fuel oil.

Carbitols are lower alkyl ethers of diethylene glycol, $R\cdot O(CH_2)\cdot O(CH_2)\cdot OH$.

Terpineol has been used to a considerable extent in laboratory testing because, in addition to being a powerful frother, it can be completely dissolved in water and the concentration in small machines be thus controlled, and it has no collecting properties. Hence any concentration effected without added collector can be credited to contamination present in the ore, and the effects of added collectors can be segregated.

Organic sulphates and sulphonates in bewildering variety—so far as name and detailed constitution are concerned—have been put on the market under the general classification of wetting and detergent agents. For data as to makers, trade uses, trade names, and approximate chemical nature see *31 IEC 66*, *33 IEC 16*, and *35 IEC 107*. Those of them that are satisfactory frothers comprise, in simplest form, inorganic acid esters of long-chain aliphatic alcohols and the alkali and earth-metal salts thereof, RSO_4H(or M) and RSO_3H (or M). The long-chain R may also be linked to the sulphate through the residue of a polyhydric alcohol, *e.g.*, a glycol, by partial esterification of the latter with a fatty acid and then esterifying further with sulphuric acid, yielding a product of the form

$$\mathrm{R\cdot COO}\overset{\mathrm{H}}{\underset{\mathrm{H}}{\mathrm{C}}}-\overset{\mathrm{H}}{\underset{\mathrm{H}}{\mathrm{C}}}-\mathrm{OSO_3H(or\ M)}.$$

When R is C_8 to C_{12}, these reagents are relatively unaffected by dissolved salts. When $R > C_{12}$ the reagents are asserted to be collectors (see Art. 4).

These reagents are reported (*RI 3333*) to froth excesssively in pulps of high alkalinity. Lauryl sulphate has been used at CLIMAX (*PC*) in the attempt to obtain a less tough froth than that obtained with pine oil plus a hydrocarbon collector.

Quaternary ammonium compounds are reported to be vigorous frothers (*RI 3333; PF*).

Choice of frothing agent. Of the two common frothing agents in sulphide work, pine oil is chosen when a fragile, brittle froth is required and cresylic acid when a tougher but still comparatively active froth is wanted. If a tough froth capable of carrying a heavy mineral load without showering is desired, the further addition of a small amount of a coal-tar creosote is indicated; wood-tar creosote tends to make the froth so tough that the insoluble content of concentrate is unduly high and the froth tends to build up in the concentrate thickeners.

In soap flotation the use of a minimum of excess soap and a separate frother is desirable so that collection and frothing may be controlled independently. Either pine oil or cresylic acid may be used, but the wetting agents and the C_6 to C_{10} alcohol mixtures apparently give somewhat better control.

Effect of conditioning agents. Good frothers are all nonionizing substances. When, however, they are of such nature that they form ionizable compounds with a conditioning agent, *e.g.*, phenols with strong alkalis or amines with strong acids, the ionized products are substantially nonfrothing, and in so far as such ionization occurs, the frothing effect of a given quantity of frother is decreased.

Control of frothing. The necessity for control increases with the delicacy of the separation. In one-mineral separation of sulphide from rocky gangue, control is relatively unimportant so far as ordinary operations are concerned. In ordinary differential sulphide work somewhat more care is necessary, but even here, if the neutral-oil content of the ore is low, considerable variation in frother-ore ratio can be absorbed through the action of the cleaner circuits, and the operator need only guard against loss of bubble column and runaways in the cleaner. These easy conditions flow from the sharp differentiating powers of the sulphydrate collectors as between sulphide and gangue minerals, and the great capacity of the depressant conditioners in preventing formation of hydrocarbonlike coatings on unwanted sulphides. As a result, such ores are readily floated in machines that permit little or no control of aeration; sufficient control is readily effected by relatively gross changes in quantity of frothing agent added.

When, however, the separation is delicate, as when very high grade sulphide concentrates are wanted in differential work, or as is almost invariably the case in nonmetallic work, whether high-grade concentrate is demanded or not, close control of frothing is

essential, and all available means should be provided to secure it. Usual means are: (*a*) use of flotation machines that permit regulation of the air going to the bubble column; (*b*) use of frothing agents of low viscosity and low insoluble-oil content, preferably not too powerful; (*c*) use of feeders that permit rapid and close regulation of delivery rate; (*d*) close control of ore-feed rate with prompt warning to the flotation operator of changes. In nonmetallic work these are usually preceded by more or less complete desliming of feed, and are often supplemented by the use of so-called FROTH MODIFIERS, which may be neutral oils that blanket the froth, or inorganic reagents, the mechanism of action of which is substantially unknown, but probably is different with different reagents and/or different crudes.

There are several reasons for frothing difficulties in nonmetallic work. (1) The collector is itself a frother, so that any change in quantity thereof made in response to collection demands has an effect also on frothing. (2) All of the minerals in the crude respond in some degree to the collector, and the extent of such response is dependent not only upon the mineral but upon the *p*H at which flotation is carried out (see Fig. 2; a similar condition prevails with amine-type collectors). (3) Slimes, both valuable-mineral and gangue, are readily held at the oil-water interfaces in the bubble columns, and have a remarkable stabilizing effect on the froth. They also, because of the small effect of gravity on them, tend to adhere to bubbles while larger particles of mineral are shaken off, with the result that they appropriate much of the oil. If enough oil and, necessarily, additional soluble collector are added to bring up granular material, the volume of froth becomes so great that the cell runs away, while if air supply to the column is held down to prevent the runaway, levitation is insufficient to impoverish the tailing.

FLOTATION MACHINES AND PROCESSES

Flotation machines are customarily classified on a basis which is a hodge-podge of inventor's names, litigation catch words, and sales-department slogans. As a result their fundamental mechanisms and their real similarities and differences have been widely overlooked.

A flotation machine is an apparatus to carry out a flotation process. Legally there are many of these. Scientifically the operation called flotation is separation of unlike particles at an interface between two contacting fluid phases, one of which, at least, must be liquid. The separation is effected because of the fact that one class of particles clings to the interface and the other does not. The functions of the flotation machine are (1) to produce the separating interface; (2) to bring the particles to be separated and the interface together; and (3) to lead selected and rejected particles out of the machine by different paths. The kind of interface employed and the way in which the machine performs its three functions characterize it. A classification of known types of flotation operations is shown in Table 8.

Interfaces are liquid-liquid or gas-liquid. In all ore-flotation practice the suspending medium, which forms one side of the separating interface, is a substantially saturated aqueous solution of the ore minerals; the other phase is either an organic liquid immiscible therewith, or a gas, usually air. The suspending liquid may, however, be an organic liquid, and the gas may be any gas which is substantially immiscible with the suspending liquid.

The interface may be either internal or external with respect to the suspending phase at the time of selection. If it is internal, the process is of PULP-BODY TYPE; if at the boundary, of BOUNDARY TYPE; if wholly external, of BUBBLE-COLUMN TYPE. Boundary-type interfaces are utilized only in nonfrothing processes and bubble-column interfaces only in frothing, but internal interfaces are produced and used in both.

Creation of interfaces is effected in a variety of ways. Boundary interfaces are incidental to the flow of pulp through the machine. Bubble-column interface is created by causing air in the form of small bubbles to rise through a liquid so modified as to surface characteristics (see Art. 12) that the bubbles persist on reaching the surface, and then confining the bubbles laterally above the liquid and maintaining continuous supply of new bubbles to the under side of the mass. Internal interface is created either by agitation of a mixture of the two phases, by forced introduction of one into the other, or by precipitation of one from solution in the other.

Extent of selecting interface is important from the standpoint of speed and completeness of selection, both of these increasing with increase in extent, all other things being equal. Extent is directly proportional to the degree of subdivision of the second (non-transporting) phase; it is small with boundary-type interfaces but relatively large when

pulp-body or bubble-column interfaces are employed. It is invariably increased by increasing agitation and, with mat-type pneumatic cells, by using finely porous mats.

Bringing particles to the separating interface, or the converse, is the step in which the most fundamental differences in flotation-machine operation occur. Excluding the captive-bubble procedure (Sec. 19, Art. 22) and the thick-pulp conditioning step in table flotation (Art. 30), no procedure has yet been devised to effect contact between an air bubble and a collector-coated solid particle in the interior of the suspending phase (pulp body). Hence there are no entries under "Contact" in the liquid-gas block corresponding to an internal separating interface in Table 8. Such contact is possible only when the bubble can be mechanically pressed against the collector-coated surface, as in the captive-bubble machine or in the highly viscous heavy pulp in the table-flotation conditioners. Particles do make contact with oil droplets (which are of tremendously greater weight and momenta than air bubbles) in liquid-liquid pulps, and adhere, if the conditions are such that the oil has collecting properties (Art. 3). Air bubbles are brought to and attached to collector-coated particles in the pulp body only when preferential precipitation occurs (Art. 11). Particles and bubbles adhere by contact in bubble-column machines, where the solid in the bubble walls is constrained to flow in narrow channels directly contiguous to the selecting interfaces. In skin flotation the particles are brought to the gas-liquid interface mechanically.

Certain liquid-gas machines bring into play both contact and precipitation selection and hence appear under both "Internal" and "External" columns in Table 8. Of the known frothing machines which do this, selection by precipitation predominates in the agitation-cascade type, whole bubble-column action prevails in the others. These facts are indicated in the table by typographical differences.

Separation of rejected from selected particles takes place solely by differential gravitational settling in all frothing machines. In the nonfrothing machines, it is the sole factor in some, but in others an extraneous force is applied to move one or the other of the products to its discharge port.

SELECTION AT LIQUID-LIQUID INTERFACES

These apparatus (Table 8) represent early attempts to apply the discovery that the metallic minerals in a pulverized ore cling preferentially to an oil-water interface. The majority of the methods proposed were of the pulp-body selection gravity-separation type, in which the particles of pulverized ore, suspended in the water phase, were splashed internally against the oil-water interface and the specific weights of the resultant oil-solid systems were depended upon to cause rise or fall thereof in the impoverished aqueous pulp, while the gangue minerals were caused to take the opposite path.

14. BULK-OIL FLOTATION

In processes of this type the oil used was a crude petroleum of low specific gravity, contaminated with a fatty acid, and in some processes thickened to cause it to hang together in relatively large masses. The selecting action is illustrated by Fig. 9. The contact angle of collector-carrying oil against a metalliferous mineral surface is ordinarily of the order of 160° while that against a siliceous particle is zero. Hence at an interface *AB* a siliceous particle *G* tends to remain wetted by water and to be rejected, but a metalliferous particle *S* tends to pass into the oil owing to the creep thereof over its surface and the apparent pull incident upon the outward curvature of the oil (see Art. 11).

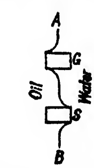

FIG. 9. Selection at oil-water interface.

Flotation occurs when the specific weight of the system composed of selected solid and oil is less than that of the pulp. The amount of oil theoretically necessary depends, therefore, on the specific gravities of the oil and pulp and the quantity of solid to be lifted. Practically such calculation is not valid, since some gangue is raised, some mineral is lost, and air entrained in mixing aids levitation markedly. The net result is that much less than the theoretical quantity of oil is necessary.

Elmore bulk-oil process (*U. S. pats. 653,340; 676,679* and *689,070*/1901; *692,643*/1902) was the best known of the oil-flotation processes proposed. It actually had mill trials. The operation consisted in first producing a freely flowing pulp by mixing pulverised ore with water in the proportions of 6 to 10 of water to 1 of ore, by weight; adding thereto a relatively large quantity of oil, up to more than a ton of oil per ton of solids, the oil being of Bunker C character with a small amount of fatty acid added; adding also sulphuric acid; mixing the ingredients in a trough provided with stirring blades on a horizontal shaft; then passing the mixture to a spitzkasten. The pulp level in the spitzkasten was kept at such a height that a slight overflow of pulp liquor was maintained. Under these circumstances the oil layer on the surface of the pulp was about one-half inch or less in thickness. The mixing was limited in violence so as not to break the oil into minute globules. Oil was recovered from concentrate by washing with solvents, filtration, centrifugation, etc. The actual oil loss is said to have been between 10 and 20 lb. per ton of ore treated. Feed must be deslimed.

For other patented methods of bulk-oil operation see *Ed. 1,787*.

Buoyant solid, such as sawdust, was added to oil to increase its lifting capacity. With this addition the oil could be broken into smaller masses, and a given weight of oil thus broken had greater selecting surface.

15. GRANULATION

This term describes a phenomenon that may be observed when finely crushed minerals, properly collector-coated, are stirred together with a relatively large amount of oil in the presence of water. Under such circumstances the minerals form with the oil a coherent mass or masses the consistency of which depends upon the kind of oil, the relative qualities of oil and mineral, and the character of the stirring. Minerals not collector-coated do not similarly granulate, hence if these are present, separation may be effected after granulation by screening or by ordinary gravity-concentration methods. Early uses and attempted uses of the method are described in *Ed. 1,944*. The only commercial use was in application to coal slurries where the large amount of oil used, amounting to upward of 50 lb. per ton of dry feed, was available as fuel in the resulting granules.

Mechanism of granulation comprises successively (*a*) selective collector-coating of the mineral to be separated, (*b*) bubble attachment by violent agitation (see Art. 19), (*c*) overoiling of the bubbles with

a neutral oil modified by a surface-active agent, as a result of which the levitated particles pass into the oil-water interface, (*d*) release of the bubbles, when the mineral-loaded oil sheath becomes heavy enough; and finally (*e*) rolling up the irregular oil-mineral agglomerates into rounded granules by slow rotary agitation.

16. MUREX PROCESS

The Murex process is a combination of magnetic separation (Sec. 13) with the differential-oiling phenomenon that is utilized in flotation processes. It is applicable to the separation of any minerals that can be selectively collector-coated. In the Murex process the oil is first loaded with powdered magnetite, then mixed with the aqueous pulp and the whole is presented in a thin film under the poles of a magnet, when the oil-coated minerals are attracted to the magnet because of the magnetite in the oily coating, while the noncoated gangue particles pass on. One oil mixture that has been used was composed of fuel oil, tar, and resin. This had the power to hold the magnetite as well as to coat sulphides preferentially.

At CLAUSTHAL (*100 J 429*) 3- to 4-mm. material was ground in a pebble mill in a thin pulp with the above oil mixture to effect coating, the product passed through a screen with 2×4-mm. openings, then spread out on a shaking table under an overhanging magnet. Galena was thus separated from barite and siliceous gangue minerals. At DARWIN LEAD & SILVER MINES (*104 J 58*) a 50-ton mill treated a partly oxidized lead-silver ore. A recovery of 80 to 85% of the mineral content was claimed at a cost of $1.78 per ton. Oil consumption was 15 lb. petroleum residuum and 0.8 lb. oleic acid; magnetite, 17 lb. per ton. See also flowsheet of MAWCHI MINES, Sec. 2, Fig. 157.

17. GREASED-SURFACE CONCENTRATORS

The usual apparatus comprises a solid surface, *e.g.*, a shaking table, moving belt or fabric, an inclined trough or the like, coated with a thickened oil (grease) or wax, over which an aqueous pulp is flowed. One class of minerals, which must be collector-coated or become so on contact with the surface, adheres while noncoated particles pass on.

These apparatus apply the same principles of selective wetting and mechanical holding by an anchored liquid that are utilized in amalgamation (Sec. 14, Art. 6). The chemical principle is that of selective collector-coating followed, usually immediately, by adhesion or spreading thereover of viscous oily liquid.

Use. Various patented methods are described in *Ed. 1, 944*. The only instance of commercial use is in diamond milling (Sec. 3, Art. 12). A recent laboratory attempt at treatment of coarse particles (*153 A 557*) consists of a cone with greased inner surface, loading selectively below water line and discharging into a launder above.

SELECTION AT LIQUID-GAS INTERFACES

All commercially successful flotation apparatus have utilized the liquid-gas interface for selection, and with one exception (skin flotation) bubbles have been used for levitation and gravity for separation.

18. SKIN FLOTATION

This is the term used to describe separation at the free boundary of a liquid. In ore flotation the liquid is water and the selecting surface is the upper boundary against the atmosphere. The force system employed to select and carry the selected material is air-water interfacial tension, and is the same as that employed in suspending the floating needle in the familiar parlor trick (Art. 11). In commercial application the feed should be deslimed, conditioned, and then brought gently to an air-water interface.

The process was developed to bring feed to the selecting surface either from above (TOP-FEED) or from the pulp (SUBMERGED-FEED). In the former case rejected material sinks through the underlying water and is removed by gravity, but with submerged feed the rejected material is moved away mechanically.

Wood top-feed film-flotation machine (*U. S. pat. 1,088,050*/1914) is typical of dry-feed apparatus (Fig. 10). It consists of two tanks *A* and *P*, filled with water. A roller *C*, covered with corrugated rubber belting and submerged with its center well below the surface of water in the tank *A*, rotates in the direction indicated. As the roller emerges from the body of liquid, it carries with it, covering its upper surface, a thin layer of water. Dry ore is fed onto the surface of the revolving roller, in a thin sheet, by means of the shaking feeder *G*; the gangue minerals tend to wet and sink into the grooves, while the minerals of metallic luster tend to float. When the floating and submerged minerals are carried over to the point where the surface of liquid in the tank intersects the surface of the roller, the floating mineral rides out onto the water surface because the surface film is continuous over the tank

and the roller. The gangue minerals remain submerged and finally fall off and settle to the bottom of the tank. At the opposite side of tank A is another roller I. An endless rubber belt K passes over this roller, thence in turn over pulley R and guide roller M. A gentle current is maintained from C toward I by reason of the constant addition to the surface film at C and constant removal at I by the traveling belt K. The surface film is continuous from the liquid in tank A to the liquid in tank P over the surface of belt K. Owing to the disturbance at the point where belt R passes below the surface of the liquid in the tank P, the less tightly held material in the film is shaken out and settles to the bottom of tank P. This material constitutes the middling of the process and is re-treated on gravity-concentration apparatus. Tailing is discharged through valve B. Floating concentrate overflows lip W, the level of liquid in tank P being maintained so as to overflow a thin sheet of liquid at this point.

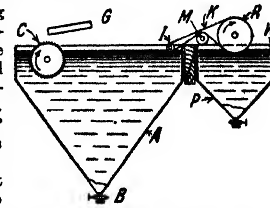

FIG. 10. Wood skin-flotation machine.

The machine as built had a feed roller 3 ft. wide, required about 0.25 hp., and is said (*44 A 684*) to have had a capacity of 1,000 to 2,000 lb. per hr.

Dry-feed machines, usually of crude form, have had considerable use in the small graphite mills in the eastern and southern U. S. No conditioning has been practiced, the accidental contamination incident to mining and crushing being sufficient to oil-coat the graphite particles.

DeBavay film-flotation process (*U. S. pats. 864,597*/1907; *912,783*/1909) was used in Australia. Tailing from gravity concentration, crushed to pass about 40-m., was first deslimed, then fed into a mixing tank and agitated for a considerable time with cold sulphuric acid solution, about 0.2% strength, in a pulp containing 15 to 20% solids, the acid solution was decanted, the settled solid washed twice with fresh water, then thoroughly agitated with water containing about 0.02% chlorine and from 2 to 3 lb. per ton of ore of a mixture of 1 part of castor oil and 4 parts of low-grade kerosene. The oiled pulp was elevated by a monte-jus onto a series of separating cones of the type shown in Fig. 11. Concentrate floated from A to B, gangue sank and discharged through D. The floating material was principally froth.

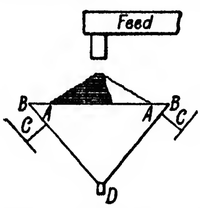

FIG. 11. DeBavay separating cone.

Macquisten film-flotation machine (*U. S. pats. 865,194; 865,195; 865,260*/1907) comprised (Fig. 12) a rotating rifled tube b, 1×6-ft., set horizontally, with central opening at the inlet end and full opening at the discharge end into a pointed box d with overflow lip. Water level was maintained in box and tube about 3 in. above the bottom of the tube so that a film of water about $1/_{32}$ in. deep overflowed the discharge lip. Liquid pulp was introduced through the feed trough a. The tube made 30 r.p.m. The solids in the pulp were thus raised above the surface of pulp in the tube, water drained away, most rapidly and completely from particles of metallic luster, and, as the material slid back, the minerals of metallic luster floated in part, while the gangue minerals submerged. This operation was repeated many times as the pulp passed through the machine. Slime tends, in large part, to pass through in suspension and thus gets no chance to separate. A gentle surface current (about 10 ft. per min.) was maintained from feed to discharge end. When the submerged solids reached the tank they sank and were withdrawn as tailing. Floating concentrate passed over the lip. Tailing was re-treated in another tube.

At the MORNING MILL (*43 A 692*) 175 to 200 lb. of zinc concentrate assaying 48% zinc was floated per tube per 24 hr., representing a recovery as high as 85%. Three tons of solid per 24 hr. was passed through four tubes in series. The feed sized about 9% >40-m. and 11% <200-m. The feed pulp carried from 14 to 20% solids and was deslimed.

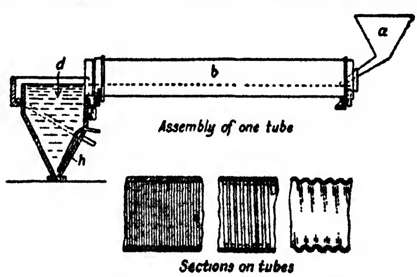

FIG. 12. Macquisten skin-flotation machine.

Size of particles that can be supported at lightly contaminated water surfaces is relatively enormous, as may be seen from Table 9.

Table 9. Flotation of dry, oiled sulphides at clean water surface (*CU*)

Mineral	Sp. gr.	Percentages of different sizes floating a (mm.)				
		3.3~2	2.4~1.6	1.6~1.2	1.2~0.83	0.83~0.59
Galena........	7.5	....	....	6	77 to 85	100
Chalcocite.....	5.7	2	14	72 to 80	100	....
Sphalerite.....	4.0	3	42	80 to 92	100	....

a Mineral was oiled with oleic acid, applied in benzol solution, from which the benzol evaporated, leaving oleic acid as a film coating on the solid; particles were slid onto the surface from the dome of an inverted watch glass with one edge submerged.

Use. Skin flotation of ores is not practiced commercially at present (1943) except in a few small graphite mills, as previously mentioned, and as an incidental minor phenomenon in table flotation (Art. 30). A variety of methods is described in *Ed. 1, 783.*

FROTH FLOTATION

Froth flotation comprises two entirely different types of processes which resemble each other only in the fact that in both the concentrate is removed in the form of a froth or foam composed of gas, liquid, and a solid which is preponderantly one of the minerals or classes of minerals in the feed. In the early days the mineral that was floated had metallic luster, but greater knowledge of controlling conditions has now made it possible to float any kind of mineral. The processes differ fundamentally both in the place in which selection is effected and in the mechanism of selection itself. On the basis of the first difference the processes are classified as pulp-body type or as bubble-column type. On the basis of mechanism they are of contact type or precipitation type (see Table 8).

19. MECHANISM OF FROTH FLOTATION

Coursing-bubble slogan. In the early days of practice of froth flotation a plausible assertion was made to the effect that selection occurred at the surfaces of air bubbles coursing through the pulp, striking here a gangue particle, there a collector-coated particle, rejecting the former and adhering to the latter, and finally rising to the pulp surface, armored with selected solid, and gathering there to form a mineral-bearing froth. This idea, conceived in ignorance and born in litigation, was fostered by selfish interest and, unfortunately, was copied into some textbooks. It never had any technical utility, since design and operation based on its teachings are completely uncertain and inefficient. It was worth many thousands of dollars to its proponents as a slogan of litigation. It is slowly dying now that its commercial utility is over.

Error in the coursing bubble idea is made apparent by a few simple experiments and considerations. If a bubble is anchored in a conditioned pulp, deslimed to promote visibility, and the pulp is agitated so as to shower a stream of particles against the bubble, only an occasional collector-coated particle striking it adheres, and complete armoring of the bubble never occurs (*Ed. 1, 798*). The degree of adherence is greater the less vigorous the agitation. Yet when the same pulp is agitated violently, heavily armored bubbles form (see Art. 11).

If a pulp, properly conditioned for agitation-froth operation, is placed in an agitation-froth machine (Art. 27) and the agitator is run at low speed, finely divided air bubbles being introduced at the same time, so that the pulp is impregnated with small coursing bubbles, no effective froth is formed. Yet from the preceding experiment this is the agitation condition most favorable to effectuation of particle-bubble cling in an agitated pulp. Here again violent agitation will produce a good mineral-bearing froth. If, further, a barometric leg of clear water, held in an inverted burette, is placed with open end in a body of bubble-swept pulp in an operating pneumatic cell (Art. 20), some of the bubbles from the pulp enter the water column and rise therethrough above the level of the top of the bubble column in the cell. Here they can be observed to be substantially free of solid load, and such load as they carry is predominantly gangue slime. Finally, flotation recoveries can be made from pulps conditioned in such a way that if captive-bubble tests (Sec. 19, Art. 22) are made on particles of the mineral floated, after similar conditioning, considerable pressure and an induction period of many seconds are needed to effect bubble attachment.

The implication of these experiments is clear. It is not sufficient for the degree of bubble attachment necessary for effective flotation simply to cause bubbles to course around through a conditioned pulp. Such procedure cannot either impose the necessary pressure between bubble and particle to effect attachment nor can it maintain contact for the requisite induction period. The contact-angle tests prove that bubble-particle attachment can be effected by contact within the pulp body, but the other tests just as unmistakably prove that such attachment is not effected in operating machines.

Pulp-body froth flotation effects selection in the body of a conditioned pulp by causing gas bubbles to precipitate from solution in the liquid phase preferentially at the surfaces of collector-coated particles, and to cling to these particles. The particle surface thereupon becomes a part of the bubble surface, in contact with the air therein, and surrounded in the surface by the suspending liquid. Coalescence of such loaded bubbles, which observation of water containing operating quantities of frothing agent shows to occur rapidly and frequently, results in increased surface loading of the resultant bubble, due to surface-volume relationships. Thus armored bubbles and heavy laden bubble-mineral aggregates build up quickly. These are characteristic of this type of flotation. They are readily observable in operating machines having transparent walls. They can be caught and observed in the water-filled barometric leg described earlier in this article.

Precipitation contact is induced by HEATING, by CHEMICAL REACTION, and by PRESSURE REDUCTION, in fact by each and all of the known means of producing evolution of gas from a liquid.

Experimental verification of selective precipitation is simple. If particles collector-coated and the reverse (the kind of particle is unimportant) are placed in clean water in petri dishes and these are respectively heated, placed under a vacuum, or subjected to gas evolution by chemical means (*e.g.*, attacking $CaCO_3$ with H_2SO_4), bubbles precipitate selectively on the coated particles and adhere to them. Observation of the precipitation with a low-power glass, preferably of binocular type, makes it apparent that the attached bubbles were not migrating bubbles elsewhere formed, but that they formed in place. If a collector-coated particle is pushed or shaken into contact with a bubble held on another particle, adherence usually occurs, and, depending upon relative sizes of bubble and particle, the beginning of an armored bubble or of a heavy agglomerate is formed.

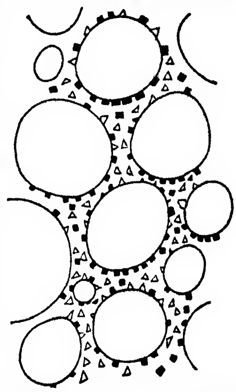

FIG. 13. Concentrating action in a bubble column.

Bubble-column flotation effects selection by gravitational contact presentation of pulp particles to the upper surfaces of a mass of rising bubbles (a BUBBLE COLUMN) which rests on a relatively quiet mass of pulp through which bubbles are continually rising. The bubbles rising through the body of pulp push pulp before them mechanically and lift it out of the body into the bubble column, where selection occurs.

Action in the bubble column may be seen to comprise behavior such as that diagrammed in Fig. 13. (Observation should be made through a transparent wall with a 10X glass, preferably of a pulp of dark valuable minerals and light gangue minerals, relatively coarse, say 48-m. maximum, and lightly deslimed. The observer should practice until he can distinguish individual grains readily.) All grains are falling relative to the bubble walls, streaming through the inter-bubble spaces. Both dark and light grains fall upon and slide along the upper surfaces of bubbles, but below the horizontal bubble equators only dark particles cling. Groups of dark particles collect at the lower poles of the bubbles, forming a pendent tip from which particles appear to string out and fall away. Gross observation of the column shows by color that the concentration of dark particles in the inter-bubble spaces increases from bottom to top of the column. This is readily confirmed by sampling (Fig. 14).

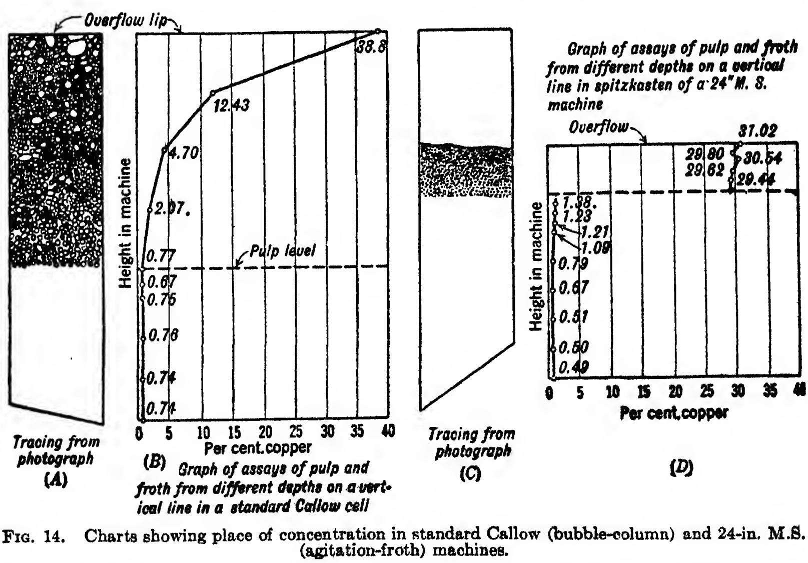

FIG. 14. Charts showing place of concentration in standard Callow (bubble-column) and 24-in. M.S. (agitation-froth) machines.

With all particles falling and the bubbles rising this change in concentration can only occur by reason of the fact that the average rising rate of bubbles lies between the average falling rates of the light and dark minerals.

Contact attachment in bubble columns is hard to understand in view of the difficulty of effecting it in a body of pulp. The conditions of presentation are little different from

those of the showered bubble described earlier in this article and do not approach the pressure and time-factor frequently necessary in contact-angle tests. All of the facts are consistent, however, with the hypothesis that the selecting surface in a bubble column is a liquid-liquid interface.

Contact angles of oil with collector-coated particles in water are about 160°, as against about 60° for air against the same surfaces. Ease and rapidity of attachment increase with increase in contact angles. Substantially all ores arriving at the flotation machines contain lubricating oils in quantities ranging from 0.05 to 0.25 lb. and upward per ton of ore, picked up in the mine and crushing plant. This oil is rendered highly surface-active by frothing agents and in such state spreads instantly at air-water interfaces. It concentrates rapidly in bubble columns because only a small part of the air-water interface entering the column as bubbles at the bottom overflows as froth, the remainder is lost by bubble coalescence in the column and bubble bursting at the top, and the oil and frothing-agent load of the lost surface is transferred to that remaining. Bubble columns do not start to operate immediately air is turned through a pulp, particularly in a cell in which pulp has not been standing. A considerable period is required to build the column up to overflow level, the period being greater with fresh water than with reclaimed, and greater with purified and with relatively soluble frothing agents such as amyl alcohol, terpineol, and pure cresylic acid than with those containing oily constituents (pine oil, commercial cresylic acid) and those of relatively low solubility, *e.g.*, the 8- to 10-carbon-atom alcohols, xylenol, etc.

Even with feeds free of oily matter other than air-borne contamination and with oil-free frothing agents, layers of saturated solutions of water-in-frothing-agent, similar to the layering of ether-water and phenol-water mixtures, apparently build up around the bubbles. This is indicated by the fact that while an unsaturated solution of water and amyl acetate is not colored by a small amount of the oil-soluble water-insoluble dye Sudan III, a bubble column formed therefrom is pink, which is the color of the dissolved dye.

Further, the ready dropping of attached mineral from bubbles in an operating bubble column, long before the push of the superincumbent load approaches that carried firmly by an armored bubble in a pulp-body-process froth, is consistent with the low surface tensions of the liquid-liquid interfaces involved (15 to 20 dynes per cm.) compared with the air-liquid tensions (60 to 65 dynes per cm.) in the same pulps (*87 A 285*). The formation of the pendent tip of mineral at the lower pole of the bubbles in an operating bubble column is never seen on bubbles carrying loads at the air-water interface, but can be simulated with captive oil droplets.

It would appear, then, that bubble-column flotation operates by and depends upon selection at liquid-liquid interfaces.

Bubble-column *vs.* pulp-body flotation. Quantitative experimental evidence of the difference between bubble-column and pulp-body flotation is presented in Fig. 14. A pneumatic bubble-column machine and the spitzkasten of a Minerals Separation standard machine were fitted with 1/8-in. sample pipes projecting inward 6 in. from the inner surface of the walls, arranged in vertical rows running from bottom to top of the respective apparatus. Simultaneous samples from all pipes were drawn from each machine, assayed, and the assays plotted against position in the machine. Plot *B* shows that bubbles on emergence into the bubble column in the pneumatic cell are carrying a load of pulp; that no concentration at the bubble surface has taken place in the pulp body. Plot *D* shows that the solid load on the bubbles emerging from the pulp in the agitation-froth process is a concentrate of substantially the grade of the finished concentrate from the cell.

The tests recorded in Fig. 14 were made in regular mill operation. In all, tests have been made in a 24-in. M.S. standard machine, a Janney mechanical machine, a standard Callow machine, two special large-size Callow machines, an Inspiration-type pneumatic machine, and a cascade machine. These tests all show that plots *B* and *D*, Fig. 14, are typical of the behavior of bubble-column and agitation-froth machines respectively. Laboratory observations, in which judgment was based on the color of the froth layers, have been made on Denver, Fagergren, and Ruth subaeration machines, a K and K machine, and a Forrester cell, all of which were of bubble-column types.

Pneumatic cell without pulp body. It logically follows from the conclusions reached in the preceding paragraph that the body of pulp in the bubble-column type of machine can be eliminated without affecting the concentration.

A cell built to eliminate the pulp body, 10 ft. long, 14 in. wide inside and 12 in. from blanket to overflow lip, with bottom horizontal (see Fig. 15), was run side by side with a regular mill cell in the MIAMI COPPER Co. plant. This shallow cell recovered the same weight of copper per square foot of blanket area that was recovered in the standard cells adjacent, and made the same grade of concentrate.

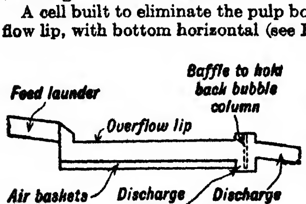

FIG. 15. Shallow pneumatic cell.

Gaudin (*F*), after analyzing the experimental evidence for and against the precipitation and contact hypotheses as applied to the agitation-froth machine, concludes for the latter on the score that fine-particle losses in this machine are much higher than coarse-particle losses, that this is explicable on account of the difficulty of effecting bubble contact with small particles but that gas precipitation should take place on them as readily as on the coarse. This is a persuasive argument. It is buttressed by the established fact that while the size at which recovery troubles start in undisputed contact processes such as the pneumatic is finer than in the agitation-froth process, the same difficulties are met therein. The argument would be stronger if it were established that the nature of the surfaces of fine valuable-mineral particles in tailing is the same as that of those in concentrate, which the available evidence contradicts. A much stronger *contra* argument would seem to be that while the other pulp-body

processes, which are undisputably of precipitation type, will not treat slimes at all, the agitation-froth process does. On the other hand, in the latter process, anything that is done to aid in the passage of gas through solution therein, such as heating the pulp or using more soluble gas than air, increases the speed of separation.

BUBBLE-COLUMN MACHINES

Bubble-column machines are practically the only ones in use in concentrating mills today (1943). They have almost completely displaced pulp-body machines over the period of 20 yr. past. They comprise a bewildering variety of forms, so different in outward appearance that their essential similarity is frequently overlooked. The three main classes are (1) pneumatic, (2) cascade, and (3) subaeration. They are characterized by the fact that all of the concentration is done in the bubble column. They use large volumes of air, of the order of 1,000 to 2,000 cu. ft. and upward per cu. ft. of solid floated. All operating machines consist of an open-top chamber through which pulp flows continuously, an external or an internal air pump, means to introduce air in the form of small bubbles at a point well below the surface of the pulp body, means to confine a bubble column above the pulp body, means to protect the bubble column from excessive shock and disturbance by the pulp, and separate ports or weirs for discharge of products.

PNEUMATIC MACHINES

Pneumatic machines are the simplest of the bubble-column types. They consist essentially of elongated open-topped boxes or deep troughs through which pulp flows from end to end and at or near the bottom of which air is introduced from an external pump or blower through pipes or some form of porous septum. The aim in air introduction is to have the bubbles that rise through the pulp under the bubble column as small and, within limits, as numerous as possible.

The first pneumatic machine to get into the mills was the sloping-bottom Callow cell (*54 A 14; Ed. 1, 809*) in which subdivision of the air supply was effected by introduction through a canvas blanket. The Inspiration cell and Miami-type cells (*Ed. 1, 810*) were large-tonnage developments of this machine. The modern Callow cell is a flat-bottomed type, and the MacIntosh is the latest form of the porous-septum machines. The majority of pneumatic machines nowadays introduce the air through down-pointing pipes that are not subject to clogging and high back pressures to the extent that occurs in the porous-bottom machines. The Forrester was the first of this type to get into the mills. Modifications involve additionally some aeration by cascade action (Art. 22) in the forms described by Welsch (*U. S. pat. 1,253,653*/1918; *Ed. 1,823*) and Dunn (*U. S. pat. 1,219,089*/1917; *Ed. 1,823*). These are known variously as the Hunt-Dunn, Southwestern, Miami, etc., types. They are collectively known as air-lift machines.

20. BLANKET-TYPE PNEUMATIC MACHINES

Callow cell (Fig. 16) consists of an open trough *a*, 2 or 3 ft. wide, 6 to 60 ft. long, and 18 to 22 in. deep, with a feed box *b* from which pulp enters through a submerged slot, a

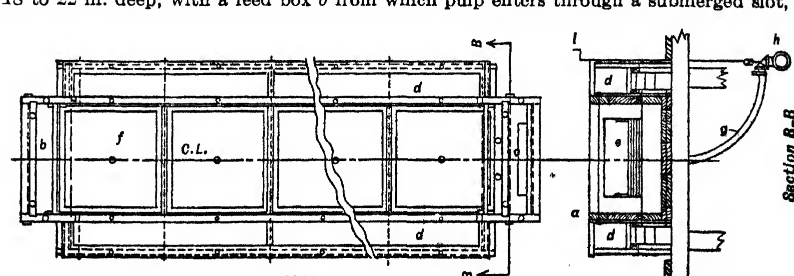

Fig. 16. Callow flat-bottom cell.

tailing-discharge box *c* into which pulp spills over an adjustable weir *e*, and froth-overflow launders *d* which slope both ways to a central discharge. Cast-iron air pans *f*, 3 ft. long by 2 or 3 ft. wide, are laid in the bottom of the trough and are supplied with air through

flexible rubber pipes *g* from a header *h* with a main supply-control valve and individual controls *i* for the separate pans.

Porous medium is canvas or rubber. For canvas covers No. 3 O.C. National Weave canvas is recommended by General Engineering Co.; this is practically a 3-ply canvas woven into one cloth. Rubber mats are pure-gum No. 2 sheeting, 5/64 or 3/32 in. thick, perforated with 0.038- or 0.045-in. punch respectively, 200 holes per sq. in. The punching makes a hole that is constricted somewhat at the center of the sheet. The holes are about 0.01-in. diameter and the blankets pass about as much air at 1-lb. pressure as canvas blankets pass at 4-lb. (*IC 6358*). The mat is bolted tightly under peripheral metal strips to the top of the air box, and is kept from bulging by longitudinal strips. The cell is made single or double, and is rated by the width and number of pans, *e.g.*, 3-ft. 8-pan, or by width and length of trough, *e.g.*, 3×24-ft. Cells longer than 8-pan are usually divided transversely by a weir as shown in Fig. 17.

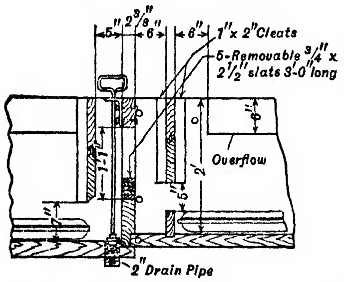

FIG. 17. Weir divider in long Callow cells.

Capacity may be calculated from the required time-factor (p. 57), allowing for a 6- to 8-in. bubble column in rougher service and 8- to 10-in. in cleaners.

Performances reported for roughers range from 0.1 to 0.8 ton per sq. ft. of blanket area per hr. AIR CONSUMPTION in roughing service ranges from about 7 to 15 cu. ft. of free air per min. per sq. ft. of blanket and averages close to 9 cu. ft.; in cleaners it is about half this. PRESSURE DROP through new wet blanket is about 1.5 lb. per sq. in. and through rubber sheet about 50 to 75% of this. Blinding by sand and slime cemented by carbonates will raise the pressure drop with blankets to as much as 3 times the initial figure; the rise with rubber is not as great. The pulp imposes additional pressure, dependent on its specific gravity and depth. POWER CONSUMPTION depends, of course, upon the blanket area per

Table 10. Recoveries in successive compartments of a four-compartment pneumatic cell at Miami Copper Co. (1921)

daily ton and the total back pressure. Production of low-pressure air in Roots-type blowers may be estimated at 155 cu. ft. of free air per min. to 1-lb. pressure per hp.; and within normal operating pressure ranges, power consumption is proportional to back pressure. These figures correspond to 0.5 to 3 hp-hr. per ton.

Most of the recovery in a pneumatic machine is effected in the first few feet. Table 10 shows results of a test on a Miami-type cell. In one test on a standard Callow cell in the Miami mill over 80% of the total recovery was made in the first 16 in. of length.

Table 11 shows assays of individual concentrates from the various compartments of a Miami-type cell. This is typical of the multi-compartment cells and also of discharges from corresponding positions along the side of the standard Callow and other trough-type machines.

Table 11. Assays of concentrate from different compartments of a 4-compartment pneumatic cell at Miami Copper Co.

Compartment No.	Assays, % Cu

4	11.01	4.30	9.35
Total	27.21	23.55	23.00

Proportions of mat-type cells have varied gradually from the original Callow, 2 × 8 ft. in plan, 18 in. deep at the head end, and a bottom slope of 3 in. per ft., through a number of forms of increasing length and gradually decreasing bottom slope, which were compartmented by transverse weirs in order to maintain a pulp level, to the final long, narrow, shallow, uncompartmented form with little or no bottom slope. This development has been accom-

panied by a progressive improvement in metallurgical results, power and maintenance costs, ease of operation, and capacity.

The latest form at RAY comprises 2 1/2×15-ft. flat-bottom units; 8 of these in series, 2 acting as roughers and 6 as scavengers, treat 2,000 tons per 24 hr. In a test against matless cells they were sufficiently superior in metallurgical performance to justify retention despite higher operating costs (*IC 6241*).

Maintenance in blanket-type cells tends to be high on account of clogging of blankets and the harshness of the methods used to relieve it. At the best these involve emptying the cell and scrubbing with a wire brush, frequently with hydrochloric acid; at the worst the blankets are pounded with the end of a 2-by-4 until, usually, it penetrates.

Life of 4-ply 18-oz. quilted blankets in normal service is 60 to 180 days. At NEVADA CONSOLIDATED (*A TP 6*) it averaged 150 days with a minimum of 2 or 3 days. At OLD DOMINION, using lime, the blankets required an acid bath every 4 days and had an average life of 16 days; by this time pressure had risen to 6 or 7 lb. per sq. in. (*IC 6792*).

Hearing cell is an air-pan cell comprising a V-shaped box averaging 42 in. wide at the top, 14 in. at the bottom, with mean depth to overflow of 36 in. Bottom slopes 1/2 in. per ft. Length is a multiple of 24-in. air pans. Cell is provided with a weir discharge.

Three @ 5-pan cells in series are used at BUNKER HILL & SULLIVAN for each cleaning circuit. Each machine takes 250 cu. ft. of air per min. at 4-lb. pressure. The lead section treats 6 tons per hr., the zinc 4 tons in pulps containing 10, 8, and 6% solids respectively in successive machines.

MacIntosh cell (Fig. 18) has the porous medium wrapped around a rotating perforated pipe *a* mounted near the bottom of a V-shaped trough. The rotor *a* constitutes an air

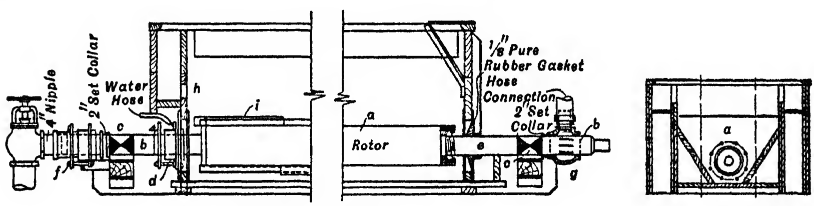

FIG. 18. MacIntosh cell.

chamber which is mounted on axial hollow shafts *b*, carried on bearings *c*. The shafts are usually carried through the feed end in a water-packed gland *d* mounted on rubber, and through the discharge end by means of a so-called gland eliminator *e*, comprising a soft-rubber gasket carried on the end wall and lapping against a cone-shaped collar on the shaft Leak through the gland eliminator, amounting to about 1 qt. per min., is routed into the tailing. The gland eliminator may be used on head end also, but then provision must be made to return leak to the feed stream, or some place of corresponding assay. Air is supplied at one or both ends, as desired; with two-end supply a transverse diaphragm is inserted in the rotor. Supply is either through a gland *f* or a rotating valve *g*. The rotor is driven at 15 to 20 r.p.m. by pulley, sprocket, or geared individual motor, as desired. Feed enters at *h* and leaves through a slot near the bottom at the opposite end, discharging into a box in which level is maintained as desired by a weir overflow. Rotors are covered with canvas socks or with perforated rubber, the materials being the same as recommended for Callow cells, *q.v.*; choice is on the same bases as for the Callow cell, except that the rubber is somewhat more difficult to mount than the canvas. Longitudinal scrapers *i* are carried at 180° and staggered lengthwise to prevent packing under the rotor.

Sizes range from 10-in. (wide) × 4-ft. tank with 4-in. rotor to 48-in. × 30-ft. tank with 2 parallel 9-in. rotors. Depth is such as to have the top of the rotor about 18 in. below the overflow lip.

AIR PRESSURE required averages about 2 lb. per sq. in. for rubber and 3 to 3.5 lb. for canvas. AIR CONSUMPTION in roughing service is from 3.5 to 7 cu. ft. of free air per min. per sq. ft. of rotor surface, or 10 to 20 cu. ft. per ft. of cell length. Power consumption per cell for air may be estimated as for Callow cells; add 0.4 to 0.5 hp. for turning the rotor. Capacity and power consumption per ton of ore must be estimated from time-factor. Bubble columns should be estimated of the same depth as in Callow cells, *q.v.* AERATION is definitely more efficient in the MacIntosh than in the Callow machine, owing to the fact that the blanket is kept substantially free of settled solid and sands are kept in suspension better, hence time-factors are lower. For rough estimating the makers state that roughing capacity ranges from 4 tons per 24 hr. per lineal ft. of rotor for a slow-floating ore to 16 tons for a fast-floating ore. At NORANDA the primary (copper-section) roughers treat 0.5 ton per ft. of length per hr. and the secondary

(pyrite) and tertiary (pyrrhotite) machines treat 0.4 ton. PERFORMANCE FIGURES range from 0.75 to 2.5 hp-hr. per ton, including roughing and cleaning. Rose and Cramer (*IC 6358*) reported that the change-over from Callow to MacIntosh cells at NACOZARI resulted in a reduction in cell power consumption from 3.75 to 0.55 kw-hr. per ton, and that 6 @ 10-ft. roughers plus 4 cleaners treated 1,000 t.p.d. McLachlan (*N. Y. meeting AIME, 1928*) reported use of a MacIntosh cell as a unit cell at NACOZARI, taking <3/8-in. primary rod-mill discharge. At VERDE CENTRAL (*IC 6489*) 3-ply blankets lasted 30 to 40 days, scrubbed every 5 days.

21. AIR-LIFT MACHINES (MATLESS CELLS)

These apparatus are so named because in the process of dispersion of air through the pulp they employ the mechanism of the air lift (Sec. 18, Art. 21), and porous media are eliminated. This principle of aeration was disclosed in a number of early flotation patents but was first built in practical form by Forrester. With his lead a number of the older names have been resurrected and applied to modifications.

Forrester cell (transverse section, Fig. 19) consists of a V-shaped trough, long in proportion to its width and depth, bottom horizontal, through which pulp to be treated is flowed from end to end. Inclined baffles *7*, spaced about 6 in. apart at the top, and vertical baffles *3*, perforated along their lower edges with round holes or slots *9*, extend from end wall to end wall. Air is introduced through 1/2- to 1-in. pipes *6* depending from header *2* to within about 6 in. of the bottom and spaced at 4- to 6-in. intervals along the length of the cell. With heavy feeds, as at BRITANNIA, 1/2-in. pipes spaced 3 in. are used in the first 20 ft. of cell. Supply for the whole cell is regulated by valve *1*, or separate regulation for sections may be arranged. Members *4* are splash boards. Feed enters through a bottom slot from a penstock at the head end, and tailing discharges over a regulable weir. Height of froth overflow is adjustable in some forms. The machine is made of either wood or steel. It may be divided by transverse partitions.

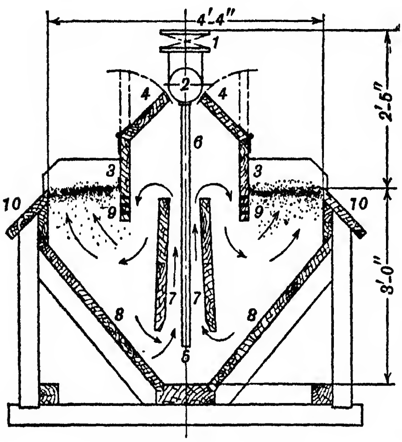

FIG. 19. Forrester cell.

Air entering the pulp at *5* rises in the space between baffles *7*, mixing with the pulp therein and lowering the bulk density of the material in this zone below that of the material outside the baffles. As a result it is displaced upward by difference in hydrostatic pressure with sufficient momentum to be thrown upward into the space between baffles *3*. It splashes back into the pulp between *7* and *3*, which is maintained at a level lower than the top of *7*.

Considerable agitation occurs in the air-lift zone (between baffles *7*), and more occurs in the splashing zone (between *7* and *9*). As a result air introduced at *5* and additional air introduced by the falling pulp masses in the splashing zone is dispersed throughout the pulp flowing away from the splashing zone and rises between *3* and the side walls, pushing up pulp to form a bubble column.

Pulp follows a path that is roughly a double spiral with horizontal axes, being circulated round and round the baffles *7* by the air-lift action and forced lengthwise of the cell by the head of the entering stream. It is thus presented many times, more or less aerated, at the bottom of the bubble column, with repeated opportunities to be carried up into the column for concentration. The effective air-swept volume of the machine is dependent upon the design and operation of the air lift and upon the depth of the baffles *3* and the area of perforations *9*. The desideratum from the standpoint of introduction of pulp into the bubble column is to decrease downward momentum of solid particles leaving the splashing zone and yet to get as much entrained air as possible from the splashing zone out under the bubble column. On the other hand the bubble column must be protected against the agitation of the splashing zone. The greater the agitation in the air-lift and splashing zones the finer is the dispersion of air and the greater the quantity carried out under the bubble column. Perforations *9* permit some aerated pulp that would otherwise become deaerated to feed more directly into the bubble column. This serves to build up a head of froth along *3* which produces a more rapid flow of froth toward overflow *10*. The elements of control are apparent from this analysis of the cell action.

Size of transverse section is normally close to that shown in Fig. 19, which has a nominal cross-section of 8 sq. ft.; length ranges from 3 to 100 ft. ROUGHING TIME is usually between 5 and 10 min. in pulps that contain 20 to 30% solids for low-sulphide ores, and 30 to 45% solids for high-sulphide ores. Contact times as high as 30 min. are reported. Southwestern Engineering Co. gives 6 to 30 tons per 24 hr. per ft. of length as a basis for estimate of ROUGHING CAPACITY. CLEANING TIMES are usually 2 to 3 times the roughing time in pulps of about half the solid content, but in differential cleaning of bulk concentrates the pulps are usually of higher solid content than in the rougher cell and the time is about the same or even shorter. MAXIMUM FEED SIZE at 20 mills reporting was a fraction on 35-m. AIR CONSUMPTION ranged from 45 c.f.m. per ft. of length for a fine-ground low-sulphide ore to 100 c.f.m. for a coarse heavy-sulphide ore and averaged about 75 c.f.m. Variation in air consumption with width is roughly plus or minus 10% per ft. of width either way from 4 ft. Consumption in cleaning cells is normally about 75% of that in roughers, but with heavy sulphides it may be 200%. At MATAHAMBRE (*IC 6544*) consumption was 43 c.f.m. per ft. of total cell length (roughers and cleaners). Power consumption may be estimated at 1 to 2 hp-hr. per ton for roughing and at 1.5 to 4 hp-hr. per ton total for 1-mineral separations; it will run up to 8 hp-hr. per ton for complicated differential treatment. The manufacturer estimates 0.6 to 1 motor hp. per ft. of length of a rougher cell 4 ft. wide, corresponding to blower efficiencies of 80 and 63% respectively, and 0.4 to 0.7 hp. per ft. for cleaners. Except in the largest mills, one attendant cares for all of the flotation. Maintenance is substantially nil. At NEVADA CONSOLIDATED (*A TP 6*) the saving in maintenance over Callow cells was 1.41¢ per ton, with a saving in power of 1.44¢ per ton (2.6 kw-hr.) due to a reduction in blower pressure from 5 1/2 lb. to 1 1/2 lb. Table 12 gives performance data on a variety of ores.

a Roughing and cleaning in single unit, after amalgamation. b Estimated.

Modifications of Forrester Machines

Hunt (or Hunt-Dunn) cell differs from the standard Forrester cell in that the air lift is carried higher relative to

the pulp level, a deflector above the lift concentrates and directs the plunging stream downward, thus increasing the cascade action, the baffle plates protecting the bubble column extend relatively deeper into the pulp, and they are not perforated.

At MUFULIRA the Hunt machine has been modified as shown in Fig. 20, by moving out the baffles protecting the bubble column to the varying extents indicated by X, thus crowding the bubble column, and

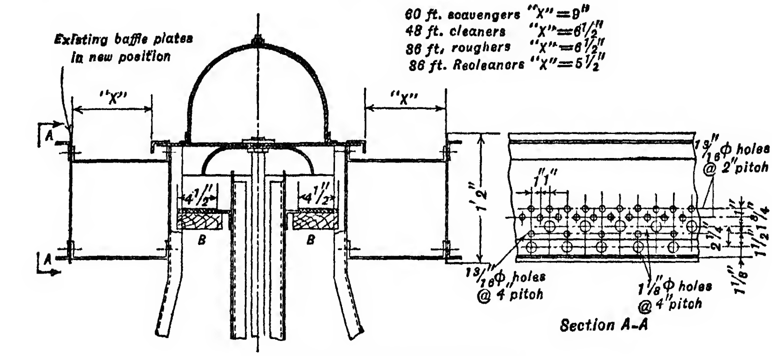

FIG. 20. Hunt cell at Mufulira.

installing splash boards *B* to divert the cascade near to the back of the baffles in their new positions. See also Sec. 2, Fig. 38.

CAPACITY of 62-ft. rougher cells at AJO (*134 A 445*) is 2,000 tons per day at 20 to 25% solids, making a 16 to 25 : 1 ratio of concentration: a 12-ft. cell cleaning this concentrate treats 80 to 125 tons per 24 hr.

Steffanson cell is a modification of the Hunt cell having a perforated deflecting cap. The result of this variation in structure is to cause a finer dispersion of bubbles under and in the bubble column.

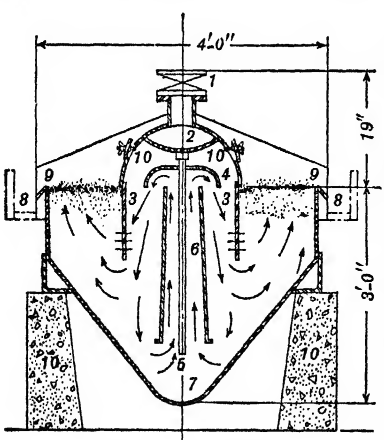

FIG. 21. Welsch cell.

Welsch cell (Fig. 21) is designed to permit depression of the pulp in the splash zone by building up pressure thereon. The extent of depression can be regulated by the air gates, *10*.

St. Joe cell is a special narrow and relatively deeper cell with 4-in. downcomers fishtailed to 1/4-in. slots. As a result back pressure is reduced to 0.75 to 1 lb. At BALMAT the lead roughers treat 11.5 tons per ft. per 24 hr. and the zinc and iron roughers 7 tons. Installed power is 2.4 hp-hr. per ton for the lead machines and 2.8 each for the zinc and iron.

At the Flat River mills of ST. JOSEPH LEAD CO. (*IC 6658*) the cells are 37 in. wide and carry an 18- to 21-in. pulp level and 24- to 39-in. depth to froth overflow, increasing with the grade of concentrate desired. Lengths are 36 ft. for roughers, 12 to 42 ft. for cleaners and recleaners. Air consumption is 100 to 150 c.f.m. per ft. of length at 12 to 16 oz. pressure.

Emery (*U. S. pat. 2,202,484*) describes an apparatus (Fig. 22) in which the side of the trough is pinched in at the top as at *a* and the splash baffle *b* is oppositely flared at the bottom and so placed as to give a narrow doubly crowded bubble column, which accelerates overflow for sluggish froths. The air lift is a continuous narrow box *c* with a plurality of short pipes *d* at the bottom, which makes for easy removal of this unit and good dispersion of air.

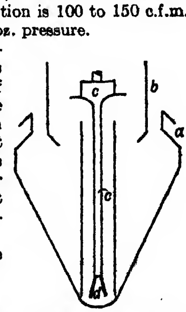

FIG. 22. Emery cell.

Shimmin cell at SUNSHINE (*136 J 269*) is of air-lift type with overflow on one side only; it is about 1 ft. wider (5 ft. 4 in.) and somewhat deeper (3 ft. 8 in.) than the standard form.

Deep air cell (*Bul 31[2] CIMM 473*) is a modification of the Forrester cell, differing principally in that the depth is 7.5 to 10 ft. and width is made somewhat greater. A 5×8×100-ft. cell at Britannia replaced more than 500 ft. of standard Forrester cells treating 5,500 to 6,200 tons dry feed per day. Comparative operating data for deep-cell *vs.* a 4×3(deep)×100-ft. Forrester in roughing service, stating deep-cell figures first, are: air pressure at header, 3.9 to 4.1 *vs.* 1.9 to 2.0 lb. per sq. in.; c.f.m. free air per lineal ft., 60 *vs.* 75; daily ca-

pacity, 6,000 tons *vs.* 1,000 at 26 to 29% solids; power input, hp., 180 *vs.* 95; power consumed per ton of ore, hp-hr., 0.72 *vs.* 2.28; tailing assay, % Cu, 0.06 *vs.* 0.045. About 80% of total recovery is made in the first 30 ft. of cell. A machine built of 3-in. and 2 1/2-in. plank, with 12-in. header and 3/4-in. drop pipes at 2 1/2-in. centers for 20 ft. and 3-in. for balance cost $2,600 (1937). Tie-rods and drop pipes are covered with rubber hose. Pinched rubber sleeves (Goodyear Tire and Rubber Co.) are used on the lower ends of the drop pipes to prevent clogging in case of unexpected shutdown. See also Sec. 2, Fig. 38.

In substituting deep cells for shallow, length should not be diminished, but rather the substitution should be on a time-factor basis in the air-swept zone, with the length held constant.

Air-lift *vs.* agitation-froth machines was subjected to thorough testing at BRITANNIA (*Bul 244 CIMM 323*). A summary of the findings was: Pine oil consumption was 0.13 lb. per ton of feed in the air-lift *vs.* 0.23 in the M.S. machine; the air-lift took 28% less power, amounting to 0.8 hp-hr. per ton of feed; maintenance was substantially nil for the air-lift *vs.* 0.3¢ per ton for the M.S.; the air-lift required less attendance, less floor space, made better recovery and a higher grade of concentrate (+1.5% Cu).

The significance of this latter ability is made apparent from a competitive test at MIAMI in which the matless cell made a concentrate containing 15.2% Cu and 33.6% Fe as against 13.3% Cu and 34.3% Fe in the competing machine; recoveries were 91.1 and 91.7% respectively, *i.e.*, against the matless cell. Yet the net profit after smelting, on the basis of a 5-mo. test, was 5.6¢ per ton of flotation feed in favor of the matless cell.

At UTAH (*IC 6792*) power consumption for 1930 was 4.9 kw-hr. per ton in Janney mechanical-air machines and 1.8 kw-hr. per ton in an Inspiration cell. In the same year the minima and maxima for copper flotation as collected by the U. S. Bureau of Mines (*ibid.*) were 2.1 to 4.9 kw-hr. per ton for mechanical machines and 0.8 to 6.6 for pneumatic.

It must be borne in mind, however, that heavy quick-settling pulps may require such excessive aeration in pneumatic cells as to make it difficult to maintain a smoothly working froth, so that tailing and power consumption may both be high in comparison with mechanical machines.

Air-lift *vs.* mat-type cells. The essential factors in this choice are size and character of ore. If the ore is a heavy sulphide or coarsely ground and hard to suspend, or if sulphide is to be depressed in the operation, both power and maintenance in the mat-type cell will be so much more costly than in the air-lift machine that even a competitive run is unjustified so far as a stationary-mat machine is concerned, and the result of a test against a rotating mat is almost a certainty in favor of the air-lift. But with fine grinding, a low-grade ore, and little or no sulphide depressed, the mat-type cell will tend to give sufficiently better metallurgical results to overcome any advantage of the air-lift in lower power consumption and maintenance.

At INTERNATIONAL NICKEL it is reported (*130 J 465*) that the power consumptions per ton of ore were 2.2 kw-hr. for stationary mats, 1.3 for rotating mats, 1.8 for matless cells.

Competitive tests. It is worthy of note at this point that the reported results of competitive tests are always to be scrutinized critically, and frequently skeptically when the report is in favor of the home team. Usually the prevailing operation has been built up over a period of years to favor every idiosyncrasy of the installed apparatus. The newcomer must not be damned because it cannot compete in absolute parallel. Time, place, nature and extent of conditioning may need change in order to attain optimum conditions for the new cell; this requires time, intelligence, and a sympathetic attitude.

22. CASCADE MACHINES

Cascade machines effect aeration by causing a stream of water or pulp to plunge into a body of pulp. Air is entrained by pushing it into the body of pulp ahead of the masses or droplets into which the entering stream is broken. Any stream of pulp that falls through a distance greater than a few times its diameter breaks up into distinct masses, the breaking being greater the greater the velocity of the stream and the further its free fall. Each mass of entering pulp, if moving at sufficiently high velocity, introduces a small volume of air in substantially the same way as an air bubble is pushed into water by a pebble thrown therein. The air thus introduced is broken up into smaller bubbles by reason of the swirl and movement caused by the entering stream and, rising to the surface of the pulp, forms thereon a bubble column in which concentration takes place as previously described. The efficiency of the operation depends on the effectiveness of the apparatus in forming and maintaining an undisturbed, highly aerated bubble column.

A form of cascade machine that was installed at CENTRAL MINE, Broken Hill, Australia, is shown in Fig. 23. It consisted of a battery of boxes *a*, *a'*, etc., placed in vertical relationship to each other as shown, with provision for pulp flow through the series by means of down-pipes *b* and overflow pipes *c*.

Froth overflowed lips *d* into launders *e*. Aeration was effected in the top box by the plunge of the feed stream from feed launder *f* into the body of pulp standing in box *a* at a level determined by the setting of weir *g* operated by lever *h*. The aerating stream to subsequent boxes was confined by the down-pipes *b*, after emerging from the nozzle *i*. Detail of the nozzle is shown in Fig. 24. Crowding boards *j* served to increase the depth of the bubble column and to prevent overflow of froth into pipes *c*. Downward projection of the pipes *b* below the upper surface of the bubble column protected the latter from being broken down by spray from the falling stream.

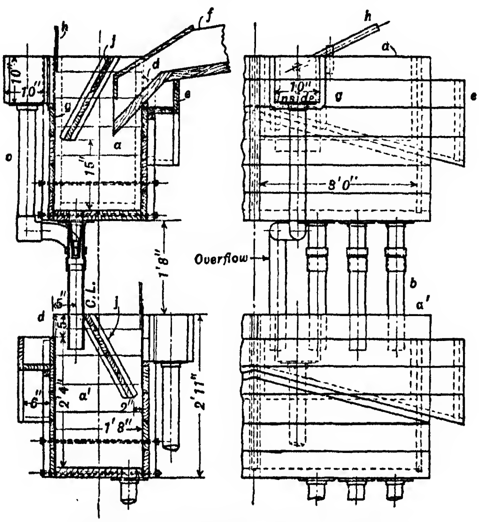

Fig. 23. Cascade boxes at Central Mill.

Nozzle (Fig. 24) comprised the downwardly converging cast-iron pipe *k*, bushed with the hardened-steel wearing bushing *l*. Clamp *m*

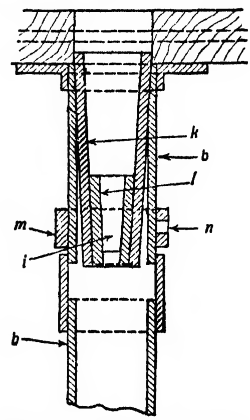

Fig. 24. Aerating nozzle for cascade machine.

had threaded hole *n* for a 1/2-in. petcock, and registered above a hole drilled in *b* to admit air into the space around the stream emerging from the nozzle. The petcock permitted regulation of the quantity of air admitted to the pulp in the lower box. Tests at Miami demonstrated that this regulation was unnecessary, and that the only function of the downward extension of pipe *b* below the nozzle was to protect the bubble column in the lower box from spray. A similar machine was used for roughing at Phosphate Recovery No. 2 plant, but was not satisfactory and was replaced by subaeration machines in later plants (*112 A 474*). Details of a machine at Premier are given in *IC 6742*.

Use. Cascade machines have been used very little in the mills. Recoveries are low except with ores that float easily. Capacity per unit of volume is low and the height required makes for expensive installation. Control of aeration is difficult and unsatisfactory. Such little use as the machines have had was in skimming off a high-grade concentrate ahead of the main roughers, or as scavengers, in both cases the prerequisite being headroom to waste or cheap power for elevation.

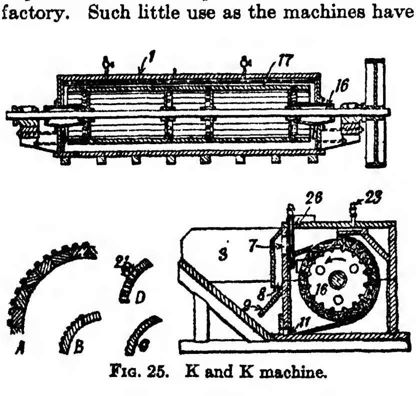

Fig. 25. K and K machine.

Mechanical cascade machines are those in which the pulp to be splashed is elevated by the machine. Of these the Kraut and Kohlberg (K and K) and the Kraut machines are the only ones that have had more than local use.

K and K machine (Fig. 25) consists of a slotted cylinder *16*, 20 to 30 in. diam. and 10 to 16 ft. long, mounted horizontally so as to be driven (counterclockwise in the view shown) at 160 to 200 r.p.m. It is enclosed in a boxlike housing which opens full length at *7* into hood *8*, which discharges below the surface of pulp in spitzkasten *3*. Rotation of the cylinder carries pulp in the interslot openings to the top of the box and splashes it through *7* and *8* into the body of pulp in the spitzkasten, thus aerating the latter. Baffle *9* prevents aerated pulp from short-circuiting through *11* so that the

air bubbles rise in *8* and form a bubble column on the pulp therein. Froth overflows the lip along the front of the spitzkasten; pulp circulates back through *11*, thus following a spiral path around the partition from a feed point at one end of the spitzkasten to a tailing discharge at the other. CAPACITY is rated at 30 to 100 tons per 24 hr.

Butchart machine has the same type of rotor as the K and K, but it is fitted with toothed spiders between the teeth of which hardwood slats are keyed with hardwood keys. The spitzkasten is divided transversely into compartments about 30 in. long, and gates control the amount of recirculation of pulp to the corresponding section of the rotor before it passes on to the next compartment. An adjustable submersion baffle is also provided in each compartment. At EAGLE PICHER, Ruby mill (*IC 6497*), the coarse feed to the Butchart cells wore the rotors excessively, *e.g.*, life was only 10,000 and 7,100 tons in primary (slime-bearing) and secondary pulps respectively; replacement costs were 0.5 and 0.7¢ per ton.

Owen and Dalton machine at MORNING mill (*IC 6587*) is a K and K-type machine 60 ft. long, 6-compartment, with 2 @ 36-in. rotors per compartment, driven at 80 r.p.m. Slats are spaced 2 in. Capacity is 150 t.p.d. for a 60-ft. lead rougher; power consumption, 9 hp-hr. per ton for roughing and cleaning.

Kraut machine (Fig. 26) utilizes a vertical spiral pump *a* placed in a rectangular tank to elevate pulp, which is discharged into hood *b*, internally baffled to reduce swirl, and forced to flow out under the edges thereof. The splash in the hood, which has an air-inlet entry through the hollow pump shaft, aerates the pulp, and the bubble column which forms outside is protected by the hood. Pulp flows generally from one end of the cell to the other, with confused and undirected circulation on the way. The complete machine comprises 2-, 3-, and 4-cell multiples. Cell SIZES are approximately 30, 36, and 48 in. square; corresponding cell capacities are 7.5, 14, and 26 cu. ft.; maker's CAPACITY ratings, 2 tons per 24 hr. per cu. ft.; SPEEDS, 1,100, 925, and 825 r.p.m. respectively with estimated POWER CONSUMPTIONS, 1.2, 4, and 6 hp.

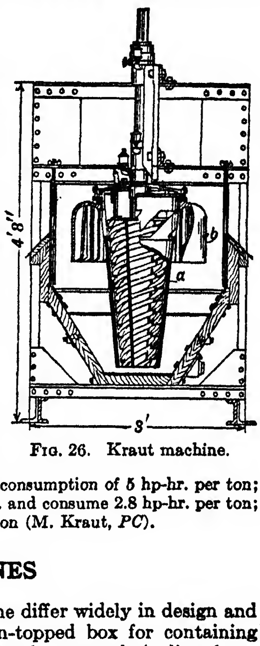

FIG. 26. Kraut machine.

The battery of six Kraut cells cleaning pyritic gold concentrate at IDAHO-MARYLAND (Sec. 2, Fig. 64) treats 5 tons feed per hr. at a reported power consumption of 7 1/2 hp. per cell. At LAKE SHORE 70 rougher and 16 cleaner cells treat 2,500 t.p.d. with a consumption of 2 hp-hr. per ton; at CUSI MEXICANA 20 lead roughers and 4 lead cleaners, 20 zinc roughers and 6 zinc cleaners treat 600 t.p.d. with a consumption of 5 hp-hr. per ton; at MURCHIE MINING Co. 12 roughers and 2 cleaners are fed 300 t.p.d. and consume 2.8 hp-hr. per ton; at BEEBE MINE 10 roughers receive 30 t.p.d. and draw 2 hp-hr. per ton (M. Kraut, *PC*).

23. SUBAERATION MACHINES

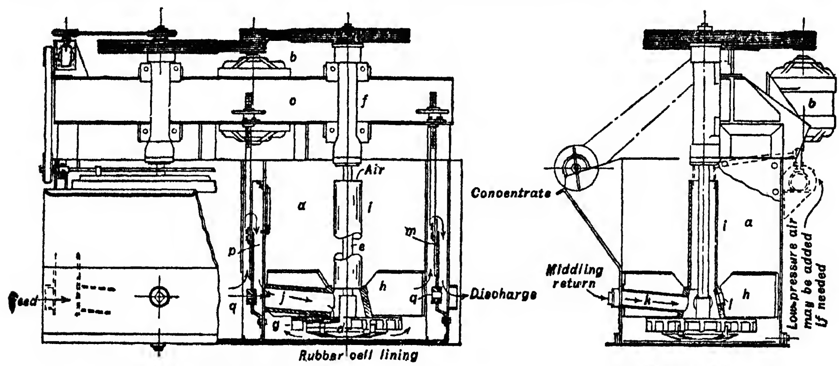
Introduction. The machines grouped under this class name differ widely in design and operation. Their common structural features are: an open-topped box for containing pulp, a rotary agitator at the bottom of the box, means to supply external air directly to the agitator, means to confine agitation of the pulp to a zone directly around the agitator, particularly to reduce swirl or surging at the top of the pulp, a froth-overflow lip at the top of the box, and feed and discharge ports for pulp. Their common operative characteristic is that separation of concentrate from tailing is made in the column of bubbles maintained above the pulp in the box. They are readily divisible into two groups, distinguished by the manner of introduction of air. In one group the impeller acts as a centrifugal air pump submerged in the pulp, with its suction pipe, usually a hollow impeller shaft or a pipe surrounding the impeller shaft, passing from the surface of the pulp to the impeller zone. In the other class air is pumped in to a point directly under the impeller by an external pump; this arrangement, incidentally, gives an additional operating control.

Differences in type of impeller and in operating speeds introduce a difference in flotation mechanism. Low-speed machines and those with double-shrouded impellers are pure bubble-column apparatus, the impeller serving simply as a device for dispersing air bubbles and distributing them under the mass of semiquiescent pulp above the impeller zone. High-speed machines with impellers that minimize mass cavitation effect more or less precipitation selection in the impeller zone, which aids carriage of floatable mineral to the bubble column. After this selected mineral arrives at the base of the bubble column, however, it merges into the other mineral therein, and selection is effected by pure bubble-column action. This merger is effected because of the fact that when surface-active material in an amount sufficient to form a separate liquid phase is brought to the surface of a bubble carrying solid in the gas-liquid interface, the surface-active material intrudes

itself into the air-liquid interface and displaces the attached solid into the liquid-liquid interface.

Machines with Internal (Submerged) Air Pumps

Denver Sub-A (Fahrenwald) machine (Fig. 27) consists of a series of substantially identical cells *a* set side by side on the same level, with party side walls and continuous front and rear walls, comprising a compartmented open-top box longitudinally, above which a frame *c* for support of a driving mechanism is placed. Impellers *d*, one to a box,

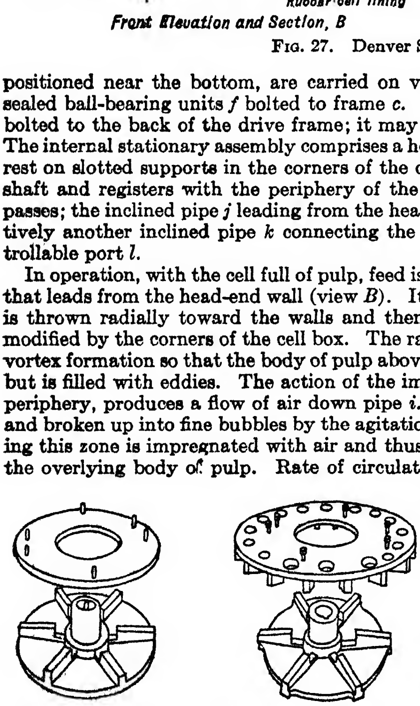


Front Elevation and Section, B   Transverse Section, A

FIG. 27. Denver Sub-A machine.

positioned near the bottom, are carried on vertical shafts *e*, supported by long grease-sealed ball-bearing units *f* bolted to frame *c*. Drive is by V-rope from vertical motors *b*, bolted to the back of the drive frame; it may be either single, dual (as herein), or triple. The internal stationary assembly comprises a hood *g* bolted to four diagonal baffles *h*, which rest on slotted supports in the corners of the cell; the vertical pipe *i* which surrounds the shaft and registers with the periphery of the hole in the hood through which the shaft passes; the inclined pipe *j* leading from the head-end side wall to the vertical pipe; alternatively another inclined pipe *k* connecting the vertical pipe to the front wall; and a controllable port *l*.

In operation, with the cell full of pulp, feed is introduced continuously through the pipe *j* that leads from the head-end wall (view *B*). It flows onto the revolving impeller whence it is thrown radially toward the walls and thence starts upward in a roughly spiral path modified by the corners of the cell box. The radial baffles *h* stop the spiraling and prevent vortex formation so that the body of pulp above them is substantially quiescent as a whole, but is filled with eddies. The action of the impeller, in displacing pulp from its center to periphery, produces a flow of air down pipe *i*. This air is engulfed in the inflowing pulp and broken up into fine bubbles by the agitation in the impeller zone so that the pulp leaving this zone is impregnated with air and thus supplies the air necessary for treatment of the overlying body of pulp. Rate of circulation of pulp through the impeller zone and, consequently, the extent of aeration are controlled by the opening in port *l*, which is regulable. The pressure drop generated on top of the impeller and the fineness of dispersion of air depend to a considerable extent upon the configuration of the impeller and of the under side of the hood plate, upon the spacing between the impeller and the hood plate, which is regulable, and, of course, upon the speed of the impeller.



(A)   (B)

FIG. 28. Impellers and hoods for Denver Sub-A machines.

Impellers and hood plates are of two forms, as shown in Fig. 28. View *A* shows the older, so-called CONICAL-DISK FORM with 6 radial blades on the disk, tapering slightly toward the periphery, and a hood plate of substantially the same diameter, smooth on the under side but coned conformably. View *B* shows the RECEDED-DISK TYPE, with a similar impeller, differing in that the ribs are somewhat more tapered and project slightly beyond the bottom plate. The hood plate projects beyond the

impeller, the projecting part carrying depending lugs and having circular perforations between the lugs. This arrangement provides additional agitation at the periphery of the impeller and a consequent finer dispersion of air, while at the same time the perforations tend to direct aerated pulp upward nearer the center of the cell than otherwise, thus producing a more uniform distribution of rising bubbles. Wear is greater with the receded-disk type, hence it is not recommended for coarse pulps.

Bubble-column action is normal in the area embraced between the vertical walls of the cell. If the quantity of floatable mineral is small or the air supply deficient, so that it is difficult to maintain a good bubble column over this entire area, crowding boards are inserted. A small spitzkasten is normally provided, particularly for cleaner cells, in order to afford area over which there is no rise of bubbles, so as to allow some slow-draining solid to fall back before overflow, thus enriching the overflow material. For ores from which a bulky overflow is taken, a back overflow lip is provided.

Tailing is discharged over an adjustable weir *m*, the weir box being located toward the back of the cell. The small hole indicated by the arrow at *q* permits heavy sand to short-circuit the weir.

By suitable arrangement of the middling launder and capping or opening middling-return pipes *k*, froth overflow from any cell can be re-treated in another cell in the same machine. Thus it is usual to use, say, cells *4* to *10* of a 10-cell machine as roughers, feeding at cell *4;* return combined overflow to the middling-return pipe of cell *2*, making cells *2* and *3* primary cleaners, discharging cleaner tailing into the new feed in compartment *p* at the head of cell *4;* return cleaner concentrate to the middling-return pipe of cell *1*, which acts as a recleaner and discharges its tailing by weir to cell *2*.

Size is denoted by the manufacturer's number, which is approximately impeller diameter in inches, and the number of cells comprising the unit. Essential dimensions, and operating data corresponding to the numbers as compiled from the manufacturer's catalogue, are given in Table 13. The power figures

a Tons new feed to grinding circuit. *b* For one cell only.

check with those reported (*Q*). Peripheral speeds in operation range from 1,450 to 1,850 r.p.m. Capacity is rated by the maker as 0.025 to 0.028 ton of slow-floating ore in a pulp of 25% solids per cu. ft. of rated cell volume per hr., and roughly double this for a medium-floating ore. Performance figures tend to fall between 0.015 to 0.04 in pulps this dilute, averaging about 0.02, but in pulps containing 30 to 45% solids, which is a more usual range in practice for this type of machine, capacities range from 0.035 to 0.06 ton per cu. ft. of cell volume, with treatment times of 10 to 20 min. in roughing service; the figures are not greatly different in cleaner service. Power consumption ranges normally from 2.5 to 5 hp.-hr. per ton. Small amounts of low-pressure air are added (Fig. 27, view *A*) in practice when exceptionally dilute pulps are treated. Attendance requirements appear to be somewhat greater than for air cells, but 50 to 75 cells per man is not unusual.

Maintenance has been greatly reduced in this cell as compared with that in the older impeller-type machines by elimination of gear drive, use of heavy impeller shafts and long ball bearings, sturdy mounting of bearings and motor, and the use of rubber to cover the impeller, hood-plate, and diagonal baffles and to line the bottom and walls in the impeller zone. Field reports (*Q*) indicate that where cast-iron impellers and hood plates have lives of 15 days to 6 mo., according to size and abrasiveness of feed, and cast-iron baffles and liners from 60 days to 1 yr., rubber-covered impellers and hood plates last 3 to

6 yr. and liners and baffles more or less indefinitely. Old elevator belt used at BUNKER HILL & SULLIVAN to cover baffles and line walls and baffles lasts 2 yr. At BALMAT (*IC 6574*) cast-iron bowls and impellers in the lead circuit were replaced after 238 days (107,000 tons), and the impellers were again replaced after 173 days (99,000 tons); in the zinc and pyrite circuits the life of bowls and impellers was 411 days (201,000 and 164,000 tons respectively). Life of grids was 300 days in all machines. Hoods on the lead roughers treated 199,000 tons.

Feed sizes treated in subaeration machines are quite generally coarser than those sent to pneumatic cells, ranging, for some 30 mills reporting, from 65-m. maximum to 6% > 28-m.; the average is near 1% > 35-m. From a statistical standpoint, also, the great bulk of the USE is on high-sulphide ores. There is no doubt that these can be maintained in suspension more effectively in mechanical machines than in pneumatic, and when coarse sizes are treated to make low-grade bulk concentrates for regrinding and re-treatment, as is modern practice for auriferous and cupriferous pyrites, the maintenance of suspension in the flotation machine becomes important. FLOTATION TIME is definitely longer than in pneumatic machines for ores and pulp consistencies suited to the latter.

MT. LYELL reports that as between a subaeration and a matless cell working in parallel on a heavy sulphide feed <65-m., the subaeration machine is slightly superior in metallurgy and power consumption while the matless has the smaller maintenance, and that both are efficient and easy to operate.

Unit cell is a particularly rugged one-cell sub-A unit designed to scalp coarse pulps. It is frequently used in grinding circuits between mill and classifier. It is provided with a conical bottom trap with plug-cock discharge for collection and intermittent removal of coarse and heavy material. A sand-relief outlet, placed at q, Fig. 27, view B, leads by pipe to the bottom of the tailing weir box. Tailing discharges at a level sufficiently above the feed inlet, owing to the pumping action of the impeller, so that even with a trunnion screen, which it is advisable to install to scalp out tramp oversize, the cell can be installed without the use of auxiliary elevation in the ball mill-classifier line. A plan for installation is shown in Fig. 29.

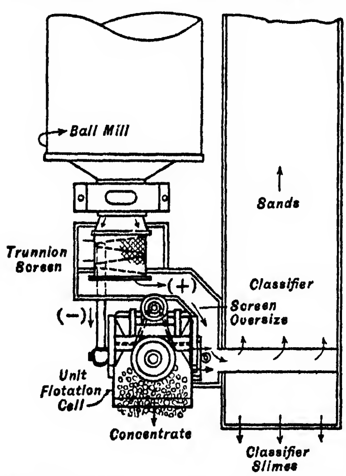

FIG. 29. Setting of Denver Unit cell in ball mill-classifier circuit.

SIZES and CAPACITY ratings are shown in Table 13 from manufacturer's figures. The "No." is the tons of solid per 24 hr. that the machine is rated to circulate in a grinding circuit.

Rubber-covered surfaces in the grinding zone are essential. At MCINTYRE PORCUPINE such surfaces on impeller and hood plate lasted about 9 mo.; at OMEGA the impeller lasted 40 days, hood plates 6 mo., and liners 12 mo.

Performance figures indicate capacities to be from 1 to 3 tons per hr. per cu. ft. of cell volume at pulp densities of 50 to 60% solid. The cell has been used principally in the treatment of sulphide gold ores and in lead-carrying ores; with some of the latter it can make a high-grade lead concentrate without the use of zinc or iron depressants, using starvation quantities of collector and frother. Early recovery of galena will normally have the effect of increasing over-all lead recovery because of its tendency to slime in a grinding circuit and the higher-than-average losses that occur in the finest fractions of flotation tailings. The cell has the incidental useful effect of tending to iron out the effects of irregularities in value of feed and to make operation of subsequent flotation units more uniform and, consequently, more efficient. At PILGRIM (*IC 6945*) a unit cell operating at 45% solids on <4-m. feed recovered 85% of the gold present with a ratio of concentration of 700 : 1.

Fagergren level-type machine (Fig. 30) comprises a trough A with vertical and sloping sides and a flat bottom, divided into cells by transverse partitions with upper and lower ports Q and Q'. In each cell is rigidly mounted a cylindrical grid or stator B (shown broken away in item B) carrying a standpipe C. The base plate D, carried on longitudinal angles K, supports the standard E and bearings F for the vertical rotor shaft G at the lower end of which is mounted the rotor H. This consists of a squirrel cage, the end plates of which are cut-out propellers. Feed pulp, introduced through box L and a low-level port, flows by gravity through the machine under a head determined by the height of tailing weir M. Centrifugal force imparted by the whirling squirrel cage causes the pulp and air pumped down by the rotor through standpipe C to stream out together between the bars of the rotor cage into a zone of intense shearing between rotor and stator, where the air is entrained and bubbles are broken fine. The aerated pulp then streams out through the stator bars into the surrounding body of pulp and the bubbles rise to form a bubble column at the

surface of the pulp. A sand gate *N*, adjusted by capstan *R*, discharges material too coarse to be lifted over the weir.

The form illustrated is new (1942). The STANDARD SQUARE FORM which preceded it was of the same general construction except that each cell was a unit, driven by an individual vertical motor, successive

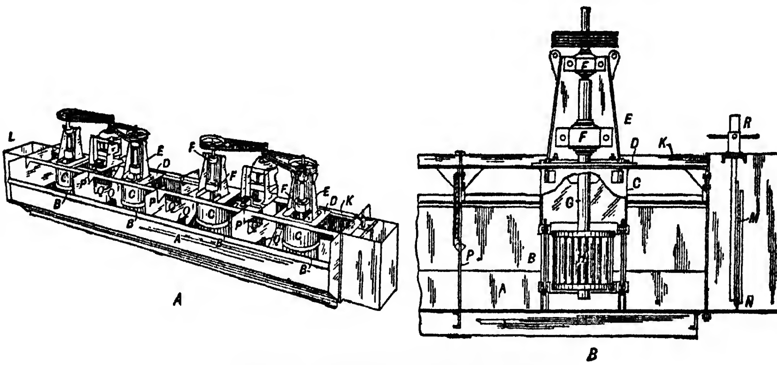

Fig. 30. Fagergren machine, level-type.

cells being set on successively lower levels, with individual pulp-level regulation by weirs, which discharged into under-floor conduits that fed up through the floor under the impellers, while intra-cell circulation was effected by a cruciform under-floor conduit, the arms pointing toward the corner of the cell, receiving pulp through ports in the cell bottom and delivering into the feed conduit and thence back to the impeller. A ROUND FORM differs in that the pulp chamber is a cylinder with overflow all around; no scraper is used, hence the cell is adaptable only for voluminous free-frothing conditions. Mead *et al.* (*U. S. pat. 2,304,270*) describe a form of round cell in which the tailing is drawn from a submerged circular weir below the froth overflow lip, so that the tailing stream cuts across the stream of bubbles rising to the bubble column. The specification asserts higher grade of phosphate concentrate than was made on standard Fagergren cells in parallel, at the expense of a higher grade of tailing. An oblong form, as installed at the UTAH COPPER Co. mills, is shown in Fig. 31. It illustrates the under-floor feed and circulation conduit with plugs in the floor for regulating circulation.

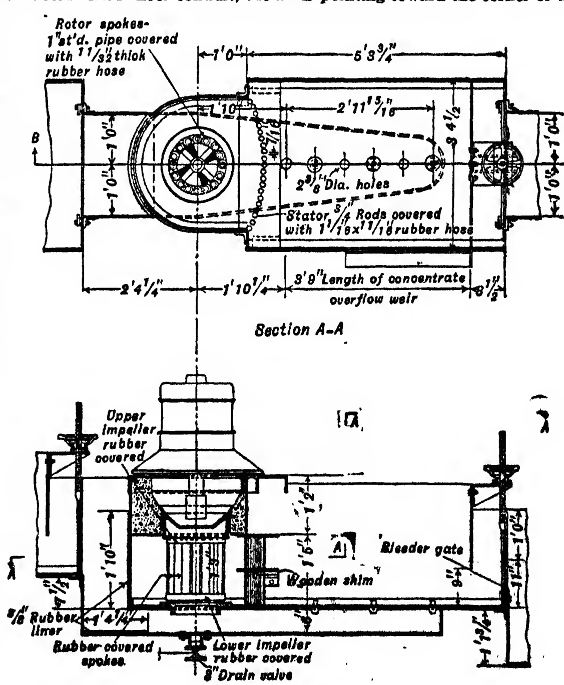

Fig. 31. Fagergren machine, oblong-type (UTAH COPPER Co.).

SIZE of cell is indicated by the number of inches length of one side of the square cell, the diameter of the cylindrical box of the round cell, and, for the oblong cell, by the size of the square cell in which a motor-rotor combination of the same size would be used. Standard sizes are 28-, 36-, 44-, 56-, and 66-in. Corresponding square cell volumes are 5.5, 13, 23, 47, and 70 cu. ft. Manufacturer's maximum CAPACITY ratings are 0.063, 0.11, 0.15, 0.15, and 0.20 ton per hr. per cu. ft. of cell volume respectively for the five sizes. Corresponding estimates of POWER CONSUMPTION are

1, 2, 4, 6, and 8 hp. per cell for square cells and about 30% higher for the level type. SPEED is about 2,100 f.p.m. peripheral.

Performance reports (Q) are substantially all for the 56-in. size; they indicate that the above maximum figures for capacity are reached in lead flotation in pulps containing 35 to 45% solids; that in roughing zinc, copper, and gold ores in pulps containing 25 to 35% solids the figure averages 0.09, with a range of 0.03 to 0.15; that in cleaning these same ores the average duty is 0.03 with a range of 0.01 to 0.07, and finally, on the basis of two reports only, that in roughing lead ore in pulps of 45 to 50% solids, figures of 0.2 and 0.6 ton per hr. per cu. ft. of cell volume are being reached. POWER CONSUMPTIONS are close to the above estimates, which give an average range of 1 to 2 hp-hr. per ton for roughing service, but this figure rises rapidly to two or three times the maximum, if roughing time is permitted to rise, or in difficult cleaning service. MAINTENANCE may be estimated from the following field reports. White cast-iron rotors and stators have a life of 40 to 50 days with hard ore and moderate loads; the same parts rubber-covered last from 220 and 400 days, respectively, to upward of 4 yr., the lower lives being for relatively heavy service.

TREATMENT TIMES reported range, in general, from 5 to 15 min. in roughing service, the higher figures corresponding to the more dilute pulps. These figures show much more rapid flotation action than occurs in most other cells and indicate that considerable precipitation-type levitation is superimposed on the very effective bubble-column action that is evident in observation of the cell. Such action is to be expected from the high peripheral speed of the rotor and the fact that the great part of its agitating surface is concentrated at its periphery.

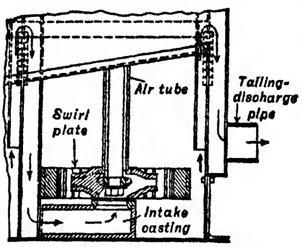

FIG. 32. Interior of UIW cell.

UIW machine (Fig. 32), used at BUNKER HILL & SULLIVAN (Sec. 2, Fig. 108), is of the square-cell one-level type with a small spitz at the front and the back crowded in as in Fig. 38. The double-shrouded tapering impeller with a central opening top and bottom is carried on a solid shaft surrounded by an air tube with adjustable air inlet at the upper end. A circular swirl plate with the comblike configuration of an internal gear surrounds the impeller. Pulp level is controlled in the individual cells by adjustable weir overflows and middling is returned from the launder to the head cells by a pipe or pipes to the respective intake castings.

SIZES are stated as the edge dimension of the square cells; 24-, 32-, and 42-in. sizes are standard. Corresponding impeller diameters are 11, 16, and 20 in.; spitz projections, 9, 12, and 15 in.; cell volumes, 10.2, 27.8, and 49.4 cu. ft.; and approximate POWER CONSUMPTIONS per cell, 0.8, 2, and 4 hp. Maker's CAPACITY ratings average between 0.04 and 0.045 ton per hr. per cu. ft. of cell volume.

Pan American machine (Fig. 33) is of pure subaeration type, designed to minimize power consumption. This is effected by placing a relatively small (8-in. in a cell 48 in. square) cavitation-type impeller *a* near the surface of the pulp in a deep cell, so arranging it at the throat of a low-pressure submerged ejector *b* that rapid circulation of the pulp upward through the ejector and downward outside is effected. Air for ejection flows by atmospheric pressure into the low-pressure zone behind the impeller blades through the hollow shaft; the bubbles are sheared and finely subdivided by turbulence effected by baffles *c* and conical deflector *d*, and the overlying bubble column is protected by perforated plate *e*. Feed enters the cell at *f* and pulp passes to the following cell through port *g*. Overflow is front and back and is controlled by raising or lowering the V-shaped crowding board *h*. Pulp volume of the 48-in. machine, 9 ft. deep, is about 115 cu. ft. The ratio of air-swept volume to total volume is low. Maker's figure for power consumption per 8-in. rotor is 3 hp.

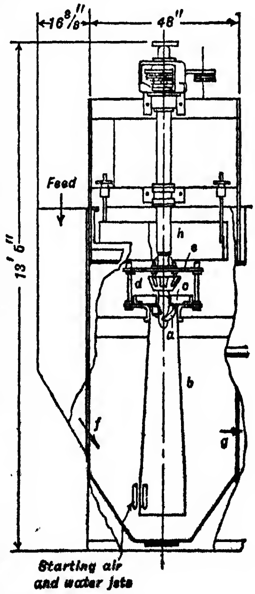

FIG. 33. Pan American cell.

Machines with External Blowers

Minerals Separation subaeration machine is made in three principal forms known respectively as the BRITISH-TYPE, AMERICAN-TYPE, and COUNTER-CURRENT machines. The American type, shown in Fig. 34, consists of a series of square cells *a* set side by side on the same level, each fitted with a top-shrouded pump-type impeller *b* (Fig. 35, item *b*) mounted just above a false floor, a perforate baffle plate *c*, a crowding board *d*, a weir compartment and weir *e*, and a small triangular offset zone *f* on the front. Feed enters the head cell

through a box which delivers to the passage g under the false floor whence it is forced through port h and a registering port in the impeller bottom plate into the zone of subatmospheric pressure engendered within the rotating impeller. Air is likewise introduced into this zone through pipe i. The mixture of air and pulp is discharged at the periphery of the impeller, the shearing action with the mass of slower-moving surrounding pulp serving to break the masses of air into small bubbles. The mixture of bubbles and pulp rises through the openings in c, swirling and surging being diminished thereby, and the bubbles rise through the substantially quiescent pulp above to form a bubble column thereon. The

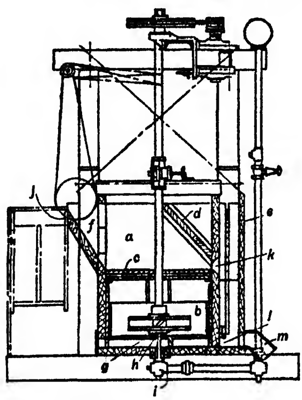

Fig. 34. M.S. subaeration machine (American-type).

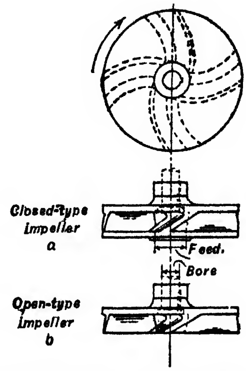

Fig. 35. Impellers for M.S. subaeration machines.

crowding board has the effect of pushing the whole bubble column horizontally toward overflow lip j, and the decreased bubbling in f permits a less impeded drain-back over this zone. Pulp flows through port k, over weir e, and thence through passage l to the subfloor feed passage of the next cell. Final tailing discharges through port m, which is on the last box only.

Size of machines is indicated by impeller diameter and number of cells. Usual impeller diameters are 12, 15, 18, and 24 in.; horizontal cell dimensions are twice the impeller diameters; corresponding cell pulp volumes are 12, 22, 36, and 72 cu. ft. with normal depths of bubble column. The maker's capacity rating is about 0.04 ton solid per cu. ft. of machine volume per hr. in a 25% pulp. Speed is about 1,450 f.p.m. peripheral. Maker's estimates of power consumption for this speed are 1.5, 2.2, 3.2, and 4.5 hp. per cell respectively for the 4 sizes of cell, exclusive of air supply. At Tybo (*IC 6430*) 18-in. impellers drew 2.6 hp. in pulps containing 30 to 35% solids and 2.4 in pulp with 25% solids. At Broken Hill North (*134 #2 J 61*) 15-in. impellers at 560 r.p.m. consumed 6 to 7 hp. per spindle.

Performance figures as to capacity, mostly on lead-zinc ores, fall well below manufacturer's figures; for pulps containing less than 25% solids the range is 0.015 to 0.024 ton per hr. per cu. ft. of machine volume in roughing service, average 0.018, and 0.029 for one operation in cleaning service; for 25 to 35% solids the average is 0.017 (range 0.014 to 0.021) in roughing service; for 35 to 45% solids the average, all in roughing service, is 0.030, with a range of 0.020 to 0.040 (8 cases); for greater than 45% solids one figure is available for roughing, showing 0.06 ton per hr. per cu. ft. of machine volume, while two figures for cleaning are 0.011 and 0.014. Figures from the field for power actually consumed in driving impellers are few, but those available indicate that the manufacturer's figures are safe for estimating purposes. Average power consumption on this basis ranges from 2.5 to 5.5 hp-hr. per ton. Air consumption is 10 to 30 cu. ft. per min. per 24-in. cell at 1.5 to 2 lb. per sq. in. pressure, with the average between 20 and 25 cu. ft. Cast-iron impellers last from 150 to 2,000 days, the lower figures being for 35-m. pulps in roughing service and the higher for fine sulphide pulps in cleaning service. Cast-iron liners last one year upward and rubber-covered wood lasts indefinitely in this service.

Countercurrent machine (Fig. 36), the latest form of M.S. machine, is essentially the same as the American-type subaeration machine except that the transverse partitions are broken with large ports just above the perforate baffle plates c (Fig. 34), and the forward flow of pulp is through a port in the false floor against the transverse wall and thence by an underfloor channel to the next impeller, which is shrouded on the top side only. The theory of the manufacturer is that since the pumping capacity of the impeller is normally greater than the feed rate and the discharge weir is higher than the bottom of the slots in the transverse walls, a back head is built up on these slots and a counter flow of pulp thus effected. Control of level in individual cells is sacrificed, there being only the tailing weir. Air is forced in under the impeller. The cell is shallower than the regular M.S. subaeration cell,

so that somewhat less power is required for pumping, and back pressure on the external air is slightly less.

IMPELLER DIAMETERS are 12, 15, 18, 21, and 24 in.; corresponding cell volumes are 8, 16, 27, 43, and 64 cu. ft. Maker's CAPACITY rating is 0.1 ton per hr. per cu. ft. of machine volume in a 25% pulp. This

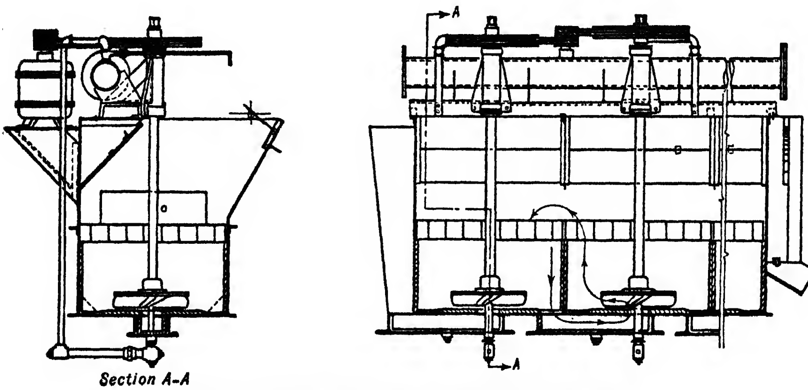

FIG. 36. Minerals Separation countercurrent machine.

corresponds to about 4 1/2-min. treatment time. PERFORMANCE figures are few but they do not indicate any such capacity. Normal treatment times are 10 to 20 min. Corresponding capacities would be 0.027 to 0.045 ton per hr. per cu. ft. of machine volume in a 25% pulp.

Geco machine (Fig. 37) is of the square-cell single-level type with single or double spitz. All cells in a block are on the same level. Inter-cell transverse walls terminate at *a*, some distance above the cell floor, affording a continuous open passage for pulp from feed intake to tailing weir. An annular plate casting *b*, resting on the cell floor, carries upwardly projecting radial blades *c* which surround the impeller *d*. The latter is of the top-shrouded form with cruciform vertical dependent blades. Underneath it is placed a shallow conical pan *e* with 8 baffles radiating from a central pipe through which blower air is introduced from the bottom. Baffles *c* are surrounded by a circular band *f*, welded to the corner braces *g*.

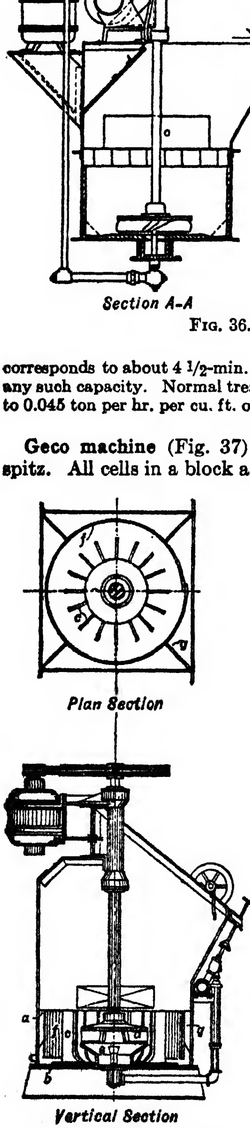

FIG. 37. Geco machine.

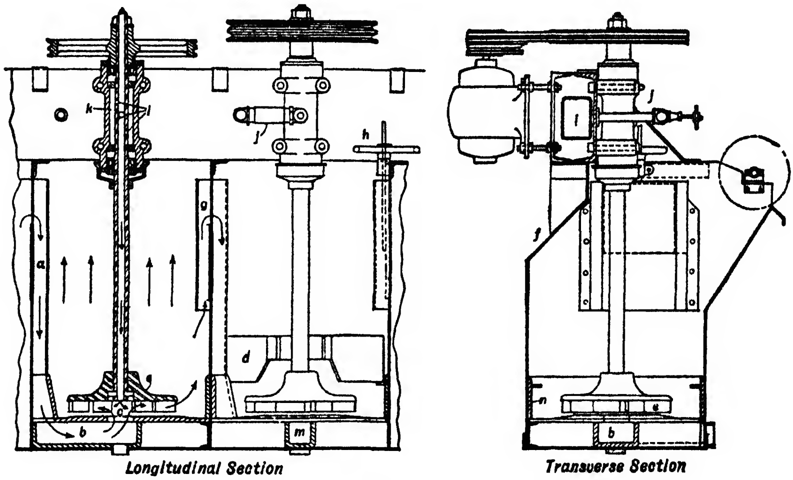
SIZE is indicated by the dimension of the square plan section of a cell in inches. Standard sizes are 24-, 30-, 36-, 42-, and 48-in., available in 2- to 12-cell blocks in 2-cell steps. Corresponding operating cell volumes are approximately 6, 14, 20, 32, and 48 cu. ft. CAPACITIES are to be estimated on time-factors.

Weinig machine, Fig. 38, is a single-level square-cell machine built in 2-, 3-, 4-, 6-, 8-, and 10-cell blocks. Feed enters a given cell through down-passage *a* and thence by underfloor passage *b* through passage *c* into the impeller zone. Cruciform baffles *d* prevent swirl. The impeller *e* is bladed as shown in Fig. 39. The bubble column is crowded at the back side by the in-slanting back wall *f*, and column drainage is provided at the front by flaring the upper part of the front wall. Cell tailing is discharged over weir *g*, adjustable by handwheel *h*. Air is introduced from main *i* via valved branch pipes *j*, stuffed compartment *k*, and holes *l* into the hollow impeller shaft and thence to the lower face of impeller *e*. Passages *m* are provided for middling return from the overflow launders and may be opened or blocked off as desired. Liners *n*, baffles *d*, and impellers are hard iron in standard equipment, but molded-rubber impellers are available and recommended for coarse abrasive pulps. Clearance between impeller blades and cell bottom is 1/2 to 1 in. Drive is designed for impeller speeds of 1,500 f.p.m. peripheral.

Impeller diameters are 10 in. in No. 6 1/2 cell, 15 in. in Nos. 10 and 16, 18 in. in No. 22, 21 in. in No. 40, and 24 in. in Nos. 50 and 75. Cell numbers, indicating machine sizes, are the nominal cubages per cell. Power consumptions per cell, as estimated by the manufacturer, are respectively for the



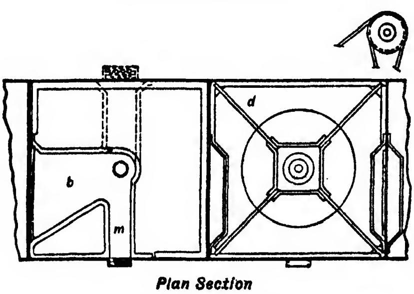


Fig. 38. Weinig machine.

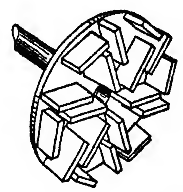

Fig. 39. Impeller for Weinig machine.

sizes listed 1, 1.5, 1.8, 2.5, 3.2, 4.5, and 5.5 hp. Air is recommended in an amount equivalent to 0.5 cu. ft. per min. per cu. ft. of cell volume. Capacities are to be determined from time-factor. For estimating purposes the manufacturer gives from 0.6 ton per 24 hr. per cu. ft. of cell volume for the No. 6 1/2 cell to 0.75 ton for the No. 75 cell for a slow-floating ore and 1.5 times these figures for average ores. At Climax, 30 No. 40 Weinig roughers in series treat 62 tons per hr. of <35-m. feed in a pulp containing 40 to 50% solids. Forty cu. ft. per min. of air at 1-lb. pressure is supplied to each cell, and impeller power is 4 hp. per cell, making 2.1 hp-hr. per ton for roughing. In primary cleaning, 36 No. 40 cells treat 25 tons per hr. with the same power consumption per cell or 6 hp-hr. per ton. In recleaning, 6 tons per hr. is fed to 24 cells or 17 hp-hr. per ton. Over-all consumption for the three steps is about 6 hp-hr. per ton of original feed. These figures are in no way excessive for the service.

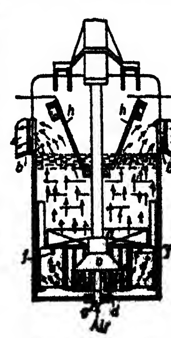

Fig. 40. Agitair machine.

Agitair machine (*U. S. pat. 2,182,442*/1939) consists of a rectangular trough, subdivided into a plurality of square compartments (Fig. 40) by transverse partitions with slotted openings *a* connecting adjacent compartments; a feed box at one end; an overflow weir at the other end for tailing discharge; two froth-overflow weirs *b* on opposite sides of each compartment; and an aerating agitator in each compartment. The agitator comprises an inverted cone *c* with cylindrically disposed teeth *d* depending from the periphery of the base, all mounted on a centrally placed spindle. Sixteen radial baffles *e*, equally spaced, are carried on a ring *f* and the structure is supported in place by the four corner baffles at such a height that a free circulation space is left underneath. Air introduced through pipe *g* is finely dispersed by the coaction of the impeller

teeth and the radial baffles; the latter also prevent swirl. Breaking down of bubble column by the agitator shaft is prevented by the V-shaped crowding baffle *h*, which is set to dip below pulp level; it also does away with the necessity for scraping froth.

SIZES are Nos. 24, 36, and 48, signifying the length in inches of the sides in plan of the square agitating compartments. Corresponding cell volumes are 10, 22.5, and 44 cu. ft. Drive is V-belt by 2-cell units; POWER installation is 1.5, 2.5, and 5 hp. per cell. Impeller SPEED is about 1,700 f.p.m. Units are 2-, 4-, and 6-cell and are built with registering feed and discharge ports in the end walls, to which feed and discharge boxes may be bolted or through which, when two sections are bolted together end to end, pulp in process passes. Bottom is lined with rubber and lower side walls with manganese steel. The baffle unit is supplied of alloy steel, reversible to permit double wear. IMPELLERS are of hard cast iron. Rubber sleeves therefor, enclosing the sides and outer surfaces of the teeth and the lower outer surface of the cone, are available, as are also impellers with standard rubber covering. Maker's statement as to POWER CONSUMPTION is that it ranges from 0.9 to 2.6 hp-hr. per ton according to the speed at which the ore floats. L. E. Booth (*PC*) reports 250 t.p.d. fed to a 10-cell 24-in. machine at MONTEZUMA-APEX, power consumption 0.9 hp-hr. per ton; at MAGMA, 250 tons to an 8-cell @ 36-in. machine, 1 hp-hr. per ton; at VIENNA, 75 tons to a 6-cell @ 20-in. machine, 1 hp-hr. per ton.

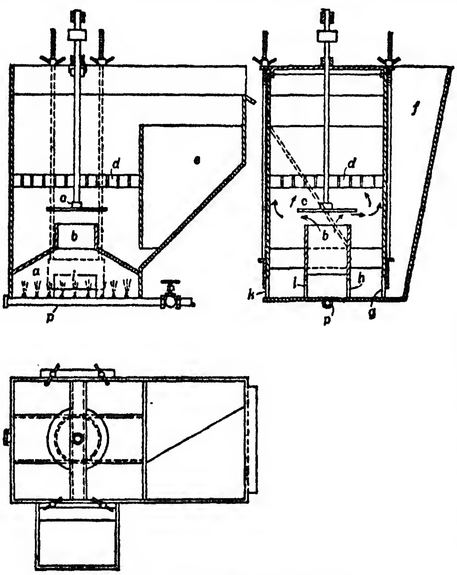

FIG. 41. Hall deep-cell machine.

Hall deep cell (*U. S. pat. 2,141,862;* Fig. 41). Pulp is aerated and circulation induced by introduction of multiple streams of air through pipe *p* into the pulp in a bottom compartment *a* of the cell; the coarsely aerated pulp discharges by internal air-lift action through a chimney *b* under a smooth disk c about 2 ft. diam., rotating at about 5,000 f.p.m., which produces very fine dispersion. Grid *d* prevents swirl. Feed is introduced at *f* and flows through ports *g* and *h* into compartment *a;* entry into *a* is also had by port *i;* middling drops out in *e* and is returned by the eccentric hopper to the feed side of compartment *a*. Tailing discharges through port *k*. The machine was designed for use at ALASKA JUNEAU for ores containing a very small amount of floatable material. Considerable saving in power and maintenance is claimed.

Gayford *et al.* (*U. S. pat. 2,073,148*) describe a perforated bladeless impeller over a canvas or rubber mat of slightly smaller diameter. The purpose is to reduce power and swirl. Compartment area to disk area should be about 3.8 : 1; cell area to mat area 5.7 : 1. Cell is 24 in. square, disk 14 in. diam., mat 12 in. diam., peripheral speed, 2,200 to 2,500 f.p.m.

Subaeration *vs.* **pneumatic machines.** Reliable comparative data are scarce. The weight of the evidence appears to be that for easily floatable ores of normal maximum sizes (65-m.) treated at usual pulp density (20 to 30% solids) the pneumatic cell gives the same metallurgical results as the subaeration but more cheaply. The subaeration machine, because of partitioning, permits greater flexibility in variation of treatment along the flow; it can handle thicker and coarser pulps; is more intense in its aerating action; by its attrition effects, it decreases harmful multicoating by collectors, and is, therefore, superior for the more soluble salt-type minerals (nonsilicate nonsulphides).

Logue, writing in the house organ of the manufacturer (*Tref 9/40*), gives comparative sizing-assay tests on Denver and air-lift machine products operating on the same ore (Table 14). With over-all recovery the same in the two machines, the subaeration made 1.4% better grade of concentrate, primarily because of better rejection of <10-μ gangue, the resulting loss in recovery at this size being compensated by a higher recovery in the coarser sands. Similar experience is reported on molybdenite at QUESTA (*IC 6551*), where the Ruth subaeration machine gave superior recoveries on sandy feed but the Callow was better on slimes.

At POTOSI (*IC 6706*) it was found that pneumatic machines would not float coarse mineral. At PECOS (*IC 6605*) it was concluded that air-lift machines with heavy sulphide pulps tend to float everything when enough air is used to maintain suspension, and that they are not good for close separations because the air cannot be cut below the suspension minimum, which may be too much. This view is not, however, generally accepted.

Table 14. Sizing-assay test of products of subaeration and air-lift machines in parallel service (*After Logue*)

PULP-BODY MACHINES

These machines may be classified, on the basis of the method of effecting gas precipitation (see Art. 11), into three types: (1) boiling, (2) chemical-generation, (3) pressure-reduction. The machines are characterized by the production of heavy-laden clotted froths, unless the amount of material floated is minute. They utilize relatively small amounts of gas, rarely more than 100 cu. ft. per cu. ft. of solid floated, running down to 20 cu. ft. per cu. ft. or less. Their elements vary somewhat according to the type, but comprise as essentials a tank to contain the pulp during the time of treatment, means for effecting gas precipitation therein, a tank (which may be the same as the first) in which the pulp is sufficiently quiescent to permit separation of agglomerates of gas and selected mineral from rejected mineral by gravity, and separate weirs or ports for discharge.

24. BOILING PROCESS

This process, described by Bessel Bros. in 1887, was the first of the froth-flotation processes. It is operated by heating a conditioned pulp, preferably containing some oily collector and preferably also lightly deslimed, to a temperature preferably below that of active boiling. Apparatus comprises any mixing tank in which oiling may be effected, and a second tank in which the settled sand underneath a relatively dilute pulp (15 to 25% solids by weight) may be heated and at the same time stirred gently to release gas-mineral agglomerates. Separation is rapid and relatively complete.

The method has not been used commercially for ores. Heating is expensive and slow. The process is operative with deaerated water in a sealed flask, *i.e.*, with water vapor only as the bubble filling.

25. CHEMICAL-GENERATION PROCESS

This process depends upon chemical reaction to generate gas in the pulp. The usual reaction is that between a carbonate and an acid to generate CO_2. Decomposition of the pulp water by electrolysis has been described (*Brit. pat. 13,579*/1904; *U. S. pat. 1,329,127*/1920). Deslimed feed and an oily collector are preferable. Apparatus for the CO_2 process comprises a mixing tank for conditioning and a separating tank in which the conditioned pulp mixed with finely granular limestone or dolomite is relatively quiescent. Here acid is added and the settled sand is stirred just enough to release agglomerates. Heat aids the operation materially.

Potter-Delprat process (*U. S. pats. 735,071*/1903, *763,662*/1904, *768,035*/1904, to Delprat and *776,145*/1904 to Potter) was the first froth-flotation process commercially successful with sulphide ores.

Dewatered pulp is fed into an apparatus of the type shown in Fig. 42. Hot sulphuric-acid solution of 1% to 10% strength or acid salt-cake solution of 1.3 to 1.4 density is introduced through the pipes *a* to the bottom of the vat. Dewatered sand carrying carbonate is fed to maintain a layer of solids 2 ft. or more in height, depending upon the depth of the vat, teetering above the spigot. A coherent froth overflows. The tailing is drawn off as a thickened product from the spigot at the bottom of the box. The compartment without a spigot is for the purpose of collecting any coarse particles that would tend to clog the spigot. Temperature was high enough in Australian operations to precipitate considerable air and water vapor. No oil is added, but there is no doubt that the lubricating oil introduced in ordinary mining operations is sufficient for collection and froth stabilization.

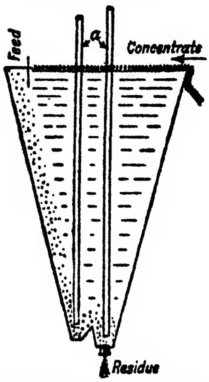

FIG. 42. Delprat frothing box.

Performance (*117 P 375*). The principal use of this process was at the BROKEN HILL PROPRIETARY MINE, N.S.W. Feed was deslimed tailing from the gravity-concentrating mill, practically all of which would pass a 40-m. screen and from 20 to 25% remained on 60-m. The gangue was principally quartz, rhodonite, and garnet with some gneiss from the walls and small amounts of rhodocrosite, siderite, and calcite, totaling about 0.5% CO_2. Feed assayed about 17% Zn, 3% Pb, and 4 oz. Ag per long ton. The boxes were cast iron, 8 ft. × 9 ft. surface area, 2 ft. × 1 ft. at the bottom, and 15 ft. deep. Solution pipes were cast iron, tipped for 2 ft. 6 in. with 2-in. lead pipe drawn down at the end to 1/2-in. and perforated near the end with 1/4-in. holes. Sulphuric acid solution (1%) heated to about 190° F. in stock-solution tanks by the use of superheated steam was mixed with the moist ore (6 to 9% H_2O) in the tank. Capacity was 10 to 20 long tons per hour. Recovery occasionally got up to 90% but the general average was 80%. Grade of concentrate was worked up to 48 to 49% Zn, 6% Pb, and 10 to 12 oz. Ag. Concentrate was about 8% >40-m. and 17% <200-m. Tailing assayed 3% Zn, 2% Pb, 2 oz. Ag per long ton. Three to 3. 5 tons of solution was added per ton of ore, entering under a pressure of approximately 15 lb. per sq. in.; acid consumption, including 1 to 2 lb. per ton of original feed discarded with the tailing, was 25 to 30 lb. per ton; strength of solution returning to stock tanks, 0.6% acid. Temperature of solution in the frothing boxes was 165° F.; and of solution drained from concentrate and returned to the stock tanks, 145° F.

At this same plant slime feed was concentrated with heated (140° F.) acid solution (0.3% H_2SO_4) without oil by sending the pulp through a series of four centrifugal pumps and separating boxes in alternate series. Concentrate assayed 34% Zn, 25% Pb, and 40 oz. Ag; tailing, 4% Zn, 9% total Pb (8% oxide), and 4 oz. Ag. Plant capacity was 3,000 tons per week.

Froment process was patented in 1902 in Italy and Great Britain but was not patented in the United States.

Finely pulverized ore with 1 to 2% of limestone is fed into a mixer in a pulp containing about 30% solids; animal or vegetable oil in an amount equivalent to 1 to 1.5% on the ore is added and the mixture agitated at the rate of 1,000 to 1,500 f.p.m. peripheral speed. The agitated mixture is next run into a shallow vat provided with a slow-moving rake at the bottom. Sulphuric acid of about 30% strength in an amount sufficient to react with the limestone present is slowly added through a perforated coil suspended just above the rakes. Desliming of the feed aids in making clean concentrate, but is unnecessary with certain oils or if a small amount of acid is added in the mixing vat.

The Froment process never went into commercial operation. Tests in a laboratory apparatus treating zinc ore gave rough concentrates assaying 35 to 45% Zn and tailings 0.6 to 0.8% from feed assaying 11 to 12%.

Other chemical-generation patents are described in *Ed. 1, 792*.

PRESSURE-REDUCTION PROCESSES

These processes have been described in three forms: (1) Plus-pressure type, in which an oiled (and preferably deslimed) pulp was subjected to superatmospheric pressure in a closed tank by pumping in air, and was then jetted into an open tank provided with a froth-overflow weir and a tailing spigot. This was never used commercially. A modern form for treating coal is described by Price (*U. S. pat. 2,142,207*). (2) Vacuum type. (3) Agitation-froth type.

26. VACUUM PROCESS

The essential elements of vacuum-flotation operations are conditioning of the pulp and subjection of conditioned pulp to a vacuum in apparatus that permits separation of froth and tailing. Deslimed pulp and an oily collector are desirable.

Elmore vacuum plant, which had limited commercial use, is shown in Fig. 43. Pulp ground to at least 0.5-mm. maximum size and containing about 50% solids was mixed in tank *d* with oil in an amount generally less than 0.5% on the ore, with or without acid, and thence was discharged into the feed pipe *a* of the separating apparatus. Here water was added to bring the pulp to a consistency of 15 to 25% solids. The separating apparatus was a closed conical chamber fitted with a slowly revolving rake at the bottom, a tailing-discharge pipe *b* at the periphery, and a concentrate-discharge pipe *c* from near the apex. The separating chamber was attached to a vacuum pump. The lower ends of pipes *b* and *c* were sealed by causing them to discharge below the surface of liquid in tanks as shown. The vertical lift in the pipe *a* was about 25 ft. and the vertical length of the pipes *b* and *c* was somewhat over 30 ft. A vacuum of 20 to 27 in. of mercury was maintained. Under the influence of this vacuum the pulp fed into pipe *a* passed up into the separating chamber. Froth overflowed into an annular launder and passed down pipe *c*. At the same time tailing was slowly scraped to the periphery of the floor and passed down pipe *b*. The rate of flow in pipes *a* and *b* was so regulated that the pulp level was maintained slightly below the overflow lip.

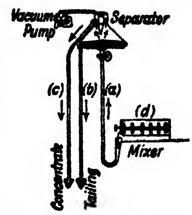

FIG. 43. Elmore vacuum plant.

Capacity of a 5-ft. separator was from 25 to 50 tons of ore per day. Re-treatment of concentrate was not ordinarily necessary. Power consumption per pan was well under 5 hp. for mixer and vacuum pump together.

Development of the vacuum process was stopped by the introduction of the agitation-froth process, but it is probable that if the same amount of work had been expended in attempts to make the vacuum process highly efficient, as was spent in bringing the agitation-froth process to its present degree of efficiency, the results would have been equally favorable. Slimes are easily treated, if sufficient agitation with proper agents precedes the vacuum treatment, but granular sulphide is most easily treated out of the presence of slime.

At ZINC CORPORATION (*88 J 205*) the feed to vacuum machines contained 20% Zn, 5.75% Pb, and 8 oz. Ag per long ton. Concentrate assayed 43% Zn, 11% Pb, and 17 oz. Ag.; tailing 3.5% Zn, 2.2% Pb, and 2.2 oz. Ag. ACID CONSUMPTION ranged from 10 to 20 lb. per long ton; Texas fuel oil, 6 to 8 lb. per ton. Cost of flotation alone (1909) was $0.55 to $0.60 per ton. Claudet (*103 J 786*) says that a standard unit will treat 35 tons of <10- or <20-m. molybdenum ore per 24 hr., using a small quantity of coal oil (kerosene) and that molybdenite floats preferentially to pyrite and pyrrhotite. Slime is overflowed before flotation. At KVINA MINES, Norway (*19 CMI 127*), feed assaying 0.8 to 1.0% MoS_2 produced concentrate containing 75 to 85% MoS_2, representing 80% recovery.

27. AGITATION-FROTH MACHINE

This machine is essentially a device for continuous production of localized superatmospheric pressure and partial vacuum in pulp in a tank open to the atmosphere. This result is effected by rotating a bladed agitator at high speed below the surface of pulp in an open-topped tank square in cross-section or baffled so as to prevent centrifugal swirl. The pulp in front of the impeller blades is under superatmospheric pressure, owing to its inertia and the pressure of the blade; that directly behind the blade is under reduced pressure owing to its lag behind the rapidly receding rear face of the blade. The rotation of the impeller introduces air by engulfment at the surface of the agitated pulp and, in shallow boxes, by downward extension of the vortex until its tip is cut off into the pulp by the revolving impeller. The engulfed air is broken up into fine bubbles by shearing action in the liquid induced by agitation, and dispersed throughout the mass of pulp in the box. That part of the aerated pulp in the region of superatmospheric pressure ahead of a blade dissolves air. When it escapes from this region, particularly if the escape is into the region behind a blade, there is rapid and pronounced pressure drop and gas precipitates. In so doing, if collector-coated particles are present, the precipitation is preferential thereonto. In continuous apparatus pulp discharges from the agitation chamber into a settling box provided with a froth-overflow weir and a tailing-discharge port.

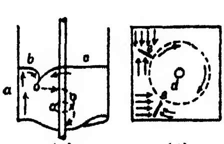

FIG. 44. Aeration by rotary agitation.

Aeration is readily observed in a deep square glass jar with a cruciform agitator near the bottom. When the jar is partially filled with water and the agitator is rotated at such a speed that occasional bubbles of air only are introduced, these act as tracers and the action of surface engulfment may be seen as in Fig. 44. In elevation *A* water forced up the corner *a* of the jar flows down hill at *b*. As it comes to the lower level *c* of the swirling water mass surrounding the impeller (*d* in plan view *B*) an irregularly oscillating downward-pointing V is formed along lines *e*. At irregular short intervals these close together above the point of the V and a bubble of air is engulfed. This travels in to the impeller

shaft and thence along a spiral path downward around to the region around the impeller blades, where it is broken up and dispersed. As speed increases the rate of surface engulfment increases until it becomes substantially continuous.

Gas precipitation by agitation. If the square glass jar is provided with horizontal baffles fitting as closely as possible around the shaft and against the walls and placed just below the water level, when agitation is started there is no surface engulfment and no vortex forms, hence there is no introduction of air from the surface. If, however, the rate of revolution of the impeller is gradually increased, a speed is finally reached at which the liquid in the vessel becomes cloudy, showing the presence of finely divided gas bubbles. When agitation ceases, air bubbles collect under the baffle plates. If these bubbles are released by tilting the plates and the impeller is again started, a higher speed must be reached before gas again precipitates, provided the temperature of the water has remained the same. Increase in temperature from 12° C. to 30° C., the heating being accomplished on a water bath without stirring, lowered the critical speed of gas precipitation with a 3-in. impeller from 1,535 to 395 r.p.m. When heating to the same temperature was done by an electric heater, on which much gas precipitated during heating, the critical speed was 940 r.p.m. Adding pine oil to the water (0.006%) lowered the critical speed at 12° C. to 980 r.p.m.

Table 15. Suction behind blades of the impeller of an agitation-froth machine

R.p.m. of impeller	Vacuum, in. Hg	R.p.m. of impeller	Vacuum, in. Hg
370	0.22 *a*	1,380	4.4
475	0.29 *a*	1,490	5.2
580	0.43 *a*	1,595	5.9
685	0.68 *a*	1,700	6.8
740	0.9	1,810	7.5

a Calculated from observations on water gage. Temperature approximately 20° C.

Vacuum produced by agitation. In the apparatus described in the preceding paragraph an opening in the back of one of the beater blades, near the tip, was connected to a vacuum gage by a conduit within the blade and by a hollow shaft with a stuffing box at the top. Pressures were read at different speeds with the results given in Table 15. At the higher speeds the vacua recorded were well below those actually existing, because of the fact that air coming out of solution behind the blades broke the vacuum by passing into the hole in the beater arm.

Effect of agitation on froth formation is shown in Table 16. The critical speed for the Gabbett laboratory apparatus at approximately ±30° C. lies between 310 and 380 r.p.m., but at this speed the rate of precipitation of gas was so slow that 75 min. was required for frothing to start. At 380 to 420 r.p.m. fair concentration was attainable in 70 min., but at 40 min. it had not started. Compare these results with those in tests 10 to 13, representing the normal speed range for this machine. The speed at which froth production begins corresponds with that at which gas precipitation begins in the square glass jar machine of corresponding size.

Table 16. Effect of agitation on froth formation in agitation-froth process

Test number	Impeller, r.p.m.	Duration, min.	Temperature, deg. C.	Froth, in.	Segregation of sulphide *a*
1.......	170 to 235	75	34 to 30	0	0
2.......	265 to 320	75	32 to 29.5	0	Very slight.
3.......	310 to 320	15	31 to 30	0	Slight.
3 con'd.	310 to 370	30	31 to 29	0	Do.
3 con'd.	310 to 370	45	31 to 28.5	0	Slightly increased.
3 con'd.	310 to 370	60	31 to 28	0	Do.
3 con'd.	310 to 380	75	31 to 27.5	1/4	Partial.
4.......	380 to 390	25	31 to 30.5	0	Very slight.

Laboratory Gabbett mixer (see *Ed. 1, 799*). Zinc ore, 18.7% Zn. 18.8% solids. Oleic acid, 3.0 lb. per ton; H_2SO_4, 36.6 lb. per ton.

a Degree indicated by change in color of settled solids from gray to white and actual appearance of agglomerates.

Minerals Separation machine (Fig. 45), as installed, consisted of a plurality of connecting cells on the same level. Each cell comprised an agitating compartment *a* and froth-separating compartment *b*. The cruciform agitator had blades inclined 45°, and was carried close to the floor on a vertical spindle *c*, driven through enclosed bronze bevel gears from a horizontal line shaft. End thrust was combatted by opposing the gears. Feed was introduced into the first agitating compartment, or passed first through one or more agitating compartments, without froth-separating boxes, for conditioning. Agitated pulp flowed through slot *d* into the froth-separating compartment, entering at a point about 6 in. below the pulp level. Tailing flowed from the froth-separating compartment through pipe *e* into the bottom of the next agitating compartment, under the influence of the pumping effect of the agitator therein. Rate of flow was regulated by means of valve *f* actuated by hand wheel *g*. Froth was removed by revolving scraper *j*. Six to 20 cells in series constituted a unit.

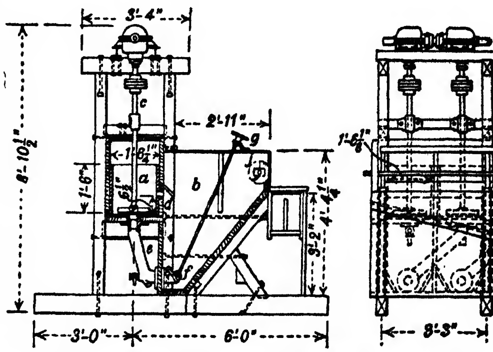

FIG. 45. Minerals Separation 12-in. standard machine.

Low-level machine had a shallower spitzkasten, the bottom of which was but little below the level of the bottom of the agitation chamber, and the overflow lip was at such a level as to maintain a pulp depth of 9 to 12 in. in the agitation chamber when the machine was liquid-filled at rest.

SIZE of a unit was indicated by the distance tip to tip of the impeller blades and the number of cells in series, *e.g.*, 24-in. 12-cell. Usual impeller sizes were 12-, 18-, and 24-in. Time factors ranged from 15 to 30 min. in roughing service at pulp densities of 25 to 45% solids for <48-m. pulps, which works out to 0.3 to 7 tons per cell per hr. POWER CONSUMPTION per cell was 1.5 to 3 hp., 2.5 to 5 hp., and 3.5 to 10 hp. respectively for the three sizes, depending upon speed, specific weight and viscosity of pulp, and the pulp level, whence consumption per ton of ore ranged from 0.8 to 15 hp-hr. and probably averaged between 2 and 4. Power for low-level machines was 60 to 70% that of the standard machine. Peripheral speeds ranged from 1,500 to 2,500 f.p.m. with the average near 1,700 f.p.m. Considerable trouble was experienced from gear wear and breakage.

Reagent consumption is, in general, higher in pulp-body than in bubble-column machines.

Use of agitation-froth machines, except for a few lingering relics, has practically ceased. They were extravagant in power consumption and maintenance and of low capacity. They served a real need in the days of oily collectors of low selectivity. They have today a restricted field for the treatment of ores containing particularly refractory primary slimes where attrition cleaning (Sec. 10) of sandy particles is helpful. Forms of agitation machines that had definitely local use are described in *Ed. 1, 803.*

28. COMBINATION MACHINES

Pneumatic and cascade machines operate by pure unassisted bubble-column or contact action; agitation-froth machines are just as distinctively precipitation-type. Utilization of precipitation selection to aid bubble sweeping in presentation of floatable mineral to the bubble column in high-speed subaeration machines has been discussed (Art. 23). Machines which thus utilize the two types of selection are called combination machines. The Janney machines described below typify two further types.

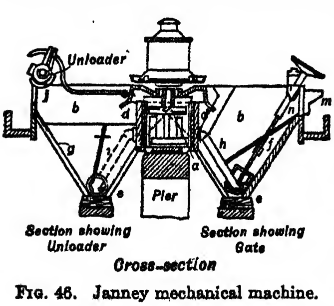

FIG. 46. Janney mechanical machine.

Janney mechanical machine (Fig. 46) shows the form introduced in the mills. It consisted essentially of an agitating compartment *a* with two froth-separating compartments *b*. The agitator shaft was an extension of the spindle of a 6-hp. vertical motor, 570 r.p.m. It carried two four-armed impellers with blades set at 45°. The agitating compartment was circular and contained four baffles extending slightly more than one-half the distance from the bottom toward the top. The arms of the lower impeller were shorter than those of the upper in order to clear the baffles. Feed was introduced through the side of the agitating compartment, near the bottom, by means of a pipe, thrown out through the channels at the top on each side of the agitator compartment, and introduced, by means of the submersion blades *d* slightly below the level of the pulp

in the froth-separating compartments. In general, several machines were installed in series on successively lower levels. For detail of pulp circulation see *Ed. 1*.

Five to 15 cells comprised a unit. SIZE was indicated by the diameter of the agitation chamber and the number of cells in series. Usual peripheral SPEED was 3,600 f.p.m. POWER CONSUMPTION of a 24-in. machine was approximately 6 hp. per agitator. CAPACITIES reported on <48-m. pulps at 20 to 25% solids ranged from 25 to 60 tons per cell per 24 hr.

The concentrating action in the agitation chamber of this machine is pure and highly efficient selective gas precipitation. The discharge into the spitzkasten aerates the pulp therein by cascade action and the introduced air sweeps up pulp and starts bubble-column action, particularly at the rear of the spitzkasten. This is rarely a happy condition in the operation for the reason that it tends to unload the floatable mineral from the air-water interface where it is tightly held to a liquid-liquid interface with much smaller supporting forces, and then, as the froth layer moves toward the overflow lip the supply of air is insufficient to maintain the bubble-column action and the loosely held material showers down into the spitzkasten and must be returned to an agitating box in order to be picked up again. The Janney laboratory machine, because of its smaller size, has much less cascade action and was much more efficient than the mill machine.

Janney mechanical-air machine utilized pulp-body concentration by the agitation-froth method and bubble-column action by pneumatic and cascade means. This combination of processes was effected by placing air baskets in the froth-separating compartments of a Janney mechanical cell. See *Ed. 1* for detailed description. CAPACITY of a 24-in., 5-cell machine on siliceous ore in a pulp containing 20 to 25% solids was 150 to 200 tons per 24 hr. POWER CONSUMPTION per agitator was 6 to 7 hp. AIR CONSUMPTION per square foot of air basket was from 5 to 10 cu. ft. of free air per min. at 4 to 5 lb. pressure, corresponding to an additional power of 5 to 8 hp. per machine.

Final separation in this machine is done by bubble-column action. The precipitation selection in the agitating compartment serves simply to hasten the arrival of floatable material at the bubble column. This, however, has secondary effects. It decreases the burden of pulp sweeping on the air rising to the bubble column; it makes the bubble-column feed effectively (although not by assay) of higher grade than it would be in a straight pneumatic cell, it reduces the amount of bubble-column air required and, by reduction in the depth of pulp body necessary (because floatable particles are carried to the column by the precipitated bubbles), it reduces the pulp back pressure and blower power consumption.

29. DESIGN OF FLOTATION MACHINES

The aims in design are high recovery, high grade of concentrate, and economy of installation and operation. The essential functions of a flotation machine are to effect attachment of floatable particles at an interface and thereafter to lead attached and unattached particles to different discharge ports. Good design is that which brings about the performance of these functions in such a way as to satisfy the above aims.

Recovery is dependent on many other factors than the machine. From the machine standpoint alone, however, it must be borne in mind that good recovery cannot be effected, no matter how efficiently all other steps of the process have been carried out, unless a flotable particle becomes attached to the separating interface and is maintained attached until it passes through its discharge port. Furthermore, since attachment to the separating interface is never immediate for every suitably conditioned particle and never permanent for all particles once attached, attainment of high recovery requires that floatable particles be afforded repeated opportunities for contact and that, contact having been once effected, the mineral-bearing interface be moved as rapidly as possible to the concentrate-discharge port, and be protected in such travel from strains and shocks that tend to break the contact. It follows also that the apparatus should be designed for repeated recirculation of particles through the air-swept zone; this is attained both by recirculation means within single compartments or cells and by multiplication of such compartments in series.

At CLIMAX (*153 A 588*) recovery was raised 1% by placing 30 Weinig cells in series as against 3 @ 10-cell machines in parallel. E. W. Engelman reports that at UTAH the capacity for a given recovery of 16 cells in series was 1,000 t.p.d. while the same cells in 2 @ 8-cell blocks in parallel could treat only 800 t.p.d.

Grade of concentrate is dependent, after given suitable pulp preparation, upon prevention of mechanical entrapment of gangue particles in the interfacial structure, and rejection of such particles as become entrapped prior to discharge of the mineral-bearing interface from the machine. The fundamental demands here are just the reverse of those of the preceding paragraph; they entail impeding, or at least not encouraging, movement of particles toward the selecting zone, and affording every opportunity for particles in the zone to get out.

Economy of installation and operation requires high capacity, low power consumption, ease of operation (low attendance requirements), and good mechanical design (low maintenance). Additionally the coarser the feed that can be handled, the less the amount that must be expended for grinding beyond that required to free the mineral species.

Elements of design common to all machines are: (1) transport of particles to the zone of selection; (2) formation and conformation of the selecting zone; (3) separation, including movement of separated products to the discharge ports; (4) recirculation of unfinished material; (5) utilization of machine volume; (6) mechanical features. The incidence of these factors differs according to the selecting interface employed and to the method of

effecting attachment thereto, *i.e.*, whether by contact or precipitation. Consideration is easiest if the various classes of machines are considered separately.

Design of Bubble-Column Machines

Selecting zone is the bubble column. It must be supported laterally and at the bottom. Its capacity depends, all other things being equal, on the interfacial area that it contains. This is determined by its over-all volume and by the size of the constituent bubbles. Height of column and rate of bubble rise determine time available for separation of any given mass of pulp presented to a given horizontal area at the bottom; barring inoperatively restricted air supply which produces a bubble-rising rate so low that floatable mineral can fall back into the pulp after it has made contact with and become attached to a bubble, and barring overloading and local breakdown, particles once attached to a bubble tend to be carried to the top of the column. Consequently depth of column and rising rates within the operative range affect only grade of concentrate. Horizontal extent of column determines the amount of pulp that must be treated per unit volume of column for a given depth with a given feed rate or, conversely, the amount of feed that may be presented to the column per unit of time and yet permit the required time to make the desired concentrate grade in the overlying volume. In other words, requirements as to concentrate grade set column depth for a given rate of bubble rise; recovery requirements set horizontal column area for a given capacity and grade. In general, high-grade feeds require less air than low-grade; more air is, therefore, required in scavengers than in roughers.

Transport to selecting zone. The bubble column in all commercial machines excluding, perhaps, that at the back of a Janney mechanical-air machine (Art. 28) rests upon the body of pulp undergoing treatment. Transport of feed to the column is effected by sweeping pulp upward from this body into the column in minute masses held around the bubble by viscosity.

Gaudin (*F 92*) states that the liquid pulp in an operating pneumatic machine is expanded 15 to 35% by the air contained at any instant. Taking 25% as an average and 2 mm. as average bubble diameter, and assuming rectangular-packing arrangement of the rising bubbles (assumption of diagonal packing changes the calculation but little), the average face-to-face spacing of bubbles in any plane (closest approach if the rise were vertical) would be about 1 mm., the maximum (diagonal) spacing would be about 2.5 mm., and the average horizontal cross-sectional area occupied by bubbles would be about 35% of the total. It will thus be seen that 35% of the cell cross-section is swept by each layer of rising bubbles. Since the velocity of rise of 2-mm. bubbles is about 150 mm. per sec., disregarding water currents, the number of rising-bubble layers per sec. is about 50, which means that each horizontal sheet of pulp in the cell is completely swept through by bubbles between 17 and 18 times per sec. While not too great dependence can be placed on an approximation of this character, it does serve to explain, since each rising bubble carries a sheath of pulp upward into the bubble column, how the pulp is raised into the separating zone.

One test of the effectiveness of air sweeping is the quantity of air per minute per cubic foot of cell volume; if this is low, sweeping is comparatively inefficient. Transport is aided by directing pulp flow toward the under side of the bubble column. To sweep the pulp effectively it is essential that as large a proportion thereof as possible shall be undergoing sweeping at any given moment. Unswept pulp fills dead cell volume so far as concentration is concerned.

Mat-type pneumatic cells with fixed bottom-positioned mats and vertical side walls (Fig. 47, item *A*) maintain the greatest proportion of pulp in sweeping position of any of the bubble-column machines, but lose sweeping effectiveness because of large-sized bubbles, loss of effective mat surface through clogging of mats and sand sedimentation, and eddy currents which produce actual downward movement of bubbles relative to the cell walls in some parts of the cell.

Rotating-mat V-type cell (Fig. 47, item *B*) sweeps a large proportion of the total pulp. It does not suffer serious loss from sedimentation, but does have a tendency to boil at the center by reason of greater air supply at this point owing to lower back pressure; the pulp below the center of the air tube is substantially non-air-swept. Air bubbles are of the same size as in the stationary-mat cells.

Cascade machines (Fig. 47, item *C*) are the least efficient from the standpoint of air sweeping. The air supply itself is relatively inadequate, the dispersion is low, and considerable cell volume is sacrificed in baffling *a* to prevent short-circuiting of pulp from feed to discharge.

Air-lift cells (Fig. 47, items *D*, *E*) use proportionately less of their volume for air sweeping than either the mat-type pneumatic or cascade cells. On the other hand the air is more finely and completely dispersed and the air-swept zone is more quiescent than in any other type of bubble-column cell. The effect of bubble size is illustrated strikingly by comparison of the two types of air-lift cells. A given mass of air remains in the deep-cell air lift (*E*) for a period at least twice as long as in the standard-cell lift. The degree of agitation in the lift is about the same in both. Hence the dispersion of air in the pulp cascaded to the air-swept zone is much finer in the deep cell and the volume held is also greater. The resulting capacity of the deep cell per foot of length is 5 to 6 times as great as that of a shallow cell

of the same width while power consumption shows no proportionate increase (Art. 21). Not all of the increased efficiency is due, however, to more effective air-sweeping; no small part arises from the increased selecting area in the bubble column incident to the decrease in size of bubbles going to it.

Subaeration machines show a great variety in air-swept volume and in effectiveness of sweeping. A simple lift-type impeller with underfeed of air as shown in item F would give a central air-swept cone as shown, but no bubble column could be maintained above it because of boiling at the center due to both the mechanical lift and large air bubbles. Various bafflings are, therefore, employed to protect the bubble column and to break down large bubbles; each of these has its effect on the air-swept volume. Fig. 47, item G, shows the effect of reversing the impeller in F and baffling above with a honeycomb baffle. The air-swept volume is substantially unchanged, but the surface will maintain a bubble column, if the cell is made deep enough. In item H the impeller is top-shrouded, which tends to protect the area above it from disturbance. Inwardly projecting baffles from the side break up swirl and increase agitation in the zone directly around the impeller. Downwardly projecting straight blades, which may be multiplied and variously staggered (see Weinig, Geco, Agitair, Art. 23) both increase agitation directly in the impeller zone and decrease unidirectional flow (center to walls). The air-swept volume is not substantially increased, but the effectiveness of the air itself is greatly increased by reason of the finer dispersion. The double-shrouded impeller of the M.S. American-type cell gives the same air-swept volume, but is less effective in dispersion. In the form shown in item I (Denver) the impeller is bottom-shrouded and a bladed shroud is fixed in place above it. Baffling is of the same general type as in item H. Air-swept volume is substantially unchanged, dispersion is somewhat finer owing to the shear set up between the fixed and moving shroud blades. The form shown in item J (Fagergren) has the greatest percentage of aerated volume of any of the subaeration cells. This is attained by greatly increasing both the actual depth of the impeller and the proportionate depth referred to the cell. This increase is made possible by increasing horizontal cross-section proportionately to the impeller diameter, and by breaking up unidirectional currents by means of a cylindrical grid surrounding the impeller. Excellent dispersion is attained by using high peripheral speeds.

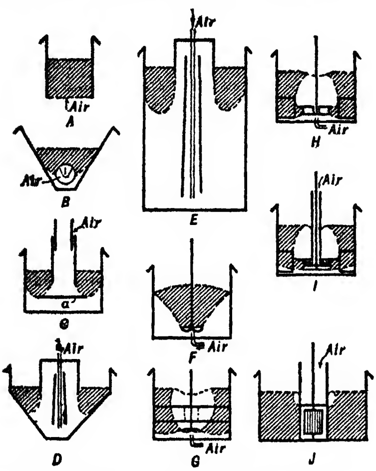

FIG. 47. Air-swept volume in bubble-column cells.

The smaller the diameter of the impeller relative to the horizontal dimensions of the cell the larger the air-swept volume, all other things being equal. But small impellers mean small blade surface and small volumes of highly agitated material, so that the volume of finely dispersed air is correspondingly small unless compensating changes are made elsewhere.

Transport of floatable mineral is aided in forms H, I, and J by running the impellers at such speeds that substantial vacua are formed behind the propeller blades and their equivalents (see Art. 27).

Separation is the entire operation of causing selected and rejected particles to follow divergent paths. It involves vertical movement of particles in the bubble column and horizontal movement of froth and pulp to and through their respective ports and conduits. It is the operation at which control is aimed, and is the most complicated of the elements of design.

The ideal bubble column is one containing sufficient separating surface to insure room for contact for all of the floatable mineral brought to it during the time interval that such mineral must spend in the column to permit separation; loose enough in texture at the bottom to permit ready egress of the large volume of reject that must be dropped out; and thin-walled enough at the top to offer viscous resistance to the fall of selected mineral in addition to retardation due to interfacial tension, in order that the selected load may be held up long enough to be overflowed. Such a column should be lively enough (have sufficient bubble coalescence) to shake out reject, but this is a matter of frothing agent rather than of machine structure. Otherwise the column should be as free as possible of strains, *e.g.*, disturbance by impeller shaft. Depth of column and rate of bubble rise should be readily regulable, if possible without changing the time available for air-sweeping of pulp.

Froth overflow may be by gravity, or the froth may be scraped off, or it may be crowded off, which is to say pushed off by rising air. In any case more or less horizontal movement occurs and external strain incident to the movement is imposed. The path may be extended by sloping the wall beneath the overflow lip outwardly, in which case the air supply to the extended path is diminished and it may be cut off entirely by suitable baffling. Any such extended path increases separating time, and with diminished air supply upsets the rising bubble-falling particle equilibrium in the column in favor of fall so that the slower

rising stratum, consisting usually of coarse and locked-middling grains, falls out. The strains incident to horizontal flow also shake down some solid.

A method of gaining separating time without losing rising-bubble support that is sometimes practiced with freely flowing froths in long cells with normally full-length overflows is to build up the sides for a greater or less distance from the tailing-discharge end toward the head end, thus forcing tail-end low-grade froth to flow back over richer pulp in order to reach its overflow port. The result is usually a higher average grade of concentrate without change in tailing assay.

Tailing flow is normally transverse to froth flow. In trough-type machines without transverse partitions, usually pneumatic or cascade types, pulp flow is commonly in the form of a confused double spiral around parallel horizontal axes symmetrically spaced on both sides of the longitudinal center plane of the trough. The tighter the spiral and the more rapid the peripheral rate the more frequently the pulp is brought into the air-swept zone.

Tank should be so proportioned and conformed as to return settled material to the air-swept zone as rapidly as possible. This is usually accomplished by sloping the tank bottom toward the point of air introduction.

Subaeration machines are usually partitioned transversely. In some of these pulp flow is simply undirected displacement through large slots in the partition walls, the cell circulation being depended upon to move pulp into the air-swept zone and to return it sufficiently often to insure eventual transport to the bubble column. Most of the machines which depend upon precipitation levitation to aid transport lead the stream entering a cell directly to the agitator in order to insure at least one passage of all pulp through the pressure-reduction zone.

Tailing-outlet ports are preferably weirs, since these are less readily clogged than submerged ports and flow across them is more easily regulated. They must, however, be supplemented by sand-relief ports unless feed is all <48-m. Compartmented cells may have weir discharges from cell to cell, this arrangement permitting control of pulp level in individual cells.

Malozemoff and Ramsey (*142 #3 J 45*) point out that machines without transverse partitions are easier to control, consume less power, are easier of access, have lower maintenance costs, and are cheaper to build. It must, however, be borne in mind that these economies are gained at the expense of reduced circulation of pulp through the air-swept zone and that unless there is compensating increase in efficiency therein, the machine must be increased in length or higher tailing will result.

Recirculation has two facets, *viz.*, (1) return of pulp to the air-swept zone and thence to the bubble column, and (2) return of low-grade overflow (middling) from the tail end of the cell to an earlier point. The first type has been discussed in considering flow of pulp, except that in some cells (Fagergren, M.S. countercurrent, Janney) attempts are made to direct recirculation to a certain extent.

Middling return can be effected by gravity flow in trough-type subaeration machines, whether compartmented or not, if the cell bottom is substantially level (see Denver, Art. 23).

Mechanical features should be considered first from the standpoint of how well they serve the primary functions of making recovery and grade of concentrate, secondly as to continuity and ease of operation, and finally as to the supply and labor costs involved in maintenance. Apart from the questions of air-sweeping, protection of bubble column, and direction of separating flows, provision must be made to prevent sanding up. This involves elimination of dead spots in the pulp path, arrangement of pulp passages so that incipient constrictions tend to increase pulp velocity and so increase carrying capacity as to scour out the settled material, and provision of sand bleeders which short-circuit settled material directly to a zone of greater agitation. It is important also to so design that a cell can be restarted after an unexpected shutdown without emptying. This is not difficult to arrange in machines operating with extraneous air supply; with other machines it is wise to provide for piping high-pressure flushing water to impeller zones, closed pulp passages, sand bleeders, and the like. Such entry points, and air-entry pipes also, should, so far as possible, point downward. All conduits should be as short as possible, particularly with heavy ores. Rubber pinch tips, which insure against sand entry, are now available (Art. 21).

Impellers should be designed to serve the purposes of effecting the desired presentation and representation of pulp to the bubble column, and of fine dissemination of air, with minimum wear and consumption of power. The rules of design are not established. Simple propulsion and circulation would seem to be best effected by upright radial blades, the propulsive effect increasing with height and length, but not directly with number. Dissemination of air is increased by placing baffling close to the impeller and by increasing the number of blades and baffles. Beyond these almost obvious considerations, design is wholly a matter of trial and error.

Rubber and rubber-covered impellers have proved consistently economical. At UTAH the covered impellers in Fagergren machines last 4 times as long and cost only twice as much new as the uncovered.

IMPELLER SHAFTS should be of large diameter, carried in long bearings, preferably of ball or roller types, mounted on a sturdy framework. V-belt DRIVES are superior to gears. Efficient protection against pulp splash and lubricant drip should be provided. With coarse or abrasive pulps, the impellers and all baffles, liners, and other stationary parts that come in contact with swiftly moving pulp should be rubber-covered. This applies also to down-pipes in air-lift cells handling dense pulps. Valves and sliding gates or weirs handling sandy pulps are anathema; when unavoidable they should be moved by heavy hardened-steel stems with power threads, well protected from splash.

Power of top-shrouded 45° impellers was tested by Read (*91 Aa 377*) who found that with constant peripheral speed the power draft increased with impeller diameter (using 15- to 24-in. impellers in a 3×3-ft. tank with different submersions) but that the volume of air did not increase proportionately, so that the smaller impellers gave more aeration per unit of power. Increasing submersion of the impeller from 28 to 40 in. increased power consumption about 12% with the 15-in. impeller and about 9% with the 24-in., but aeration decreased from 17 c.f.m. to 9.5 c.f.m. with the 15-in. impeller (44%) and with the 24-in. impeller from 24.5 cu. ft. to 12.5 (49%) so that the loss in aeration per unit of power with increase in submersion was serious. Increase in power consumed with increase in peripheral speed was at the rate of about 0.3 kw. per 100 ft. peripheral for water and about twice this figure for pulp of 1.5 sp. gr. With an 18-in. impeller at 322 r.p.m. and 47-in. submersion, power increased from 2 kw. per spindle at 1.0 gravity (water) to 3 kw. per spindle at a pulp gravity of 1.54 by substantially equal increments. Fahrenwald (*Pamphlet 64 IBMG*) obtained similar results in a miniature cell; he also estimated the extent of subdivision of the air introduced and the corresponding area of new surface, and, from known surface tensions, calculated that the efficiency of his laboratory apparatus as a producer of new surface was of the order of 0.3%.

Rose (*A TP 1702*) compared energy inputs per cu. ft. of pulp volume with cell capacity for 12 semi-random plant performances. A summary of the data follows:

Machine *a*........	1	5E	3D	2 *d*	5A	4	3B *e*	3C	3A *e*	5C	5D	5B
Capacity *b*........	2.54	2.45	1.71	1.37	1.20	0.76	0.70	0.66	0.63	0.53	0.53	0.21
Power *c*..........	0.16	0.17	0.11	0.13	0.10	0.09	0.04	0.09	0.06	0.10	0.09	0.05

a Numbers refer to 5 different plants. Cells 1, 5A, and 5B were matless type; cell 2 was a sub-aeration type with some blower air; cells 3A, 3B, 3C were of the same general type as 2 but of a different make; cells 3D, 4, 5C, and 5D were completely self-aerating; cell 5E was a self-aerating cell of a different make.

b Dry tons new feed per 24 hr. per cu. ft. of cell volume.

c Hp. per cu. ft. of cell volume.

d Feed 6.4% >28-m., 33% <200-m.; 50% solids in pulp.

e Feed 87% <200-m.

Feeds to the 12 cells ranged from 20 to 50% solids, specific gravities of the pulps from 1.15 to 1.52, percentages <200-m. from 33 to 87, and machine depths from 24 to 114 in.

The data of Read and of Fahrenwald show that the proportion of total power input required for pulp suspension is a function both of depth of pulp and of pulp density. Rose points out (notes *d* and *e* of correlation) that particle size is also a factor in the energy required for suspension, which is, of course, common experience. Recirculation of pulp through the air-swept zone consumes power, and differs in extent in different machines. Hence the fact that except in the instances in which particle size and pulp density were grossly out of line, energy consumption and machine capacity to (presumably) a common base of metallurgical performance varied directly, points to the conclusions that modern flotation machines have reached a substantially common level of design so far as effectiveness in pulp suspension and recirculation are concerned, that the five plants reported had reached a common level of acceptance of metallurgical recovery, and that the differences in the machines employed resolves itself into one of intensity of work done in dissemination of air per unit volume of pulp undergoing treatment. The necessity for fine dissemination has long been recognized. The trend from pneumatic toward subaeration machines, and the trend in design of subaeration machines toward straight-bladed impellers and shrouds and close spacing of the two are convincing evidence of this recognition. The Rose correlation is a quantification of the principle, and confirmation of the correctness of the line of attack from a power standpoint. Whether the trend is economic requires consideration of maintenance costs and scrutiny of the metallurgical results; these latter the correlation implies to have been equally efficient.

Design of agitation-froth machines differs from that of bubble-column machines in two important respects, *viz.*, (1) the selecting zone is the zone of agitation, and (2) the separating zone is the quiescent pulp after agitation. The only part of the zone of agitation that is effective for selection is the relatively minute volume of pulp directly behind the outer part of the impeller blade at any given instant. Since pulp cannot be held in this position for more than a very short interval at a time, the agitator and the agitating compartment should be so designed as to lead pulp again and again into the active position, to enlarge the active zone and to make the tendency to precipitate gas therein as great as possible.

30. TABLE FLOTATION

This process, also called AGGLOMERATE TABLING, was discovered by Cattermole in the early 1900's, rediscovered by Christensen in 1921, and patented by Chapman and Little-

ford (*U. S. pat. 1,968,008*) in 1934. The essential elements of the operation are: (1) elimination of slime and use of a sandy feed of not too great size or size range, (2) collector-coating in a thick pulp, preferably in a manner that will introduce air, (3) dilution under conditions that will introduce more air, (4) treatment in the normal way in gravity-separation apparatus, preferably a shaking table.

Desliming is done in the usual apparatus (Sec. 8), the particular type of deslimer chosen depending upon the character of the slime. If slime coats the valuable mineral and prevents collector-coating, or coats gangue and induces collector-coating, desliming must be thorough, and will generally follow conditioning with a dispersant (see Art. 8). If the slime does not coat solids appreciably, much less thorough desliming is necessary, since it is, in general, the kinds of slime that do such coating that collect in the oil-water interfaces and hinder the oil from coating the solid to be floated.

Size of feed. The maximum size of grain (sp. gr. 3) that has been table-floated commercially is about 1/8-in. The usual maximum is 6- to 10-m. Sand as fine as 200-m. can be handled but table capacities are low on sands <65-m., whether treated alone or in admixture with coarser material. Best results are claimed (*IC 3247*) when the ratio of maximum to minimum grain diameters in the feed is 2.8 : 1.

Collector-coating in a thick pulp is advantageous from the standpoint of economy of collector, conditioner capacity, and power consumption, primarily because it keeps the oil close to the solid particles at all times, thus increasing the probability of contacts, and because the rubbing of the particles together smears out adhering oil droplets into the thin films that are essential for bubble attachment. In operations in which reaction with an earth metal is involved in collector-coating, a preliminary treat with alkali, preferably followed by a second desliming, quickens collector-coating and reduces the quantities of collector required.

Aeration during collector-coating in thick pulps is desirable. The introduced air bubbles are pressed against the oil-coated particles and attached to them and then, because of the large contact angles (>90°), leave behind small residual bubbles when they are subsequently broken away by the continued agitation. The result is that the oil-coated particles become frosted, as it were, with a coating of very small, strongly adherent bubbles. Other and larger bubbles also become attached interiorly of two or more oiled particles, cementing them together into agglomerates, and being themselves more or less protected against dislodgment by their interior positions.

Dilution is and should be effected by dropping the stream of thick pulp into the dilution water, as in the feed box or onto the deck of a shaking table. The result is that each particle or droplet of pulp carries down into the water a blob of air, a part of which at once coalesces with the air bubbles frosting the particles, thus tending to produce more agglomerates.

Separation is effected because the air-mineral agglomerates are larger and specifically lighter than the nonagglomerated material. In general, the degree of levitation is insufficient to cause actual flotation in water. But reasonable separation can be made in a rising-current classifier or in a lively jig bed, and excellent high-capacity separation is made on shaking tables. On the last apparatus an additional mechanism of separation is utilized in the fact that as the levitated particles cross the riffle tops in flowing toward the normal tailing side of the table, some of them break through the water surface and are held thereon as a skin float and carried off rapidly by the surface water. The proportion thus separated increases with decrease in the volume of cross water.

Ordinary shaking tables (Sec. 11) are used, provision being made to guard, as far as possible, against high wear due to the heavy loads of coarse pulp. The oil tends to coat and form gum deposits on lineoleum decks. Masonite decks at SOUTHERN PHOSPHATE (*143 #2 J 80*) were found to resist gumming and not to warp.

Conveyor separator. At CORONET PHOSPHATE CO. (*143 #12 J 51*) conveyor belts are substituted for shaking tables as the separating means. Aeration is effected by jetting water into the pulp along the center of the belt, and agglomerates flow to and over the edge. Diagonal scrapers turn the pulp over during the run and heap up a ridge along the centerline of the belt. Rod scrapers in V-shape turn over the roughed feed for scavenging toward the tail end of the belt. Rough concentrate has to be cleaned. A 30-in. × 70-ft. level belt at 80 f.p.m. roughs 10 to 17 tons per hr. of deslimed sand containing 25% solids. The belt has straight idlers at 1 ft. centers. Two lines of pipe, 6 in. apart along the centerline, 5 in. above the belt, drilled at 2-in. intervals with 3/32-in. holes, supply jet water. Blade scrapers are used for 40 of the 70-ft. length, the V-rod scrapers the balance. A 60-in. cleaner belt, 70 ft. long, runs at 65 f.p.m. and serves the three roughers. It has 4 spray lines. RECOVERY is said to be 85 to 90%; grade of concentrate on a pilot test was 74.9% B.P.L. Three men are required for operation of the plant, including desliming classifiers, and a 20-ft. log washer and 4×30-ft. inside-spiraled drum used in series for conditioning.

Screen separation. At SWIFT & CO. (*43 #5 RP 27*) 20∼48-m. phosphate rock suitably conditioned is run over fixed, submerged screens (18-m. aperture), inclined 50 to 55°, to remove the coarse agglomerates; undersize is sent to tables for separation.

Quantities of collector employed in table flotation are larger than in froth flotation, amounting, for nonmetallic salt-type minerals, to 0.5 to 1 lb. of fatty acid and 2 to 4 lb. upward of petroleum oil per ton of feed. Circulation of water in Florida phosphate practice tends to reduce the quantities to 50 to 70% of those required in parallel operations

with fresh water. Despite high reagent costs, however, table flotation is cheaper than froth flotation because of savings in grinding, power, and installation.

Applicability. Table flotation is indicated when the spread in specific gravity between valuable mineral and gangue is too small for gravity tabling (Sec. 11, Art. 15), severance is effected at sand sizes, slimes can be discarded or otherwise treated, and subsequent use (and consequent value of concentrate) are unaffected by the oil coating.

OPERATION

Flotation is a chemical process. It follows that successful operation requires knowledge and control of the composition of the entering ingredients, their reactions and reaction rates. With this basic aim the definable elements of control are: ore, water, reagents, machine, feed rate, pulp density, feed size, temperature.

31. ORE

The genesis of ores constituting flotation feed and the story told about them by the microscope are of vital importance to the flotation operator, because not only may the behavior of a given particle in the cell be determined entirely by the chemical constitution of a very small part of its surface, but also the behavior of the ore as a whole may be influenced to a considerable extent by the presence of a gravimetrically minor constituent.

Primary sulphide ores are normally clean, *i.e.*, free of clayey and micaceous constituents; the valuable sulphide may be coarse or extremely fine grained, and separate or finely intergrown with other sulphide. In any case it can usually be broken free into grains the surfaces of which are of the same composition as the interior. The extent of grinding necessary to do this can be determined by microscopic examination of representative specimens by reflected light (Sec. 19, Art. 9).

Secondary sulphides, particularly those near the transition zone, are almost invariably coated by other sulphides at the grain boundaries and along cracks. Pyrite, for example, is usually a core mineral to chalcocite and covellite (Sec. 5, Fig. 1). It is normally impossible to separate such coatings from the underlying mineral, with the result that the coated mineral tends to float as though it had throughout the composition of the coating.

Oxidized metallic ores not only contain their valuable metallic constituents in a form that is usually soft and crumbling, but all of the ore ingredients are finer, more intermixed, more soluble, and more complex chemically than are the sulphide ores. As a result the pulp liquor is an extremely complicated system, ion concentrations are high, reaction rates high, reagent consumptions relatively great, and reagent reactions more difficult to control. On top of all this is piled the mechanical slime problem which includes particle coating by slimes, coating of oily collectors and bubble walls by slime, consequent exclusion of granular material from the froth, and probably a host of as yet unidentified further interferences.

Character of the ore delivered to the mill is not an uncontrollable element, despite the tendency on the part of mine operators to so consider it. Ore is variable enough, in all conscience, even as it occurs in large ore bodies; when it comes from small scattered bodies, the variations from place to place in the mine are frequently tremendous. In many mining operations the history of the ore from the time it is broken at the face until it reaches the flotation cell likewise constitutes an important variable, since from one face it may get to the flotation plant in a few hours while from another the duration of the trip is weeks, months, or even years; at one face it may start its trip wet or it may get wet on the trip, while from another it starts dry and comes through dry; one batch may receive the leachings from old mine timbers or come to the mill admixed with timber; another may be subject to excessive contamination by lubricant; one part of the mine may be moist and hot, another cool and dry. All of these things affect the chemical composition of the flotation feed in ways that change its floatability. Hence, if operation is to be optimum, steps must be taken to smooth out the suddenness of changes in composition, means should be devised to indicate their occurrence and character, and the operating changes necessary for accommodation should be determined and applied.

The best arrangement from the mill standpoint is probably the maintenance of a number of underground working faces with constant proportionate draws therefrom to the haulage system. This starts the mixing process early. The larger the storage provided between the mine and the flotation plant, the finer the material therein, the better it is bedded; and the greater the number of draw points, the more thorough the ultimate mixing will be and, consequently, the more uniform the flotation feed. The shorter the elapsed

time between mining and floating, the smaller the quantity of mine water accidentally admixed, the less the amount of accidental contaminant introduced, the better the flotation results will be. It will pay mine management to listen to mill complaints about ore, and compare asserted economies in mining without regard to mill problems with resultant mill costs and losses.

When the ore coming to the mill varies so greatly that radically different methods must be used on different lots, segregation and separate treatment are indicated. Occasionally such a difference exists between the hard and soft parts of an ore; in such case the practice is to separate these as early as possible by gravitational or sizing means and treat them separately.

High-grade feed makes for easy operation on account of the heavy loading of the bubbles and the consequent great stability of the froth. It is easier to make high-grade concentrate with high-grade feed, probably on account of the tendency of the mineral to crowd gangue from the bubble surfaces mechanically. On the other hand, the tailing from the treatment of high-grade feed will almost invariably assay higher than that obtained from a low-grade feed of equal general floatability. It may happen, however, as is the case with free-milling nonsulphide gold ores, that the amount of metal present is insufficient to stabilize a highly selective froth, in which case flotation is difficult.

Floatability of minerals. There is no great difference, from an operating standpoint, in floatability of the sulphides of different metals, assuming proper conditioning and choice of a suitable collector. The same is probably true of the nonsulphides, but knowledge of suitable reagents and their use is less well established. The principal differences of importance lie in the gangue minerals. An ore containing a large amount of clayey material, *i.e.*, PRIMARY SLIME, is invariably more difficult to float than an ore with a clean siliceous gangue, and different methods of treatment may have to be employed. In some mills primary slimes are separated from the granular material by classification and treated separately (Sec. 2, Figs. 31 and 36). Control of feed to keep the primary-slime content within proper limits is now the practice at all mills where such control is possible; fairly elaborate methods of mixing in the mill bins are practiced to attain this end.

32. WATER SUPPLY

The water should be as pure as possible. When contaminated water must be used, its composition should be maintained as uniform as possible. If reclaimed water is used, it must be watched to guard against building up of harmful ingredients. These are, in general order of decreasing objectionableness, organic colloidal matter, oil, frothing agents, heavy-metal salts, alkaline-earth salts, salts of the alkali metals.

Organic colloidal matter is normally introduced with new water in tropical climates. It is a general depressant, making for clean concentrate, but at the same time lowering recovery. It tends to adsorb on slimes and, in general, to flocculate them. Hence one way to eliminate it is to admix such new water with mill tailing and reclaim it from the tailing pond.

Oil, whether from lubricants or other sources, is almost never sufficiently free of fatty-acid contamination to be without chemical collecting power. This is exerted on sulphides generally and on nonmetallic minerals which contain or are activated by heavy metals and alkaline earths. Oil also tends to stiffen froths. It is usually introduced into water supply in objectionable quantities from surface runoff; the remedy is, of course, to keep this out of the mill supply.

Frothing agents are not consumed to any great extent in the flotation operation except in so far as they are lost by evaporation. They concentrate in the froth. Hence if concentrate water is returned to mill supply, there is great danger of building up frothing effect therein to the point that control of frothing through control of the amount of new frother added is lost.

Heavy-metal salts activate both sulphides and gangue minerals, the tendency being to make all minerals float alike. Certain of them also act as depressants in sulphide flotation (see Art. 10, ***Ferrous sulphate***). Fortunately they are rare in most mill-water supplies except those drawn from the mine. They are precipitated to a large extent by alkalis and by the anions of many weak acids, as well as by their activating reactions, hence do not build up in circuit.

Alkaline-earth salts build up badly because of the relatively high solubilities of their sulphates, chlorides, and hydroxides. As already noted, they tend to activate quartz and alkaline silicates. In excessive concentrations they have a depressing effect on sulphides.

At saturation concentrations, which are reached at COPPER CLIFF owing to the large additions of lime necessary to neutralize the sulphuric acid formed by oxidation of pyrrhotite, pyrite, and pent-

landite, they precipitate throughout the circuit and clog pipes, valves, launders, and cell blankets and incrust everything they splash on. No cheap methods of elimination have been devised. For bibliography on zeolite treatment see *RI 3571*. Coghill and Clemmer (*112 A 452*) assert that hard water in soap flotation is less harmful at high pulp temperatures. Clemmer *et al.* (*153 A 547*) found that in using cationic collectors the hardness of the water was unimportant, but this cannot be taken as universally true with these reagents. Salts of the ALKALI METALS are not particularly harmful.

Sea water can be tolerated as a suspending medium by proper choice of collector and frothing agent; it has been used at a few plants where other sources of water were unduly expensive. It increases corrosion of machine parts.

Change in water supply. Water supply is not normally an operating variable, except in those cases where reclaimed and fresh water are at the disposal of the operator for alternative use. Under such circumstances it is usually found that change from one to the other, in whole or in part, requires corresponding changes in reagent addition. In Arizona, where much of the mill water may be reclaimed from a tailing dam, the water frequently becomes so concentrated in soluble salts, owing to repeated leaching and evaporation, as to have a harmful effect on performance; on the other hand, a heavy rain which dilutes the water in the tailing pond may also have a harmful effect, particularly where the return water is depended upon for some of the flotation agents. In other words, the situation is that after the mill operation has been adjusted to a certain amount of contamination in the water as a regular operating condition anything that disturbs the regular condition is harmful. See also Art. 40.

At TUL MI CHUNG (*33 IMM 3*) the spring floods bring large quantities of claylike solid into the water supply, and so long as this material is present flotation is uncertain and unsatisfactory. Bates (*109 J 552*) notes similar interference with flotation in a Mexican mill. Water from bogs and swamps contains TANNIN and VEGETABLE ACIDS which are ordinarily deleterious. At COCHENOUR WILLANS (*143 #3 J 45*) flotation with lake water deteriorates in winter, probably owing to reduction in oxygen content, since the trouble is remedied by aeration.

It is an interesting commentary on the long-suffering nature of millmen that of some 50 who responded to a question as to the effect of mill water on flotation operation, some of whom reported dissolved salts in quantities as high as 3,000 parts per million, 45 stated that the nature of the water had no effect, one said he took what he could get, and two or three reported that it was all right if it wasn't muddy.

Water treatment may need to be practiced in order to soften (remove Ca and Mg ions from) waters to be used in soap flotation. The usual plant procedure is to add, in succession, lime and soda ash. The lime first precipitates carbonate ion, which holds a certain amount of the Ca and Mg in solution as bicarbonates (temporary hardness). Additional lime precipitates the small amount of $MgCO_3$ still dissolved as hydroxide. Soda ash, by raising the concentration of carbonate ion, next precipitates the Ca present as sulphate and chloride (permanent hardness). Zeolite treatment is now displacing the older method.

33. REAGENTS

Character and action of reagents have been discussed in Arts. 3 to 10. The considerations controlling choice are effectiveness, specificity, stability, ease of handling and addition, and cost per unit weight and per unit of recovery. Quantities differ according to the function and the burden. The alkalis, having multiple functions, usually are added in greatest quantity. High-sulphide ores containing large quantities of iron sulphides form considerable sulphuric acid in the course of the oxidation that they undergo and also load up the pulp with $FeSO_4$, which is a depressant (Art. 8).

Hydroxyl ion. Lime is the cheapest source of hydroxyl ion, producing, as it does, 1 lb. OH per 1.6 lb. CaO; corresponding figures for Na_2CO_3 are 1 lb. per 3.1 lb., and for NaOH, 1 lb. per 2.4 lb. Usual comparative prices for the crude chemicals are: lime, 0.3 to 0.5¢/lb.; soda ash, 1 to 1.5¢/lb.; caustic soda, 2.5¢/lb. As much as 15 lb. of CaO per ton of ore may be required to precipitate the iron, neutralize the acid, and build up excess hydroxyl (raise *p*H) to the point necessary to depress iron minerals; with clean, low-sulphide ores as little as 0.5 to 1 lb. per ton may be sufficient to produce and maintain the *p*H in the optimum range for sulphydrate collectors. When it is desired to float the iron minerals, it is usual to use soda ash (crude sodium carbonate) instead of lime. This buffers the solution at *p*H 8 to 9.5, but this is high enough for most minerals and collectors.

Quantities of collectors. SULPHYDRATE collectors are usually added in amounts ranging from 0.05 to 0.25 lb. per ton of ore. Less of the higher molecular weight homologs is required. The usual quantity of FATTY-ACID collectors is from 0.5 to 1 lb. per ton when used alone and from one-third to one-half these quantities when supplemented by neutral oils. The NEUTRAL OILS, when used with sulphydrates, are usually kept below 0.25 lb.

per ton; when used with fatty acids the quantity may run up to 2 to 3 lb. per ton, particularly in table flotation. Practice with AMINES is not yet established.

Concentration of collector. Since collector-coating with soluble collectors is a precipitation reaction, it follows that concentration of the reacting ion is a factor in its completion to an effective extent. Thus, if a copper xanthate is to be precipitated, the product of the ionic concentrations of copper and xanthate must exceed the solubility product of cuprous xanthate at the particle surface, and this may be reached by adding either copper or xanthate ion to the solution. But since addition of copper ion will tend to consume xanthate ion, by precipitation in the body of the solution rather than at the particle surfaces, xanthate ion should be added. When the mineral to be collected is relatively soluble in water, *e.g.*, anglesite, a high concentration of collector ion is necessary in order to first precipitate all dissolved lead and build up $SO_4^{=}$ concentration and then to cause precipitation of the collector-coating. Economy will usually dictate substantial closure of the surface (see Art. 3) first by cheaper means, *e.g.*, by carbonate, phosphate, or sulphide ion in the case of anglesite, whereupon a smaller concentration of collector ion will serve. Addition of $SO_4^{=}$, to drive back Pb^{++} to the anglesite surface, should also be useful. In general, without such conditioning, the amount of collector ion necessary to add is in proportion to the solubility of the mineral and of the collector-coating itself.

Use of high collector concentrations or overpowerful collectors causes extremely rapid bubble attachment, whether the mechanism be precipitation or contact. This results in premature froth formation, heavy overloading with resubmergence of overloaded clots, and abnormally high persistence of removed froth, all of which are evils from an operating standpoint.

Excess of collector is usually harmful. With soaps it causes over-frothing and a marked decrease in recovery. The increase in frothing is in accord with the recognized fact that the curve for froth volume *vs.* concentration of frother shows a maximum at an intermediate concentration well in excess of that necessary to use in chemical collection; hence when the standard is the latter quantity, excess is on the rising leg of the froth volume-concentration curve. The decrease in recovery is usually attributed to formation of multi-films on the coated particles, which films are either unoriented or, if oriented, present their polar ends toward the water. This is, for such a film, the state of greater stability; it is likewise an orientation which repels rather than invites bubble attachment.

Taylor and Knoll (*112 A 390*) have shown that lead xanthate is soluble in strong solutions of the corresponding alkali xanthate. Bubble attachment decreases with approach to this dissolving concentration and is zero when it is reached.

Excess of oil in soap flotation tends to cause all minerals present to oil and float, the explanation probably being that the gangues are at least lightly resurfaced with heavy- and earth-metal ions (see Art. 7) and that after the completely collector-coated particles are oiled the excess spreads on these lightly coated particles.

Xanthates are always sold and used as the alkali-metal salts. Since the xanthate ion is the active part and experiment has shown that the alkali-metal salts in low concentrations have no effect in flotation, the only difference between, *e.g.*, sodium and potassium xanthates lies in the cost of xanthate ion. SODIUM XANTHATES are cheaper to produce but are less pure than the potassium salts and less stable at high atmospheric temperatures; choice is a matter of experiment.

Aerofloats are not good collectors for pyrite and are often used where depression of the latter is desirable.

Thiocarbanilid differentiates between copper sulphide and pyrite to a greater extent than xanthates; likewise between galena and lead-activated sphalerite. Somewhat the same effect is observed as between Aerofloats and xanthates.

High molecular-weight collectors produce larger contact angles than their lower homologs, and since the levitating effect of a bubble increases with increase in the contact angle, it is usual to add a small amount of higher homolog toward the end of the roughing stage to lift coarse mineral.

Frothing agents are added in amounts equivalent to 0.05 to 0.15 lb. per ton. Excess of frother produces excessive froth, which loses selectivity as the volume increases; deficiency causes a weak, thin froth which showers much mineral back into the pulp.

Conditioners. The quantities of activators and depressants vary with the substance. When COPPER SULPHATE is used without cyanide the amount of the hydrated salt ($CuSO_4 \cdot 5H_2O$) is ordinarily less than 0.25 lb. per ton; when used to reactivate it may be twice this plus the copper equivalent of one-third the weight of cyanide ion previously added. The amount of CYANIDE required for normal lead-zinc ores is 0.05 to 0.2 lb. per ton; for copper-iron ores, about the same. LIME quantities for depressing pyrite in copper ores range from 3 to 5 lb. per ton. Excess cyanide depresses copper minerals; excess sulphide depresses all sulphides and gold; excess alkali depresses lead, etc. For further details see the specific reagents.

pH is always held above 7, if possible, on account of high maintenance expense in acid pulps. The only sulphide that floats best in acid pulps is PYRITE; where high recovery is

desirable, as at the BOLIVIAN TIN properties, pH is held at 4.5 to 7; otherwise pyrite flotation both in gold mills and in lead-zinc-iron differential mills is effected in the range from 8 to 9. COPPER MINERALS are floated at pH 8 to 9 when pyrite depression is unimportant or when it is effected by cyanide; if lime is used as the pyrite depressant, however, pH is usually in the range 10 to 12. GALENA is usually floated in the range 7.5 to 9 whether alone, as a bulk concentrate with sphalerite and/or pyrite, or as a differential float. SPHALERITE, after activation with copper, floats over the range from 7.5 to 11; if pyrite is to be depressed, the usual range is 10 to 12. MOLYBDENITE flotation is substantially unaffected by pH and operations are, therefore, just above neutral, except in so far as depression of accompanying sulphides or dispersion of gangue requires another value. Range for the NONMETALLIC MINERALS depends upon the collector; with soap the optimum range for a given mineral is that in which contact angle is a maximum (Fig. 2), but another point may be chosen on the basis of depression requirements; with cationic collectors the acid side is usually better on account of the effect on solubility of the collector.

Place of addition of reagents depends on their function. Reagents added for control of pulp character are usually put in the grinding mills; LIME is sometimes added at the bins when the ore is wet and acid. ACTIVATORS and DEPRESSANTS should be introduced in time to permit the required reactions to complete before aeration is started. However, since the reactions are usually ionic, and the reagents are ordinarily added in solution into a pulp undergoing agitation, addition is sometimes deferred until just before entrance into the cell. COLLECTORS are normally added after the conditioners. The controlling elements are ease of dispersion, tendency to decomposition or to reaction with dissolved salts, and speed of the collecting reaction. OILS and the oily sulphide collectors (*e.g.*, Minerec) require more time and more agitation than chemical collectors but do not need protection; SOAPS react relatively slowly on account of the low concentration of ionic material, the bulk being in molecular and micellar dispersion; the SULPHYDRATES are relatively unstable, highly ionized, and highly reactive; their addition should be held back as long as possible especially when the pulps are foul. When the collector reacts with one of the conditioning reagents, its addition should be held back as long as possible to permit time for consumption and dilution of the latter. When protection is unnecessary, maximum collection is obtained by addition in the grinding mill (*140 # 11 J 34*). FROTHERS are ordinarily added in the cell feed box.

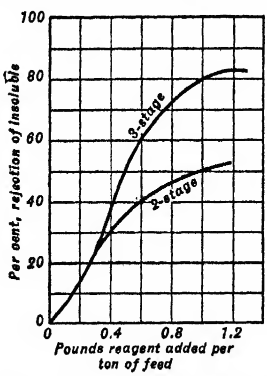

FIG. 48. Flotation of quartz with two-stage and three-stage additions of collector (*After Clemmer, et al.*).

Stage addition is stepwise feeding of the same reagent at different points along the flow of pulp through the flotation operation. It frequently starts with the grinding circuit. It serves to prevent overaction of a reagent at a single addition point with a later deficiency of action due to consumption or removal, and it decreases reagent consumption. It is especially useful and usual in differential work when the requirements as to concentrations differ at different points in the circuit. It may spell the difference between success and failure in a soap-flotation operation requiring close selection (*32 IEC 645*), or in operations requiring sulphidizing of mixed sulphide-oxide ores, where excess of sulphide ion depresses both sulphides and sulphidized oxides. The beneficial effect in cationic collection of silica from magnesite is shown in Fig. 48. It is usual in operations with powerful collectors and frothers, or with reagents which decompose readily, or when the content of soluble salts which consume reagent is high. Stage addition of collector reduces counteraction to the depressant.

34. REAGENT FEEDING

Reagent feeding must be regular and the quantity fed must be proportional to the quantities of ore and water running. No satisfactory method of effecting such proportioning automatically has yet been devised, but with the present development of automatic control apparatus there is no reason to believe that the method will not be forthcoming as soon as the demand becomes sufficiently insistent.

General requirements for a feeder are: precision to within about $\pm10\%$; certainty of operation, with, preferably, some automatic signal to warn of stoppage; ease of adjustment; reasonably wide range of adjustment; protection against dust, splash, vibration and jar; simplicity; resistance to corrosion and mechanical wear; prevention of segregation of nonhomogeneous materials; reasonable first cost and low operating cost.

Dry feeders are used when the reagent is solid, fine grained, nonhygroscopic, and the quantity fed is large enough to constitute a reasonably continuous stream. They comprise

miniatures of familar types of mechanical ore feeders delivering from a storage hopper. Belt-type feeders are most common, quantity being regulated either by varying belt speed or the width or depth of hopper opening; speed variation is preferable but more expensive. It is well to supply a rotating rake or scratcher over the discharge end to prevent hang-ups at this point, if the speed is slow. Roller feeders, plate feeders of the Challenge type, reciprocating push feeders, shaking and vibrating feeders, and screw feeders are also used, but are, in general, less dependable. A guard screen should always be provided to prevent charging lumps to the hopper; the latter should be large enough to hold a little more than one day's supply of reagent, in order to insure a daily visit and inspection by the operator, and it should be of such construction that the run of material through it is not affected by the amount present. A charge floor a few inches below the hopper top is a convenience and tends to prevent spill in charging, but it also invites introduction of extraneous matter.

Lime is normally fed dry, but unless expensive brands are purchased, it must be either crushed or slaked before it can be handled satisfactorily. As a result many plants feed it as MILK OF LIME, *i.e.*, as a thin suspension or slurry in water, normally containing about 1 part CaO to 4 of water. This is made by grinding burnt limestone in a tumbling mill, in closed or open circuit according to the grinding capacity, and is usually stored in a tank with slow mechanical agitation, whence it may be fed directly or, as in some large mills, circulated continuously by pump through supply lines to the feed points where it is drawn as required through valved outlets. High-grade powdered lime may be slurried in a stirring tank continuously fed with dry lime and water at predetermined rates to balance drawoff directly to the feed points. At MIAMI milk of lime is fed through orifices from a constant-head tank, through which circulation is maintained by pump from a storage tank.

At UTAH 1~1/4-in. limestone is purchased at the quarry, shipped in bulk by rail 25 mi. to Magna, burned in rotary kilns (1 @ 6×125-ft. and 1 @ 8×125-ft.) with a consumption of 1 lb. coal per 3.7 to 4 lb. burnt lime. The product contains 77 to 80% available CaO. It is slaked in two Hardinge mills in closed circuit with drag classifiers; classifier overflow with 20% solids is pumped through 4-in. lines to agitator storage tanks at the two mills (Sec. 2, Fig. 18), thence to feeders with gravity return of excess to the storage tanks. Cost delivered to the storage tanks is $6 to $8 per ton of lime; consumption is about 4 lb. per ton of ore.

At INTERNATIONAL NICKEL (*130 J 467*) lime received in bulk is unloaded by portable conveyor to a small gyratory and proceeds thence to a 125-ton storage bin, feeder, 3×8-ft. rod mill in closed circuit with a rake classifier (water added as required); overflow goes to an intermediate storage tank, pump, 15,000-gal. circulating storage tank with two agitators, where it is diluted and whence it is pumped through a circulating system from which it is drawn off as desired.

Wet feeding in the form of dilute aqueous solutions is preferable for all water-soluble reagents that are used in small quantities. Usual procedure is to make up solution of the desired strength in a supply tank from which it is drawn as needed to a feeder. The more dilute the solution the more accurate the addition. Concentrated solutions should not be used on account of the tendency to crystallize and clog conduits. The ordinary method of draw from the supply tank is through a valve operated by a liquid-level control device on the feeder tank. In smaller mills, the feeder tank itself is made large enough to hold supply for a shift or for 24 hr.

Copper sulphate is usually made an exception to the ban against feeding of concentrated solution. The usual method is to maintain a wooden barrel well filled with crystalline $CuSO_4 \cdot 5H_2O$, to baffle the barrel to prevent short circuiting of inflow to outflow, and then to so control the flow of new water to the barrel that it will displace the required amount of saturated solution. Rubber hose is used to convey saturated solution to the point of addition. A storage hopper for dry crystal above the barrel, with a gravity feed controlled by the quantity of crystal in the barrel, decreases the amount of attention necessary.

Wet feeders are of either constant-head flow types or mechanical; the former are cheaper to install, the latter more dependable in operation.

Flow-type feeder. A simple form used at OUTOKUMPU is shown in Fig. 49. It comprises a floating weir *a*, 2 mm. wide, formed by a slot in a piece of 3/4-in. tubing, as shown. This is mounted on a float *b*, and is regulable in position with respect to the float by means of adjusting screw *c*. Rubber tubing *d* connects with a pipe passing through the side of the tank in which the weir floats, the length of tubing, size of tank, and position of outflow pipe being so proportioned that the suspended weight of tubing does not vary between the operating full and empty positions of the float and the float cannot reach the wall of the tank. This feeder is subject to considerable variation in delivery if fibrous dust is present, and the weir cannot escape some fluctuation in submergence as the reaction of the rubber tubing changes with change in relative position between the fixed and float-supported ends thereof.

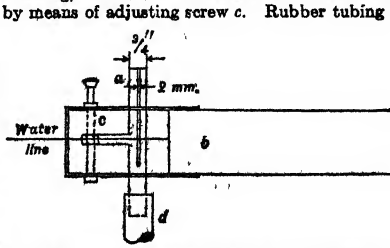

FIG. 49. Liquid reagent feeder at Outokumpu.

Siphon feeder is a siphon so mounted that submergence of the feed end is maintained and the head on the discharge remains constant between times of adjustment. The ADAMS FEEDER (Fig. 50) comprises a rectangular tank *a* of about 8 gal. capacity on which is mounted the parallel frame *b*, *c*, *d*, *e*. Siphon *f* is clamped to part *c*, so that change in the inclination of *b*, effected by screw *g*, changes the head on the siphon discharge. Float *h*, on which the lower end of *c* rests, maintains submergence. Siphon tubes are of different sizes according to the volume to be fed and the viscosity of the liquid and are made of different materials according to the chemical nature of the reagent. The parallel frame may be arranged to actuate a valve on a supply tank.

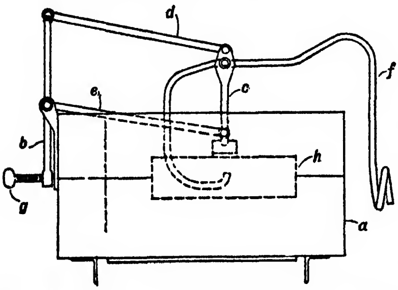

FIG. 50. Adams siphon feeder (*After Mine & Smelter Supply Co.*).

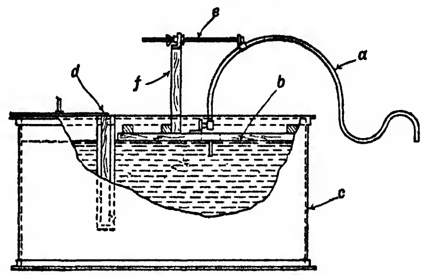

FIG. 51. Home-made siphon feeder.

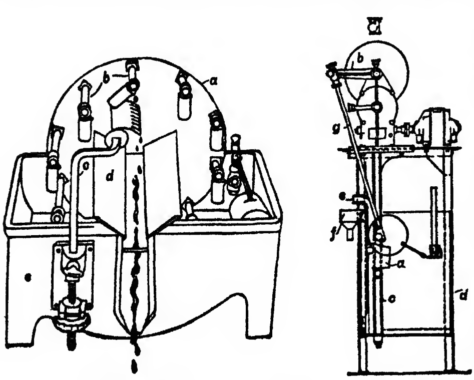
Home-made siphon feeder is shown in Fig. 51 (*139 #3 J 61*). Siphon *a*, of copper pipe, is supported by float *b* in float compartment of tank *c*. The other end of the tank is a covered feed compartment. The siphon support is hinged to the float, and the head on the siphon tip is regulable by means of a wing nut on the threaded rod *e* supported on post *f*.

At MIAMI (*Q*) xanthate solution and pine oil are fed through orifices from tanks in which constant level is maintained by automatic liquid-level control from supply tanks. Operation is reported as accurate at all times.

Mechanical feeders are of three general types, *viz.*, disk-and-cup, reciprocating-cup, and pulley-and-finger.

Disk-and-cup feeder takes a variety of forms. The best known (Fig. 52) consists of a disk *a* driven at constant speed by a small motor with speed-reducer; a number of pins *b* of different lengths mounted on the disk and carrying cups loosely suspended so as to hang vertically by gravity; bar *c*, adjustable vertically (sometimes also as to extent of projection toward the disk); and a trough *d*, mounted in such a position as to receive spill from the cups when they are tilted at or near their top positions and, in the form shown, slidable along its axis; all mounted on a tank *e*. The cups fill when revolution of the disk immerses them in liquid in the tank; they spill more or less of their load according to the degree of tilt that they receive in dragging over bar *c*. Speed must be such that the cups do not rebound on striking the bar. Disks are normally 15 to 30 in. diam., but may be made larger. Number and size of cups are also matters of design for a particular service. A form having greater flexibility has all cup pins the same length and two or three or more cups on a pin, arranged so as to be readily removable and to be fixed in any of the several cup positions along the pin.



Disk-and-cup Geary

FIG. 52. Wet reagent feeders.

In another type (CLARKSON) the cups are fixed on the disk and deliver onto a splitter adjustable to deliver any desired fraction of the stream to the discharge pipe. Another variant of this type has nontilting cups adjustable as to angle so as to spill more or less of the load before reaching the position where the balance dumps into the trough.

At UTAH adjustment is made by means of a 60-point rheostat on the variable-speed driving motors. The adjustment is easy and accurate but constancy is interfered with by dirty motor brushes.

Geary feeder (Fig. 52) is of the tilting-cup type, but the cup *a* reciprocates vertically, under the impulse of crank *b*, between guides *c*, which extend down into tank *d*. The bail of the cup is attached to the bottom and the front guide *e* is led out at the front above the delivery hopper *f*, thus permitting the cup to tilt to an extent adjustable by varying the length of the connecting rod *g*.

A homemade modification of the Geary feeder as built at ST. JOSEPH LEAD CO., Hughesville plant, is shown in Fig. 53. In the front assembly *A* is a 2×10-in. plank making about 15 @ 10-in. vertical s.p.m. under the impulsion of cranks *B* and connecting rods *C* from pulley-driven shaft *D*. Members *E*, comprising a 1/2-in. bolt welded to a 3/8×1-in. bar, carry tilting cups *F* mounted on brackets welded

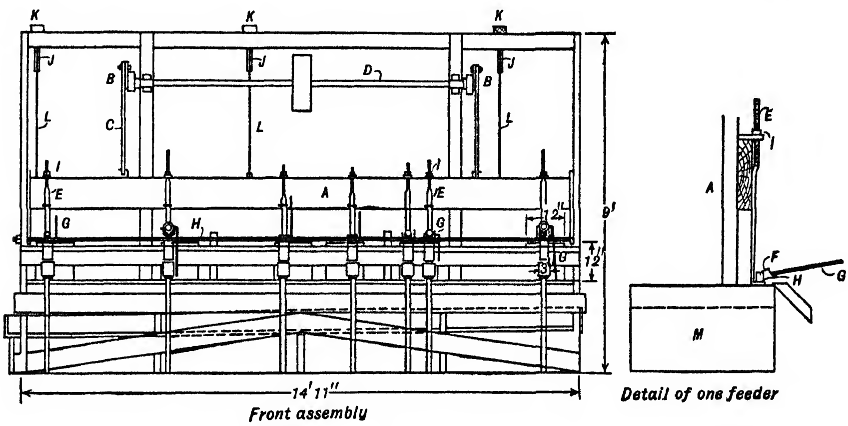


FIG. 53. Geary reagent-feeder battery.

to the lower angled end. Tipping rods *G* bearing against fixed rods *H*, in conjunction with the position of nut *I* on rod *E*, determine the extent of tilt and, consequently, the amount delivered from a full cup. The device serves additionally as a mixer; members *J* are 4-ft. walking beams suspended from members *K*, with driving connecting rods *L* linked to *A* and buckets suspended on rods at the other ends; these buckets hold weighed charges of reagents and slosh up and down in the requisite amounts of water in mixing tubs which supply the feeder tanks *M* via 1/2-in. centrifugal pumps. A 3-hp. motor drives the apparatus.

Tilting-cup feeders are not suitable for viscous liquids.

Pulley-and-finger feeder is used for both mobile and viscous liquids. The pulley is so mounted over a tank containing the liquid to be fed that it dips into the liquid therein and carries a film of liquid with it on the emerging side. The finger is a shallow trough with a chisel-pointed upper end which bears against the downcoming face of the pulley near the top in such a way as to slice off a film of liquid. The width of the slice is adjustable by sidewise motion of the trough across the edge of the pulley and the thickness or depth of slice may be varied by adjusting the pressure of the finger against the face.

Delivery for a given setting varies with the temperature, owing to change in viscosity of the liquid, so that thermostatic control of tank temperature is necessary if mill temperatures fluctuate much. Fibrous dusts catch on the knife edges and change delivery rate, grit wears both pulley face and knife-edge, and corrosive liquids pit them and make them irregular.

Pumps of piston type, of miniature size, with variable stroke length may be used for viscous liquids if the amount to be delivered is not too small. They come nearest to constant delivery of such material in the face of variable viscosity, provided pressure feed is arranged.

Use. On the basis of some 50-odd mills reporting (*Q*) about 40% of the liquid feeders employed are of the disk-and-cup type, about 25% of the pulley-and-finger type, about 12% the skip type (Geary), and the rest use siphons, drip cups, or constant-head flows through valves. Disk-and-cup type uses were 45% for viscous and the remainder for mobile liquids; temperature was asserted to affect delivery at three of the plants where pine oil and liquid Aerofloat were fed. Other interferences with delivery as reported were sediment, corrosion of buckets, and dropping of buckets. Accuracy to within 1 or 2% was

reported from two mills. The preponderant rating was good on the scores of accuracy and ease of adjustment. Pulley-and-scraper type uses were 70% on viscous liquids (oils and liquid Aerofloats). Temperature changes and dirt in the material or settled on pulley or finger were reported as the usual interferences. Ratings as to accuracy were not as high as for the cup type, but this is to be expected from the more difficult materials fed. Rating was high as to ease of adjustment. Geary-type uses were 50–50 as to viscous and mobile liquids. Ratings as to accuracy were ±2% where reported in figures. Constancy rated high, with wear, occasional binding, and level control the reported difficulties. Easy adjustment was the unanimous opinion. Siphon uses were 80% on aqueous solutions, but satisfactory performance is reported on pine oil. Drip cans are used principally for supplemental stage addition along the cell, the use being about half-and-half for aqueous solutions and for oils; dirt and changing head are the common difficulties. Constant-head tanks with valved outlets are reported for xanthate solutions, milk of lime and pine oil; at Nevada Consolidated (McGill) a constant-head tank feeds a diaphragm pump which discharges to a launder with an adjustable splitter which returns excess to the tank.

Dry feeding by belt is practiced for dry lime and soda ash at most mills where these reagents are used in the grinding circuit or conditioners. For thiocarbanilid a shaking feeder and a horizontal disk with an adjustable scraper are reported.

Feeder floor. In most mills all of the liquid feeders for the mill or for one or more sections thereof are placed on a floor which affords gravity flow to the feed points and which, preferably, is readily accessible by hand truck to the storeroom. This floor should be roomy, afford ready access to the supply tanks, and have suitable measuring buckets, scales, scoops, etc., for compounding solutions. Provision should be made for hosing down when necessary, with discharge of the cleaning water to some point from which it cannot get back into the mill stream.

At Midvale (*IC 6492*) all reagents are prepared on the top floor of the mill, which is served by push-button elevator of 2,500-lb. capacity. The floor carries 6 hoppers for dry reagents, which feed into 250-gal. Devereaux mixing tanks which, in turn, flow to 1,000-gal. storage tanks. Dry reagents which are to be fed in solution are delivered to the preparation floor in drums, weighed out in the quantities required for a 250-gal. batch, and delivered via the hoppers to the mixing tanks. Solution strengths are such (±13%) that 20 lb. of dry reagent is contained in 1-in. depth of solution in a storage tank. Oils are stored in 14,000-gal. main supply tanks outside the mill and pumped thence to the mixing tanks, from which the mixtures flow to 1,000-gal. mill storage tanks. All storage tanks feed individual Geary feeders by gravity through 3/4-in. lines.

Stage addition of a given reagent is provided for in large mills by having a separate feeder for each point at which addition may be required. At the Tooele oxide mill (*IC 6759*) there was a feeder each for xanthate and sodium sulphide for each cell of a 12-cell machine. At small mills stage additions are usually made from drip cans.

35. SIZE OF FEED

Maximum size depends upon severance requirements and levitation capacity. Maximum in sulphide flotation, using sulphydric reagents, was about 28-m. for 11 lead-zinc mills reporting, 35-m. was maximum for 6, 28-m. for 2, and 48-m. for 3. Of 14 copper mills, 6 reported 35-m. grinding, 6 @ 48-m., and one each at 65-m. and 100-m. Pyrite is floated from Bolivian tin concentrate at 20-m. maximum. Gold ores, in general, are ground to at least 65-m. and some to 200-m. before flotation. Assay of the coarsest size in the tailing is generally the highest of all of the sizes, and, for a given ore, is higher the coarser the maximum. The tonnage of such material is, however, low, so that the saving effectable by finer grinding is not, ordinarily, sufficient to overcome the additional cost thereof plus the increased loss in the finest fraction (*post*). Deslimed feeds as coarse as 10-m. are treated in nonsulphide froth flotation, particularly in the case of coal, but the usual maximum is 48-m. Table flotation has treated deslimed nonsulphide feeds as coarse as 3-mm. maximum; usual maximum is 20-m.

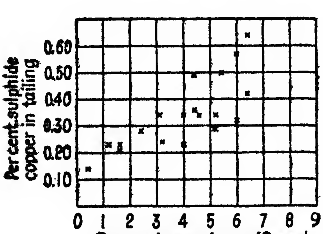

Fig. 54. Relation between size of feed and assay of tailing in a pneumatic machine (*55 A 576*).

Tailing loss *vs.* size. In treating normally ground sulphide feeds, losses in tailing are usually a minimum in the middle size range whether the maximum size is 28-m., 60-m., or 100-m. (see Tables 17 and 18 and Figs. 54, 55, 56, and 57). Similar results are reported Noranda (*119 A 576*). With such feeds it is to be noted that the failure of the

machines is actually even greater than appears, since in the classifier overflows comprising them the heavy mineral is much finer than the gangue.

Table 17. Sizing-assay test of feed and products of agitation-froth machine, Braden Copper Co. (*After Broadbridge, 22 IMM 37*)

Mesh	Feed, %		Concentrate, %		Tailing, %

Martin (*IC 6479*) reports the following relationship between grinding time in a batch mill, size of feed, and tailing assay in a series of flotation tests on UTAH ore:

Time, min..................	3	5	10	15	20	25	50	150
% <200-m.................	51.3	57.9	76.5	88.2	93.6	95.7	99.4	99.9[a]
Tailing assay, % Cu.......	0.21	0.13	0.08	0.07	0.06	0.06	0.05	0.63

[a] <300-m.

Fig. 57 (*14 MMt 421*) represents results obtained in floating sized fractions of pure sphalerite. It shows both maximum recovery and maximum rate at 150 ∼ 200-m. with the drop progressively more serious in the fine sizes. It shows also the importance of long time-factor for floating fine sizes, even when there is no interference by slime.

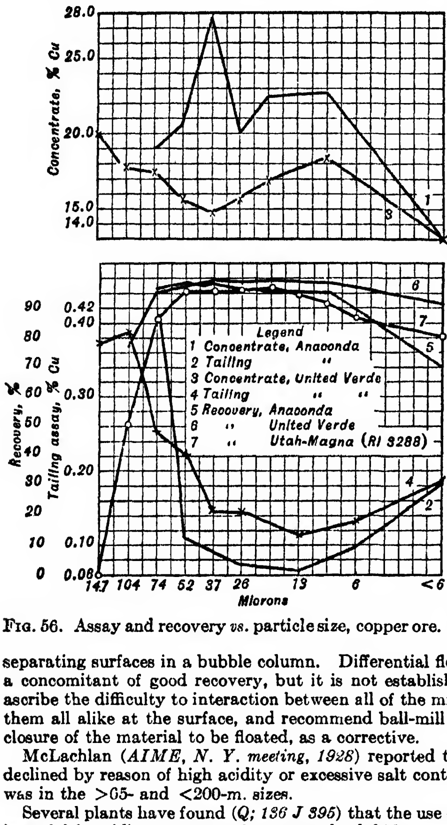

FIG. 56. Assay and recovery *vs.* particle size, copper ore.

Reasons for failure to recover large and small particles are different. Large particles are lost because of the inability of the bubbles to carry them. In the agitation-froth process many of the bubbles attached to large particles do not have sufficient buoyancy to lift them to the top of the pulp in the spitzkasten. Also in many cases the large particles are jarred loose from the bubbles that precipitated upon them, because of the relatively great inertia of these large particles. In bubble-column machines, it is difficult to lift large particles into the bubble column, on account of their greater settling velocities, and it is, of course, more difficult to lift them in the bubble column, for the same reason. As between the two types of processes, the agitation-froth process is the better fitted to hold large particles in the froth, once they have been raised to that point, both because of the firmer bond between the particles and the bubble walls and because the fine-textured froth acts mechanically as a screen and prevents large particles from falling back, even though they become detached from the bubbles.

The reason for loss of small particles is not known. Gangue flocculation in which otherwise floatable particles are locked away in gangue floccules is undoubtedly one cause. Slimed sulphide is generally more highly oxidized than granular. Fine particles are more difficult to bring into contact with the separating surfaces in a bubble column. Differential flocculation of the floatable material is normally a concomitant of good recovery, but it is not established as causative. Gaudin *et al.* (*112 A 303*) ascribe the difficulty to interaction between all of the minerals present resulting, eventually, in making them all alike at the surface, and recommend ball-mill addition of collector, with consequent surface closure of the material to be floated, as a corrective.

McLachlan (*AIME, N. Y. meeting, 1928*) reported that at NACOZARI, when flotation performance declined by reason of high acidity or excessive salt content of the mill water, the increased tailing loss was in the >65- and <200-m. sizes.

Several plants have found (*Q; 136 J 395*) that the use of neutral oil in addition to sulphydric collector is useful for aiding recovery of overgound sulphide.

The relatively great difficulty in floating slime sulphides is not universal. Of 12 copper plants reported in Information Circulars of the U. S. Bureau of Mines, 9 showed an excess of assay of <200-m. tailing over that of 150∼200-m. sand ranging from 10 to 100%, averaging 49%, but 3 plants made lower tailing in the <200-m. size, averaging 39% superiority. Eight out of 10 lead-zinc plants showed excess values in <200-m. slime over 150∼200-m. sand ranging from 17 to 380% and averaging 116%; 2 showed the reverse to an extent of 37%. Zinc excess in slime occurred in 8 out of 12 cases; the range was 25 to 1,220%; the average (excluding the maximum) 52%. In the 4 plants in which slime zinc tailing was superior, the range of superiority was 17 to 50%, and the average 43%.

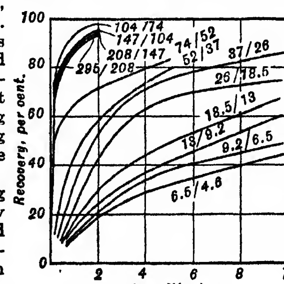

FIG. 57. Recovery time *vs.* size in μ (standard reagents).

The same condition exists in nonsulphide flotation, prompting Coghill and Clemmer (*112 A 452*) to generalize that the distinctly crystalline, lustrous minerals are the more readily floatable and that the earthy ores are difficult to concentrate. Further experience in the nonsulphide field has shown that the decomposition and alteration of which earthiness is a mark have resulted in such complete infiltration of the residual structure of the earthy ores by the decomposition products that all particles after comminution tend to present one kind of mineral only at the surface, irrespective of their interior composition. The remedies are dispersion of the alteration products, either by chemical means or attrition mixing (Art. 7) or both.

Machines. When feed is coarse, it is better to arrange the delivery slot to the spitzkasten of an agitation machine to deliver in an upward or horizontal direction so that the

bubble-mineral aggregates do not have to reverse momenta against the impulse of the pulp stream. This principle is also followed in many subaeration machines, in which considerable pains have been taken by the designers to flow the pulp being aerated directly upward toward the bubble column and thus to add to the pulp-elevating action of the rising bubbles the carrying power of the pulp liquid.

Bubble-column machines are best for fine pulps because of the flexibility that they permit in control of intensity. In order to make grade, the slow-settling gangue slimes must be given time to drain out of the bubble column, while at the same time the mean rising velocity of the bubbles therein must be greater than the mean falling velocity of the fine economic-mineral particles. Simultaneous control of pulp level and air supply aimed toward production of a deep bubble column which is highly liquid at the bottom and as dry as possible at the top is the indicated procedure. No such variation in froth consistency is possible in the agitation machine.

Froth should be made tougher and quieter for coarse than for fine feeds.

Economics of feed size is to be decided on balance between recovery and cost. Recovery is, in general, improved by finer grinding, at least down to 100-m. maximum. Grade of concentrate also tends to improve with the greater severance thus effected. On the other hand, grinding costs increase materially, capacity of flotation machines decreases, reagent consumption is higher, and concentrate handling costs more the finer the flotation feed.

It is reported from Walker Mine (*IC 6555*) that increase in feed size from 4% >48-m. to 14% >48-m. increased plant capacity (limited by grinding capacity) from 750 t.p.d. to 1,200 t.p.d., and that the concomitant loss in tailing was more than offset by decrease in milling cost. Economies at Climax, where <20-m. feed is roughed and rough concentrate is ground to 200-m., are yet more striking (*A TP 1675;* Sec. 2, Fig. 142).

Stage flotation describes a practice in which low-grade concentrate is roughed out at relatively coarse size, using very intense flotation conditions, and the bulk of the feed is discarded as tailing. The concentrate is then reground and refloated. The practice is employed both for one-mineral separation (Miami, Ajo) and for differential work (Consolidated Mining & Smelting, Tennessee, Shenandoah-Dives). Coghill (*119 P 404*) states that at the Primos Chemical Co. molybdenum plant recovery was raised from 60 to 83% by floating coarse pulp and then regrinding and refloating the tailing, and ascribes the improvement to the fact that such initial grinding of all of the pulp to ultimate flotation size overground the coarser mineral. Table 19 shows the effect of stage flotation at Allenby (*87 A 117*); Table 20 shows the effect at Miami (*IC 6573*), where marked increase in grade of concentrate outweighed a small increase in tailing assay.

Table 19. Effect of stage flotation at Allenby *a*

Without re-treatment....	0.089	0.042	0.047	20.12	22.8	26.2	34.0
With re-treatment.......	0.113	0.053	0.060	42.11	19.5	2.9	74.2

Stage flotation gives much of the economic advantage of low-cost coarse flotation without sacrifice of the metallurgical advantages of fine grinding. It has the further advantage of decreasing overgrinding of sulphides, since the quantity of very fine sulphide produced in regrinding concentrate to a given maximum size is, in general, much less than when the great bulk of gangue in the raw feed must be concurrently reduced in the same mill.

Desliming appears to be essential in table flotation, since otherwise gangue slime and levitated concentrate discharge together. Slime also tends to coat the coarser mineral and prevent oiling; and it consumes large amounts of collector both by reaction, and by coating and thus immobilizing oil droplets. Desliming aids operation in most nonsulphide froth flotation. The reasons are, in part at least, those prevailing in table flotation, with the additional one that the slime appears to form viscous films at the separating surfaces in bubble columns and thereby to exclude granular material.

At Bunker Hill & Sullivan (*IC 6314*) a very light desliming more than doubled machine capacity and reduced tailing assay from 0.7% Pb and 0.7% Zn to 0.14% Pb and 0.45% Zn. The amount of slime removed (and discarded) comprised 2.4% of the tonnage of feed to flotation; it assayed 4.2% Pb and 0.7% Zn and contained 0.9% of the lead and 1.1% of the zinc in the feed.

Separate sand-slime treatment was practiced in a few copper mills (*e.g.*, Mt. Morgan; Britannia; Anaconda; Sec. 2). The basic reason therefor is that the oxides and tarnished sulphides which concentrate in the primary slimes float slowly and only under relatively intense conditions, while in the ground-sand feeds the copper minerals float readily and quickly and flotation conditions must be relatively gentle to aid in depressing pyrite.

Differences in floatability between primary slime and fine material produced by grinding at Anaconda (*128 J 292*) are indicated by Tables 21 and 22, showing that, with very little difference in copper content and with the iron content militating against the sand so far as grade of concentrate is concerned,

a Feed assay: 4.16% Cu; 5.8% Fe.

sand concentrate and tailing were 29.6 and 0.24% copper respectively, while the corresponding figures for slime flotation were 20.3 and 0.40%. In the slime concentrate the principal difficulty was that the finest gangue floated. The natural assumption is that the 3 : 1 ratio of silica to alumina in the slime concentrate represents clay, and that the higher ratio in the sand concentrate is due to some fine silica accompanying the clay. On the other hand, applying the 3 : 1 ratio to the sand-concentrate gangue, it becomes apparent that very little of the silica in the sand concentrate is very fine, while the high-silica, low-alumina content in the coarse sizes of the sand concentrate indicate that the low copper assay of the coarse sizes is due to flotation of locked quartz middling. Sizing-assay tests of sand-

flotation feed showed that with a grind showing 7.3% on 65-m. 73% of the total copper was in the <300-m. size. Finer grinding is discouraged by the showing that losses in <300-m. are upward of 25% higher than in the coarser sizes.

At Britannia (*IC 6619*) tailing for combined sand-slime treatment is about 0.05% higher than the combined tailings from separate treatments. At a number of other copper mills separate treatment has been tested on pilot or full scale [Nacozari (*IC 6358*), Copper Queen (*IC 6404*), Utah (*IC 6479*)] but proved not sufficiently advantageous to justify final adoption. At Suyoc (Sec. 2, Fig. 62) colloidal slime washed out in the crushing plant is by-passed to the scavenger cells.

36. TIME-FACTOR

Time-factor is involved both in the phenomena of conditioning and collector-coating and in machine operation. Requirements for time for economic completion of the chemical phenomena can usually be satisfied by introduction of reagents at a point or points in the normal flow of pulp ahead of the rougher; if the time thus available is too short, a conditioning tank, which is simply a reservoir of predetermined time-factor fitted with agitation means to prevent segregation by sedimentation, is inserted in the flow. It should be arranged for drawoff at various levels in order to permit change of time-factor as an operating variable without interference with feed rate or pulp density.

Conditioning times reported for sulphide flotation range from 5 min. to as much as 3 hr. with the normal about 15 or 20 min. In most cases, but not all, it is well to err on the high side.

Time-factors in flotation machines differ primarily according to character of ore, kind of separation, size of feed, and kind of machine. As between slow-floating and rapid-floating ores there may be a difference of several hundred per cent. Thus reported time-factors for roughing and scavenging the porphyry copper ores range from 3.5 to 10 min. with an average of 7 min. while the time-factor for the pyritic copper ores ranges from 15 to 25 min. with an average of 18 min. Times for the clean lead ores and lead roughing from nonpyritic lead-zinc ores range from 4.5 to 9 min., average 6.5 min.; zinc roughing from similar ores averages 5 min. On the other hand, the complex lead-zinc-iron ores require from 15 to 20 min. for lead roughing, 15 to 30 min. for zinc roughing, and 10 to 15 min. for pyrite roughing. Clean gold ores require 10 to 20 min.; heavy pyritic gold ores and oxidized gold ores, 15 to 30 min.

Slimy feeds are always slower-floating than granular feeds; the variation may be several hundred per cent.

Machines. Subaeration machines are faster than pneumatic; of the former the machines that effect the best dissemination of air are fastest.

Cleaning time may be greater or less than roughing time, depending upon the separation to be made; when this is simply to drop rocky gangue and middling out of sulphide concentrate, cleaning times reported range from one-sixth roughing time to equality therewith; when the task is to separate sulphides, as in separating chalcopyrite or blende from pyrite, or galena from blende in bulk concentrates, reported cleaning times range from equal to 6 times the roughing times. Running up very high grade concentrates such as molybdenite or graphite requires cleaning times 3 to 10 times the roughing time.

Feed rate. There is a maximum feed rate for any cell under given conditions, but there is no minimum rate other than that imposed by economic considerations in design. That is to say, recovery in a given cell under given conditions is a maximum at the minimum feed rate, but the fall in recovery with increasing feed rate is very slow until the overload point is reached, when recovery falls rapidly with further increase. Many cells are fed far below the maximum rate. This condition of underload is more evident in series installations, such as the multi-compartment agitator machines and compartmented pneumatic machines, than with single-cell machines of trough type. In the multi-compartment machines the later compartments are acting as scavengers only, under normal operating conditions, and the recovery that they effect is small. When the feed rate is increased, more work is put on these later, normally underloaded compartments. In parallel-type installations, the machines are usually worked much more nearly to ultimate capacity, and when increased load comes on, some of the additional mineral goes into the tailing. (See also Art. 29, ***Recovery***.)

Series *vs.* parallel operation. The ultimate capacity per cell is the same in both series and parallel installations. This was conclusively proved by careful experiment, both with standard Minerals Separation machines and with Callow machines, at the Miami Copper Co. Practice favors series roughing, and scavenging with some underloading, as a precautionary measure.

Constant feed rate is important, for the reason that other variables, particularly reagent addition, are based on a given rate; change in rate changes the proportions and usually results in poorer performance.

37. PULP DENSITY

Pulp density is important on both chemical and mechanical grounds. Through its effect on volume it determines reaction times with a given flow rate of solids and a given volume of conditioning tank and flotation machine. Since most reagents are added on a pounds-per-ton-of-solid basis, pulp density determines reagent concentration and thereby both equilibrium point and reaction velocity. In general, conditioning in a thick pulp permits sensibly smaller reagent additions. This is one of the reasons for the practice of adding soluble collector in the grinding mill. When the reagent is a liquid insoluble in the proportions used, such as petroleum oil and fatty oils in flotation of nonmetallics, thick pulps are particularly helpful in effecting coating, since the oil droplets are practically smeared across the particle surfaces.

From the standpoint of levitation it is the volumetric aspect of pulp density that is important, *i.e.*, its effect on the spacing of particles. Flotation is normally more rapid and complete in the denser pulps, but concentrate grade is lower.

The following results reported by Gaudin (*F 118*) for a laboratory test on an artificial mixture of granite and galena are typical.

Solids, %	46	37.5	21	15	11.5	8
Concentrate, % Pb	43	57	62	64	68	75
Tailing, % Pb	0.12	0.14	0.14	0.27	0.45	0.56

Ralston (*U. S. pat. 2,064,031*) asserts, however, that in cleaning concentrate at United Verde the grade improved and assay of cleaner tailing rose also with increase in pulp density.

Newton and Ipsen (*139 #5 J 43*) conclude, from laboratory experiment, that pulp density has little or no effect on recovery, speed of flotation, grade of concentrate, or ratio of concentration. They do say that high density aggravates the harmful effects of slimes. The consensus of operators is that unless compensating changes are made, change in density affects all four of the above measures of performance; that optimum density for normally ground pulps lies in the range of 25 to 30% solids in roughing, with fall in recovery on both sides, usually accompanied by an increase in grade of concentrate in the more dilute pulps.

Dense pulps are better suited to agitation machines; bubble-column machines must be aerated so intensely in order to lift the heavy loads into the bubble column and support them there that it is difficult to prevent boiling, and the bubble column is so shallow that concentrate grade is low.

Coarse pulps must be denser than fine to overcome the tendency for coarse heavy mineral to settle out.

Dilute pulps are asserted to be best for floating flaky minerals (*45 CME 273*).

At Ajo (*134 A 445*) the froth on all cleaner cells is sprayed with fresh water, which tends to reduce assay of insoluble in overflow. Pulps are frequently thickened in order to wash out dissolved materials, colloids, and slimes, where other methods of removal or combat are ineffective or overcostly. Common examples are thickening between lead and zinc flotation and the use of bowl classifiers to prepare pebble-phosphate feeds (Sec. 2, Art. 29; Sec. 3, Art. 30). Filtration prior to addition of cyanide has been suggested when the concentration of cyanicides, particularly iron, is high (*U. S. pat. 2,048,369*).

Table 23. Pulp densities in sulphide flotation

Type of ore	Pulp density, %: Rougher, Range	Rougher, Aver.	Cleaners, Range	Cleaners, Aver.
Heavy sulphides:				
Copper-iron	30 to 50	35	10 to 50	30
Lead-zinc				
Lead	30 to 50	40	5 to 50	....
Zinc	20 to 40	35	10 to 45	....
Disseminated:				
Copper	18 to 33	25	10 to 23	15
Pyrite-gold	15 to 45	30	20 to 40	26
Lead	24 to 33	28	5 to 15	8

Densities used in practice (Table 23) run definitely higher in both roughing and cleaning with heavy sulphide feeds than with the disseminated ores. Densities in unit cells may run as high as 75% solids.

Density variation in machine. Pulp density falls markedly from head to tail of a long stage, particularly when the feed is highly mineralized, because of the fact that the density of a good mineral-bearing froth is ordinarily much higher than that of the pulp from which it comes.

At Consolidated Mining & Smelting Co. feed to the lead rougher was 40% solid and tailing 26%, the fall was from 50% to 40% in the cleaner and 50% to 20% in the recleaner; in the zinc section the corresponding figures were 35 to 30, 45 to 36, and 45 to 35. Hence scavenger feeds are frequently quite dilute.

Maintenance of constant pulp density is just as important as determination of the right density. Ordinarily other conditions can be so adjusted that any pulp density within a considerable range will yield the same results, but once adjusted, results will fall off, if density varies. (See Sec. 8, Art. 14, for control of density of classifier overflow.)

38. TEMPERATURE

Temperature of the pulp has marked effect in any flotation operation which is being conducted under critical conditions, *e,g.*, starvation quantities of collector or frother or depressant. Rise in temperature normally increases reaction velocity. It aids completion of reactions involving decomposition, solution of solids, or formation of a gas as one of the reaction products, but ordinarily hinders reactions involving precipitation of solids. It reduces viscosity of oils and thus aids coating.

Practice. Most mills operating where there is a large seasonal change in pulp temperature report that metallurgical results in summer are better than those in winter and that flotation is slower in the cold pulps. Consumption of frother is ordinarily higher in cold pulps, but the St. Joe lead mills in southeastern Missouri report higher frother consumption in summer. Where lime is used as a flocculant for slime, consumption increases with fall of temperature. Magma reports (*Q*) that if temperature rises too much in the grinding mills, copper recovery falls, the action being attributed, tentatively, to overoxidation of bornite. Few plants heat pulp, the principal instances of such practice being at the copper-gold plants in northern Canada, in conditioning for sphalerite flotation in lead-zinc differential work, and in destroying collector coatings on copper concentrate in molybdenite-copper differential operations. Aldermac reports optimum flotation at 80° F. Noranda reports that at temperatures above 86° F. differential work is poor, reagent consumption increases, and gold recovery falls. At Dome (*143 #3 J 46*) rise in temperature of pulp increases recovery of pyrite but not of gold. Similar action on pyrite was observed at Pecos (*IC 6605*). At Base Metals Mining Corporation (*Tref 5/42*) temperatures are 56° F. in lead roughing, 42° in lead cleaning, 61° in zinc roughing, and 90° in zinc cleaning. Diesel-engine cooling water is used for heating. The low temperature in the lead cleaner, to drop zinc, is the natural corollary of the high temperature in the zinc cleaner. At Consolidated M. & S. (*131 J 315*) temperatures are 82° F. in the lead rougher, 85° in the zinc rougher and cleaner and in the lead cleaner and recleaner, and 95° in the zinc recleaner; 12,000 lb. live steam per hr. is required for heating the pulp. Grade of zinc concentrate rises with temperature (*Q*). Potosi reports (*Q*) that at winter temperatures flotation of zinc decreases in the zinc circuit, while iron tends to float therein, the lead circuit being unaffected. Heat has been used in pilot-plant operations in which galena was depressed by chromate. In most cases, however, much or all of the improvement that can be effected by heating can be more cheaply obtained by increase in quantity of reagent or time-factor.

Wark and Cox (*134 A 47*) report that in the absence of copper ion, both cyanide and alkali are more active as depressants with xanthate collectors at 95° F. than at 40° F. They report also that the contact angle with given reagents is independent of temperature over the above range. Flotation rate at 100° F. is twice that at 43° F. (*IC 6784*); optimum temperature varies with the ore but ordinarily lies in the range of 73° to 100° F.

Temperature in agitation-froth machines has an important additional influence due to its effect on vapor pressure of the water and partial vapor pressure of the dissolved air. The speed of gas precipitation increases, all other things being equal, with increase in these pressures and they, in turn, increase parabolically with increase in temperature. Hence both capacity and recovery are increased with temperature rise. No such effect is, of course, present in bubble-column machines, but even in these, summer performances are better than winter, owing, no doubt to improved conditioning.

At Pecos (*loc cit.*) blower intake was placed under the roof and condenser water was used for make-up in order to hold temperature constant winter, summer, day and night.

39. EQUIPMENT

Machines are not, of course, an operating variable in the sense that the type of action can be changed at will, but in modern machines there is considerable operating control of intensity of machine action and not a little control of the duration of treatment of underflow and overflow respectively. Thus all bubble-column types, whether straight pneumatic or subaeration, permit control of intensity of treatment of underflow by control of air supply, the more air introduced, in general, the greater the total of the upward impulses on any particular particle in the pulp and the greater the likelihood that it will discharge in the overflow. There are limits to such variation, however; if aeration is too restricted, the bubble column breaks down, there is little overflow, and recovery suffers, although grade of concentrate is improved; if aeration is too intense, either the excessive boiling of the pulp destroys the bubble column mechanically or, if a bubble column is maintained, the excessive return of gangue lowers grade of overflow. Time-factor for underflow and

overflow, at a given intensity, are dependent, in that increase in time of treatment of underflow, which is attained by raising pulp level, results in a corresponding decrease in depth of bubble column and in time for cleaning overflow. Independent control of cleaning time may, however, be obtained by the use of crowding boards or by counterflow discharge of froth. It should be noted also that the time of treatment of overflow varies inversely with change in intensity.

40. CONSTANT CONDITIONS

Constancy of operating conditions is almost as important as the initial determination of optimum conditions. It should be apparent by this time that there is a high degree of interdependence between the various elements of a flotation operation and that quantified expression of the effects of a change in one variable on another is not possible in the present state of knowledge. Hence adjustment to compensate for change in an operating condition is usually a matter of trial and error in the mill and frequently calls for laboratory help. Meantime grade and/or recovery suffer.

Experienced operators have a collection of rules of thumb that they employ to correct easily visible faults. Increase in tailing assay (indicated ordinarily by vanning) is countered by dumping in more collector. If, however, differential work is involved, this upsets the balance between collector and depressants. In this case frothing may be increased, either by increase in frothing agent or in air supply; both tend to lower concentrate grade, and the latter may also lower recovery by mechanical disturbance of the bubble column. Increase in feed rate is usually met with more than proportionate increase in collector, rise in pulp level, and by either or both of the alternative expedients for combatting tailing loss.

At Potosi (*IC 6706*) variation in *p*H caused variation in frothing. At Mt Isa (*IC 7073*) change to mine water made it necessary to increase all reagents, particularly the frother (*AC 31*); if, however, mine-water make-up was added to the tailing pond, the difficulty was obviated.

When fluctuation in character of ore supply is inevitable, attempt is usually made to devise a pilot of some kind and prescribe adjustments in terms of the showing of the pilot. Thus at Consolidated M. & S. (*131 J 315*) a Wilfley table is inserted in the stream of lead recleaner tailing and the supply of collector oil is raised or lowered according to the width of the lead streak on the table; another table is available for testing the feed to the zinc rougher.

41. CLEANING

Cleaning in froth flotation is effected by refloating rough or primary concentrate, usually in a much more dilute pulp than that present in the rougher machine. The conditions in this refloated pulp differ materially from those prevailing in the original pulp. Activators and depressors in solution are substantially reduced in concentration unless further addition thereof has been made, which is unusual. The *p*H will have moved toward neutral, though not to a great extent so far as *p*H number is concerned. Collector concentration in solution is very low. Concentration of frother is substantially higher, owing to the marked initial adsorption in the bubble films and the build-up that occurs in the rougher because of capacity of froth to hold up the frother dropped by bursting bubbles. The slime content of the solid is proportionately low and the collector-coated mineral correspondingly high. The desideratum is to keep the liquid-solid volumetric ratio in the froth high so as to encourage dropping of all lightly held grains, such as large gangue that has been trapped mechanically in rougher froth, and middling containing only small specks of valuable mineral. Aeration must be restricted to compensate for excess of frother, but it should otherwise be the maximum possible in order to maintain high liquid content. The bubble layer should be deep to give time for draining. Coalescence should be active to enforce frequent transfer of bubble loads and encourage bubble-column action, even in agitation-froth machines. Froth should be removed promptly in order to prevent overloading. Air distribution should be as even as it is possible to effect. When overloading tends to occur, it can sometimes be corrected by restricting overflow length in such a way as to cause more rapid draw from the areas that tend to overload. Spraying the froth with fresh water or even with water containing a wetting agent tends to raise grade of concentrate by encouraging coalescence and keeping bubble walls thick.

Countercurrent cleaning, used with pneumatic cells, comprises building up the sides of the cell at the tail end so as to force the low-grade froth to flow back toward the head end in order to overflow. Additional draining time is thus afforded for draining back of gangue.

42. FLOCCULATION

Flocculation in an ore pulp has long been considered an index of floatability, the vagueness of the statement being no greater than that of the ideas underlying it. Recently (1930's) the Bureau of Mines publications have set forth selective or differential flocculation of the mineral to be floated as the condition precedent to successful flotation. This comes nearer the truth than the older legend, but is still inaccurate and undependable. The difficulty flows from the fact that the floccules or particle aggregates in mineral pulps form from a variety of causes, only some of which are, at the same time, causative of selective flotation.

The aggregation which gave rise to the flocculation legend was partial or restricted levitation of granular oil-coated sulphides, the aggregates comprising a number of such sulphide particles bound together into grapelike clusters by inter-particle bubbles of microscopic size. Such aggregation or agglomeration is a characteristic result of thick-pulp selective oiling of deslimed pulps, or of high-speed agitation with oily collectors of similar pulps of medium solid content, with restricted aeration or without an active frothing agent; it occurs less frequently in slime-bearing pulps and then only with oily collectors; it is unknown with soluble collectors. It is limited to oiled pulps for the reason that only at oiled surfaces are contact angles high enough and bubble adhesion consequently strong enough to effect contact levitation in thick pulps or to survive violent agitation in dilute pulps. Such air-bound floccules, when brought into contact with an air-water interface, transfer their solid load to the interface with great rapidity and certainty, and hence were and are of utility in both froth and table flotation.

Selective flocculation also occurs to a certain extent with soluble collectors (*153 A 493*), and as such is indicative of successful flotation. But similar flocculation may be effected by noncollectors, in which case it has no indicative value. In neither case are the floccules air-bound. They have no utility. They simply flow from the fact that the particle surfaces are not in the ionized state that prevents flocculation (Art. 7).

Overoiling of a sulphide pulp containing a gangue also susceptible from any cause to oil-coating, causes nonselective air-bound flocculation of the entire pulp, all of which will float when suitable aeration is effected.

43. ATTENDANCE

Operation of flotation processes requires a higher class of labor and more careful and intelligent supervision than does any other operation in a concentrating mill. This is due to the fact that successful operation involves harmonizing many different elements, and it is substantially impossible to formulate simple rules that set forth the proper things to do under the multifarious conditions that arise. Even in the laboratory, where conditions are under the best possible control, skilled and unskilled operators working from the same set of instructions and with the same materials will obtain results differing greatly in recovery and concentrate assay, and yet the differences in the things they do are very slight and are differences of degree rather than of kind. The early results obtained in any plant are almost invariably poorer than those attained at a later date, notwithstanding that the elements of the operation have not, in so far as they are capable of definition, substantially changed. It is not, of course, to be understood that any mystery is involved, but rather that control of the magnitude or intensity of essential operating factors and judgment of results are matters that must be gained by intelligent observation and experience, all of which may be summarized in the statement that in the present state of knowledge flotation is an art rather than a science, despite the great strides that have been made in understanding of the underlying mechanism.

Pilot apparatus is a marked help to operators, and is usual equipment in differential mills. Shaking tables are normally employed. At PECOS (*IC 6605*) a dark-colored gangue made it difficult to read the concentrate streak on the pilot table at night; a small air-lift cell was put in ahead of it and the froth therefrom—free of the obscuring gangue—was sent to the table. Oxide content of ore and degree of grind are followed on the pilot table at MIDVALE (*IC 6492*). When, as at MT. ISA (*IC 7073*), losses are in the finest slimes, pilot tables are not satisfactory; there it was found that tailing assay correlated with grade of concentrate and control was based on quick assays (20 to 30 min.). At BRITANNIA (*IC 6619*) quick assays of key products are made three times per shift. Hourly colorimetrics were made at COPPER QUEEN (*IC 6404*).

44. COST

Cost of flotation varies widely according to the ore and to the scale of the operation. The elements are power, maintenance, reagents, and labor.

Power consumption depends principally on the amount of cleaning done. Consumption per ton of ore in roughing for each mineral in a pulp containing 30% solids ranges from 0.5 to 2.25 hp-hr. in matless cells, 0.75 to 3.0 hp-hr. in mat-type pneumatic cells, about the same in subaeration, and from 1.5 to 5 hp-hr. in agitation-froth machines. The lower figures correspond to rapid-floating ores and large machines. Cleaning is normally done more slowly than roughing and usually in more dilute pulps. Hence power consumption per ton of solid treated in cleaners is higher. If the ratio of concentration in roughing is low the additional consumption per ton of rougher feed for one stage of cleaning may equal that for roughing, but normally it ranges from about 20% for ores with low content of floatable mineral to 50 or 60% with highly mineralized ores; each successive cleaning stage will add 50 to 100% as much as the preceding. Each scavenging stage will normally add 50 to 100% of the consumption of the preceding stage. Consumption at copper concentrators (*IC 6792*) averaged about 2 hp-hr. per ton total for air-lift machines, 2.5 to 3.5 for mat-type, and 4 to 6 for agitation-froth. At lead-zinc concentrators the treatment of the primary stream is doubled and more cleaning is usual; the reported figures for consumption range from 6.2 to 26 hp-hr. per ton (*IC 6776*). Costs of power (1930) ranged from 0.15 to 1¢ per hp-hr. with the majority clustering about the range 0.7 to 0.9¢.

Maintenance is relatively low in all modern bubble-column machines; it is least in matless cells and greatest in the high-speed subaeration machines. It should not, however, amount to more than 5% of the total flotation cost.

Reagent costs are best estimated from current quotations on the chemicals prescribed. For rough estimates on simple sulphide ores the following approximations will apply: collector, 0.1 lb. @ 15¢ per lb.; frother, 0.1 lb. @ 10¢ per lb.; conditioner, 1 lb. @ 1 to 2¢ per lb. (1937 prices). For simple two-mineral separations, double these figures and add 25 to 100% for depressants and activants. For difficult complex ores add 50% to the preceding maximum. Costs in 1930 ranged from 2 to 13¢ per ton for copper (*IC 6792*) and from 12 to 38¢ for reagents and maintenance supplies for lead-zinc ores (*IC 6776*).

Labor cost varies greatly according to the difficulty of flotation, the scale of operation, and union exactions. In large plants treating simple ores one operator can readily handle machines treating 2,000 to 5,000 t.p.d., if they are not too scattered, and ore and reagent feed conditions are regular. On the same treatment scale with a complex or difficult ore, particularly if ore feed is irregular in composition, one man will rarely be able to handle machines carrying more than 1,000 t.p.d. In small mills treating simple ores one man can operate all of grinding and flotation, if the plant is compact. From the practical standpoint, however, it is usually necessary to hire two to three times these minimum numbers of men for the job, and labor cost will range (1940) from 2 to 3¢ per ton in large mills in which the cells practically run themselves to 25¢ or more in small mills treating difficult complex ores. A rough labor estimate may be made by equating the item to the power estimate.

Total flotation costs (1940) for sulphide ores, on the above basis, range from 6.5 to 75¢ per ton, depending on the complexity of the operation and the tonnage treated. As a very rough figure estimate power, set labor equal thereto, and take the combined cost as 30 to 50% of total for lead-zinc separation and as 50 to 75% for copper plants. These figures check with such costs as are available from annual reports and private communications.

Costs for the period around 1930 as summarized from the Information Circulars of the U. S. Bureau of Mines ranged, for copper ores, from 4¢ per ton for slime flotation at Britannia to 24¢ at Sherritt-Gordon (*IC 6792*). The costs at the porphyry coppers was 8 to 10¢. Cost for floating straight lead and straight zinc ores runs about the same as for copper. Lead-zinc differential work (1930) ranged from 23¢ at Bunker Hill & Sullivan to 50 or 60¢ at smaller plants where pyrite was present or where precious-metal values required additional scavenging.

Costs for nonmetallic flotation must be estimated in more detail, since reagent practice is not yet standardized and experienced skilled operators are not generally available.

FLOTATION FLOWSHEETS

Flotation flowsheets have four elements, *viz.*, (1) the types of operations to which the ore is subjected; (2) the order of these operations; (3) the apparatus employed; and (4) the reagent dosage. From the standpoint of record and comparison however, the first two of these are the important features; differences in apparatus are of compensatory character, and reagent dosages are so nearly standardized for most ore types that only the departures therefrom justify recording.

The usual form of presentation of a flotation flowsheet shows the machines in some diagrammatic fashion with flow lines chasing back and forth from one cell to another and off to the periphery to accessory grinding machines, classifiers, thickeners, and the like to an extent that makes a newspaper pencil maze look like a simple figure. Yet actually most such flowsheets comprise but two, rarely three or four, complementary operations applied to each of the mineral species floated. The unit block of two operations is always required because of the fundamental inability of all concentrating machines to make finished concentrate and finished tailing in one and the same operation. Hence every complete treatment scheme shows at least these two operations.

Key to flowsheets. The flowsheets herein presented are condensed according to a scheme which gives a graphic picture of the general type of treatment at a glance and an accurate story of the flow on closer examination. The basis of the scheme is that each concentrating operation which makes two products comprises a STAGE which can be represented by a long horizontal dash, thus ——. This stage may be the whole or a part of a pneumatic cell, or one or 20 successive cells of a subaeration machine; the test is that it makes two and only two products. The overflow product of any stage is conceived as flowing down the page; if it is finished concentrate, that fact is designated by a short dash below the long dash thus $\underset{-}{——}$. If more than one concentrate is made in the entire treatment, a small capital letter designates the kind of concentrate, *e.g.*, $\underset{\text{L}}{——}$ = lead. If the overflow product is reconcentrated (CLEANED), such an operation comprises another stage and is denoted by a second dash below the first or ROUGHER stage, thus $\underset{——}{——}$. Flow of underflow of all stages is presumed to be to the right, along the same horizontal level of the paper. If the underflow product of the rougher stage is finished tailing, that fact is indicated by a pair of short vertical parallel lines placed at the end of the rougher dash, thus —— ‖. If, on the other hand, the rougher underflow is subjected to another flotation treatment for the same mineral (SCAVENGED), that fact is represented by a second dash following the first, thus —— ——. Stages are assigned numbers beginning with 1 for the first or rougher stage, and continuing through all successive stages treating the primary pulp stream, thence through the stages (not necessarily successive) treating primary overflows, thence through the stages treating overflows from primary cleaners, etc. These numbers are placed above the stage dashes, thus $\overset{1}{——}$, designating the primary rougher. (See also any flowsheet in Fig. 58.) When a stream from any stage is routed other than to an adjacent stage, that fact is indicated by a small numeral placed adjacent to the stage in the proper flow line, thus $\overset{5}{\underset{3}{——}}$ indicates an overflow from stage 5 returned to stage 3 and $\overset{2}{——}$1 denotes underflow from stage 2 returned to stage 1. Accessory equipment is indicated by signs as below, the equipment is referenced by numbers in the same way as the flotation stages; nonadjacent destinations of the products are similarly designated.

☒ Dewaterer. W	Ⓐ Aerator.

45. FLOWSHEET TYPES

The flotation flowsheets of Sec. 2 are summarized in Fig. 58. Examination shows that there are but two fundamental elementary patterns in all of the flowsheets, *viz.*, $\underset{-}{\overset{1}{——}}\ \overset{2}{\underset{1}{——}}\|$ (No. 2), and $\overset{1}{——}\|$ over $\underset{-}{\overset{2}{——}}1$ (No. 13). In the first of these, known as ROUGHER-SCAVENGER flow, final concentrate is made in the rougher and final tailing in the scavenger; scavenger froth is counterflowed to the rougher. In the second, called ROUGHER-CLEANER flow, final tailing is made on the rougher, final concentrate on the cleaner, and cleaner tailing counterflows to the rougher. Roughers may be multiplied, as in 10; scavengers, as in 7 and 10; cleaners, as in 16 and 18 and, to an exaggerated degree, as in 37. Counterflow is usually one-stage, but may skip back several stages (37). The principle ordinarily followed in counterflow is to return the stream to the point where its assay value and water composition are nearest those of the stream that it joins, thus avoiding, so far as possible, change in composition of either stream on mixing. Flow 1 is designated SCALPING; flows 3 and 4 then constitute scalping followed by rougher-cleaner flow with one- and two-stage cleanings respectively. Item 6 is simply two successive rougher-scavenger flows with intervening regrind. Item 9 is simple rougher-scavenger flow for lead, rougher-two scavenger flow for zinc, and pyrite scalping of zinc-circuit tailing. Flow 21 represents a favorite combination which may be looked upon as scavenging a rougher-cleaner tailing or cleaning a rougher-scavenger concentrate. Item 26 is the same combination with one more cleaning stage. Item 30 is simply item 16 in the lead circuit and item 26 in the zinc circuit; item 32 is item 26 in the lead circuit and item 18 plus a scavenger in the zinc circuit. Item 38 is a good example of

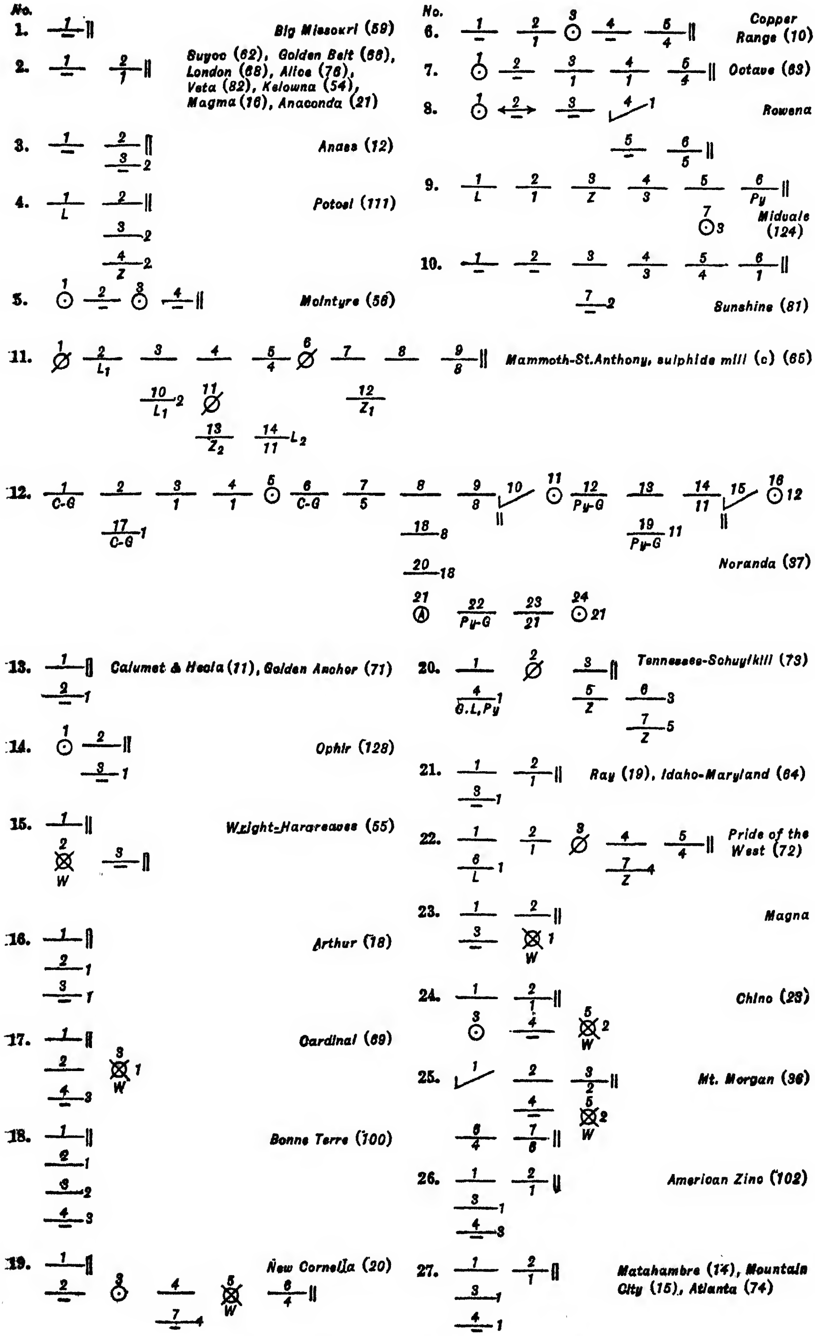

FIG. 58. Flowsheets for flotation of metalliferous ores. *a, b*

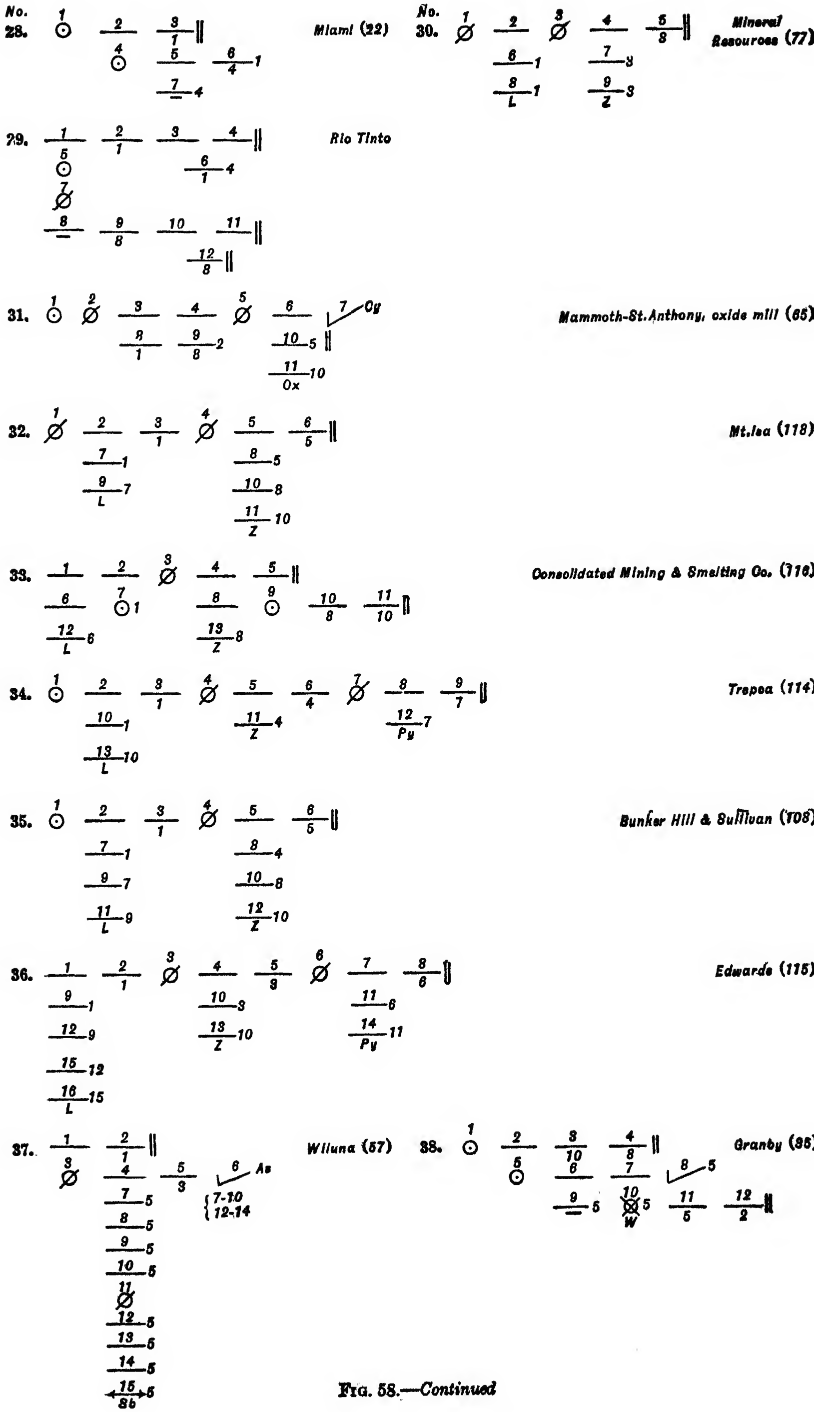

FIG. 58.—*Continued*

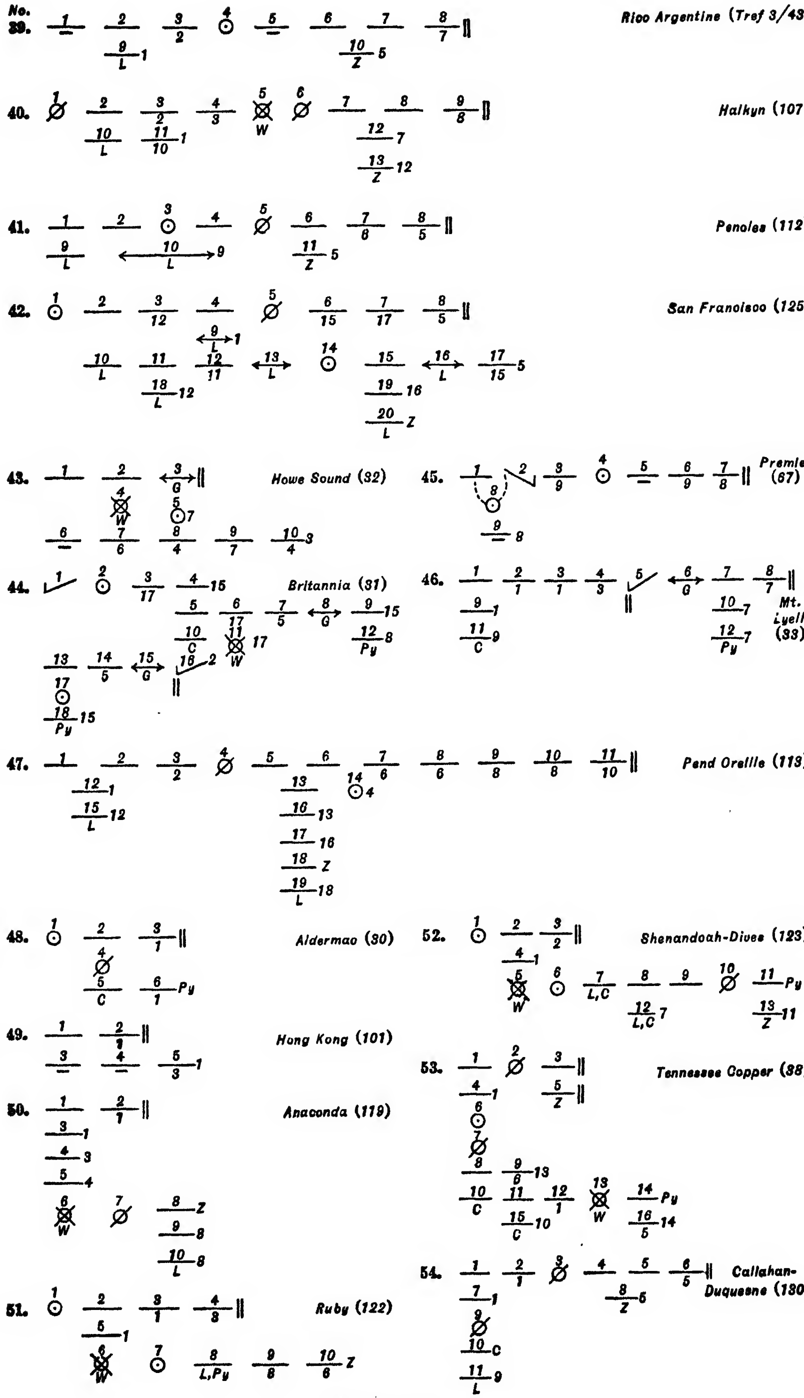

Fig. 58.—*Continued*

NOTES TO FIG. 58.

a Numerals in parenthesis following names of plants indicate figures in Sec. 2 at which mill descriptions are to be found.

b For explanation of flowsheet form see p. 103.

As = arsenic, C = copper, Cy = to cyanidation, G = gold, L = lead, Ox = oxide, Py = pyrite, Sb = stibnite, W = water, Z = zinc.

c The zinc sulphide is of two different varieties, with different colors; one depresses normally with cyanide; the other is not depressed in 1% cyanide solution nor in strong solutions of sulphites or sulphur dioxide. In the flowsheet shown, cyanide, zinc sulphate, and 0.04 lb. thiocarbanilid are added at the ball mill, cresylic acid at conditioner 1, Aerofloat 31 (0.08 lb.) at stage 4, lime and copper sulphate at conditioner 6, Z-5 xanthate in stages 7 and 9, and a 14 : 1 mixture of sodium dichromate and sodium metasilicate in aqueous solution in conditioner 11 (*A TP* 1714). Assays and recoveries at different points in the flow are shown in the accompanying table:

Material	Lead		Zinc	
	Assay, %	Weight, %	Assay, %	Weight, %
Feed	6.63	100.0	7.57	100.0
Concentrate L_1	65.50	55.2	8.04	5.6
Tailing of stage 3	3.21	....	7.67	....
Concentrate of stage 4	22.30	30.2	35.00	45.6
Tailing of stage 5	1.10	....	4.55	....
Concentrate Z_1	4.70	7.2	42.30	34.0
Final tailing	0.63	7.4	1.45	14.9
Concentrate L_2	45.50	24.4	12.85	6.8
Concentrate Z_2	7.70	5.8	47.10	38.8
Lead concentrate ($L_1 + L_2$)	54.98	79.7	9.73	12.3
Zinc concentrate ($Z_1 + Z_2$)	6.80	12.9	44.46	72.8

scavenging in the cleaner circuit; this practice usually involves regrind of rougher concentrate, either before cleaning (29) or after scalping (19), and tailing may be made on the cleaning stream (19, 38) or cleaner tailing counterflowed (28). Regrind of rough concentrate reduces grinding by permitting roughing at coarse size, with discard of coarse tailing, but it requires a coarse enough dissemination to at least insure exposure of all mineral at a size above that at which economic maximum severance is effected.

Primary-slime separation is illustrated in items 25 and 44. This practice is adopted when the character of the slime is such as to harm flotation. The flows are designed to reclaim such values as possible from the slime and then get it out of the system; thereafter the now deslimed concentrate may be admixed with sand concentrate for cleaning without harm.

Choice of flowsheet is based primarily on the prevailing economic elements and the character of the ore, particularly as regards dissemination and speed of flotation.

Rougher-scavenger flow is adapted to economic situations in which grade of concentrate is less important than recovery, *e.g.*, as for pyritic gold ores, particularly where concentrate is to be cyanided on the ground rather than shipped, or where sulphur is of value for acid, and/or iron yields a premium rather than incurs a penalty at the smelter (ANACONDA, MAGMA), or where nearness to the smelter makes additional freight on dirty concentrate less costly than additional cleaning. The simple two-stage form (item 2) requires a clean coarsely disseminated siliceous ore, which means rapid-floating, if properly conditioned. Finely disseminated and slow-floating ores, under the same economic conditions, require increase in scavenging.

Rougher-cleaner flow is used when grade of concentrate is important. If the ore is very easy to float or the operation is primarily scalping, the simple two-stage flow is used. Ordinarily, however, a scavenger is added, even for easily floated ore (21). The number of scavengers usually increases with the unit value of the metal.

Bulk-differential flows (items 50 to 54) differ in over-all pattern from those already discussed in that they tend to multiply scavengers on the cleaner streams. The reason for this practice is that the bulk-concentrate feed to the differential circuit is so highly concentrated in normally floatable material that very gentle flotation conditions must prevail in the concentrate-floating cells (these correspond to the roughers in a rougher-scavenger flow), and the scavenger cells on the same stream must be depended upon to pick up all of the floatable mineral to prevent its loss in the underflow concentrate of the last scavenger.

At ANACONDA (item 50), a rougher-cleaner circuit is used on the bulk concentrate; the lead is pulled hard on the differential rougher and zinc pulled with it is counterflowed from the lead cleaners. At MT. ISA (*IC 7073*) the lead-circuit scavenger (item 2, flowsheet 32) must be pulled hard in order to keep down Pb and Ag losses.

Scavenging is usually done in the same type of machine as roughing unless various types of machines have been purchased at different times in search for the best, or cheapest, in which case the scavenger is usually the oldest or least efficient. In light of the fact, however, that subaeration machines tend to favor the recovery of the coarser mineral and pneumatic that of the finer (Art. 35) it would seem to be better practice to make scavenger and rougher of different types, if the amount of value to be scavenged will more than pay for the extra installation and storeroom costs (see *124 J 289*).

SULPHIDE FLOTATION

46. SINGLE-SULPHIDE FLOTATION

This ranks with the rarer operations in flotation. Some of the southeastern Missouri lead ores contain galena as the only sulphide; MASCOT and some Joplin ores similarly contain sphalerite substantially unaccompanied by galena and pyrite; and gold-bearing pyrite is not infrequently the sole sulphide in gold ores. In substantially all other sulphide ores sulphides of more than one metal are present, and since concentrate predominating in any one valuable metal is usually penalized at the smelter for the presence of other metals, sulphide flotation, in most cases, involves not only elimination of rocky gangues but separation of one sulphide from another.

Separation of sulphide from rocky gangue, whether the sulphide is single or mixed, presents no problem nowadays as to the sulphide, provided the latter is not materially oxidized. Difficulty, if any, arises in the attempt to keep down some particular ingredient of the gangue. Clean siliceous ores are the simplest. Pulp is conditioned to a pH of 7 to 9, usually with lime; ethyl xanthate is used as collector and pine oil or cresylic acid as frother. Ores with clean calcareous gangues respond to the same treatment except that slightly more care needs to be taken to reduce accidental contamination by lubricants. Micaceous and other flaky gangue minerals either are coated preferentially by such lubricants or, equally coated with the other gangue minerals, they float more readily because of their smaller mass at a given grind. The usual expedients employed to keep them out of concentrate are (1) preliminary flotation with starvation quantities of frothing agent before the addition of collector, and restricted aeration; (2) conditioning for depression either with sodium silicate or with small amounts of organic colloids such as glue, casein, dextrin, or starch, and floating with a minimum of frothing agent; or (3) repeated cleaning with added conditioners of the above types. When the gangue contains considerable quantities of clay, pH must be controlled carefully to effect a maximum dispersion thereof, which usually occurs at a point slightly on the alkaline side; small amounts of sodium silicate or sodium sulphide added during grinding are frequently helpful, since these reagents tend to close up the sulphide surfaces and prevent slime coating by reaction (Art. 7); a small amount of creosote in addition to the usual sulphydrate collector apparently tends to film over light slime coatings and aid sulphide collection. Flotation of lightly oxidized sulphides is usually helped by the same expedients employed for clayey gangues, with, additionally, substitution or addition of a higher xanthate.

Floatability of sulphides varies principally in that some are more and some less subject to oxidation in aqueous pulps, and these oxidized surfaces vary specifically, according to the metal of the sulphide, in their capacity to form highly water-repellent reaction coatings with collector ions. The order of oxidizability of the common sulphides, under conditions such as occur in ordinary flotation pulps, would appear to be: Cu > Fe > Zn > Pb. The order of solubility of the thio-acid collector salts is Cu < Pb < Fe < Zn. Hence the order of floatability with sulphydrate collectors, in the absence of conditioning agents, is Cu > Pb > Fe > Zn. This order may be accentuated in certain cases and definitely upset in others by use of specific reagents. Thus in the presence of free Cu^{++}, sphalerite becomes nearly or equally floatable with galena; in the presence of CN^- or of a high concentration of lime the floatability of pyrite is greatly decreased; Na_2S in amounts near H_2S saturation decreases the floatability of all sulphides, but small amounts aid the floatability of pyrite and, to a lesser extent, galena, especially if the minerals are somewhat oxidized.

Floatability by size is normally fine sand > medium sand > coarse sand > very fine slime (see also Art. 35).

Cinnabar is readily floated at as coarse as 10-m. by small amounts of amyl xanthate (*RI 3564*). Lime and sodium cyanide may be used for depression of pyrite without effect on cinnabar flotation (*RI 3370*). Pulp made alkaline with sodium silicate is best so far as silicate gangue is concerned (*141 # 6 J 42*). Either pine oil, Aerofloat 15, or DP 23 is suitable for frothing (*RI 3564*). Rey (*153 A 586*) found that the small amount of H_2S generated in grinding a cinnabar ore containing realgar was a depressant for cinnabar in xanthate flotation. Mercuric chloride was a better activant for cinnabar than copper sulphate and permits the use of cyanide as a depressant for arsenopyrite.

Cobaltite, smaltite, and **erythrite** in a diabase gangue, assaying 2.6% Co, were floated with Flotagen, pine oil, and copper sulphate in an alkaline pulp, yielding 84% of the cobalt in a 17.8% concentrate (*Bul 724 CMB 80*). Response to flotation was slow (*ibid.* 160).

Copper sulphides generally are readily amenable to flotation. Recoveries normally range from 90 to 95%; sulphide tailing on clean ores should be less than 0.1% Cu. The best collectors are the xanthates, the ethyl variety having sufficient collecting power. The higher xanthates and their oxidation products (dixanthogens and polysulphides) and the higher mercaptans and thiophenols are recommended as selective against pyrite (*U. S. pat. 2,125,337*), but it is doubtful, in the light of Hassialis' work (*153 A 513*) whether the advice is good as to the xanthate oxidation products. Lime is almost universally used for *p*H control, and in larger quantities as a pyrite depressant. The iron-bearing copper sulphides (chalcopyrite and bornite) are susceptible to pyrite and sphalerite depressants, particularly to cyanide; nickel ion has been recommended for reactivation against cyanide, preferably in slightly alkaline pulp (*U. S. pat. 2,035,458*). When starch is used to depress MoS_2 in copper flotation it has a depressant effect on the copper minerals also; lead ion is said to have an activating influence under such circumstances (*U. S. pat. 2,070,076*). Relative floatabilities of the different copper minerals in UTAH COPPER Co. ores are to be inferred from the recoveries of the coarser sizes in Table 24. At ANACONDA the order of floatability is enargite > chalcocite > bornite.

Table 24. Recovery of copper sulphides in Utah Copper Co. ore (*After Martin*)

Mineral	Size, microns				
	>147	104	74	20	10
Chalcopyrite....	53	84	90	98	94
Bornite........	18	87	91	99	94
Chalcocite......	32	77	70	97	90
Covellite.......	54	92	96	98	93

Chalcocite; covellite. Little affected by depressants other than very high concentrations of CN^-, $S^=$ and/or OH^-. Readily collected by sulphydrates of low molecular weight (ethyl), fatty acids, and organic sulphates and sulphonates of high molecular weight.

Chalcopyrite; bornite. Less resistant to depressants than chalcocite and covellite, but more resistant to iron-mineral depressants than pyrite, *q.v.* Similarly less readily collected than the straight copper sulphides, *i.e.*, requiring somewhat stronger dosage for a given effect, but still readily floated by ethyl sulphydrates, fatty acids, and organic sulphates and sulphonates. Bornite oxidizes more readily than chalcopyrite and gives some trouble in the mills owing to over-oxidation. Chalcopyrite is depressed by cyanide in relatively low concentrations, substantially the same as required for copper-resurfaced sphalerite, while much higher cyanide concentrations are necessary to depress the other copper sulphides; hence in differential work with cyanide these other copper minerals float with the galena, while chalcopyrite is depressed with the sphalerite, and floats with it on reconditioning with copper sulphate.

Galena is activated by copper ion; under certain conditions it becomes coated with metallic copper. It is depressed by high concentration of OH^- (*p*H 10.4 with ethyl xanthate) hence sodium carbonate rather than lime is ordinarily used for *p*H control in lead circuits, in order to utilize the buffering effect of the former reagent. Galena is also depressed by low concentration of $S^=$, but not affected by CN^- or SO_3, S_2O_3, and the like. Dichromate is a strong depressant. Reactivation thereafter may be effected by reduction as with $FeSO_4$ or alkaline sulphites, or by chloridization as with HCl or NaCl in acid solution (*U. S. pat. 2,150,114*). Collected, substantially as readily as the copper minerals, by sulphydrates, fatty-acids, and sulphates or sulphonates of fatty-acid alcohols. Galena is not floated without activation by sodium Aerofloat except in highly acid pulps (*p*H = 2), but when activated by copper sulphate excellent flotation is effected.

Iron sulphides are pyrite, marcasite, pyrrhotite, and arsenopyrite. Ordinarily they are not wanted for themselves, since they lack commercial value except for acid manufacture, and cannot compete in that field with sulphur except where local markets or other special differentials act in their favor. On the other hand, certain special conditions, *e.g.*, when they are gold carriers (NORANDA; quartzitic gold ores), when they constitute otherwise inseparable impurities in concentrate (Bolivian tin), when they are a local source of arsenic, etc., may make their flotation desirable.

The iron sulphides are readily floated by fatty acids, especially in acid pulps, and by the higher xanthates in acid, neutral and even slightly alkaline pulps. The lower xanthates and the Aerofloats are not good collectors for them, particularly in pulps of reducing character (see *post*). Partially oxidized auriferous pyrite should be sulphidized, after an initial float for free gold; mercapto-benzo-thiazole is recommended for flotation of the sulphidized pyrite, with or without a higher xanthate or Aerofloat.

The iron sulphides are all highly susceptible to oxidation under the conditions prevailing in grinding circuits and flotation pulps. As a result, the pulp loads up with ferrous sulphate, the water is depleted of dissolved oxygen, and has strongly reducing quality. Oxidation is necessary from the standpoint of iron flotation with xanthates, since the insoluble xanthate is ferric. Ferrous sulphate is harmful to the flotation of other sulphides because it holds back the necessary oxidation of their surfaces. Arsenopyrite and pyrrhotite are the worst offenders. When the iron-sulphide content of the ore is high and flotation of sulphides other than iron is desired, it is necessary to oxidize ferrous ion or to remove it from solution. It cannot be oxidized so long as pyrite or SO_2 in solution remains (*RI 3263*). Precipitation is the usual procedure; it is effected by adding hydroxyl and/or carbonate ion to the pulp.

The order of floatability of the iron sulphides appears to be marcasite > pyrite > pyrrhotite. Wark and Cox (*112 A 200*) report that pyrrhotite is not coated by ethyl xanthate without resurfacing by copper sulphate.

Usually the aim is to depress iron sulphides. Cyanide ion is a powerful depressant for pyrite. The most powerful depressant combination which yet will permit flotation of other sulphides is a high-lime alkalinity with a small amount of cyanide ion. The cyanide may be omitted when, as with copper-iron or zinc sulphides, it tends to depress these associated minerals. Wark and Cox (*112 A 220*) postulate that the effect of high alkalinity and of the addition of cyanide ion is to lower the concentration of ferric ion so greatly that the solubility product of ferric xanthate is not exceeded. Sulphite ion is also a depressant. Pyrrhotite may be depressed by starch (*140 #2 J 75*). Pyrite is strongly depressed by *p*-aminophenol, which forms colloidal sols with iron salts; by phenol-sulphonic acids; by gelatin; by tannic acid and similar substances (formation of adhering and water-avid tannates and the like). Ferric sulphate is also a depressant on the acid side, although not so powerful as the ferrous salt; it is speculated that the pyrite particles become coated, even in the presence of collector, with ferric-hydroxy sol or with a layer of basic-ferric-sulphate slime (*RI 3263*), while on the alkaline side the ferric compounds flocculate and precipitate out. Arsenopyrite is reported by Wark and Cox (*134 A 45*) to respond to cyanide in the same way as pyrite when copper ion is present; in the absence of copper, however, cyanide does not affect arsenopyrite. They report a critical *p*H value of 7 for arsenopyrite with 25 mg. per li. of potassium ethyl xanthate. Lime is reported to be a better depressant than cyanide for arsenopyrite (*141 #5 J 40*). Parsons (*123 J 932*) reports that soda ash has a marked depressant effect on pyrrhotite. When flotation of pyrite in alkaline pulps is desired soda ash is used for *p*H control.

Parsons (*123 J 931*) states that soda ash is of use in reactivating pyrite that has been depressed by a cyanide-high lime mixture. Sulphide ion is sometimes used for the same purpose.

Linneite (Co–Ni·CuS) is reported (*135 J 401*) readily floated with soda ash (0.8 lb.), ethyl xanthate (0.5 lb.), and pine oil (0.1 lb.), yielding 26% Co–Ni concentrate and 0.18% tailing from a 2.2% ore.

Molybdenite is the most readily floatable of all the sulphides. It is floated at CLIMAX with a saturated hydrocarbon as the sole collector and can be refloated with the same reagent, even after depression with an organic colloid, such as starch (*U. S. pat. 2,070,076*). It floats with the copper minerals with lower-xanthate collectors and pine oil, and floats preferentially to pyrite in the presence of sodium silicate with starvation amounts of pine oil (0.03 lb. per ton) as the sole added reagent. Gaudin *et al.* (*112 A 319*) report that flotation is not markedly enhanced by xanthates; tests at Columbia University indicate that it is not coated by xanthate at all. It is depressed in copper ores by starch, glue, and other organic colloids added in controlled quantities (*U. S. pat. 2,070,076*). "Condensation products of aldehydic substances (formaldehyde, acetaldehyde, butyraldehyde) with aromatic sulphonic acids (sulphonic acids of alkylated and nonalkylated aromatic hydrocarbons such as benzene, xylene, naphthalene, etc.), and the salts of these products with salt-forming bases" are also recommended as depressants (*U. S. pat. 2,187,930*), but commercial use is not reported. Differential separation from copper is effected by making a bulk float, decomposing the xanthate coatings on both minerals by steaming (*143 #2 J 80*) or by dry heating and refloating the molybdenite with pine oil ± small amounts of kerosene (MIAMI, UTAH, CHINO). Xantho-molybdic acid is recommended as a selective collector (*U. S. pat. 2,148,475*). Marsh (*U. S. pat. 2,316,743*) recommends differential flotation of molybdenite from other sulphides by use of a mixture of C_6–C_{10} aliphatic alcohols, fuel oil, and pine oil (approx. 4 : 4 : 2 respectively). He notes that in such flotation lime in excess of $^1/_2$ lb. per ton is harmful but that soda ash producing even higher alkalinity is not.

Molybdenite, owing to its softness, acts like graphite in coating gangues by smearing, whereupon such coated gangue particles float and lower grade of concentrate; use of

sodium silicate tends to prevent the coating or to detach and disperse the adhering particles, and thus raise grade.

Realgar floats readily with a neutral hydrocarbon oil as collector. It requires activation by a heavy-metal salt for flotation with xanthate; this activation hinders flotation with hydrocarbon collectors. Dextrin is a depressant.

Silver sulphides are argentite; the arsenic- and antimony-sulphur compounds polybasite, proustite, pyrargyrite, and stephanite; and silver-bearing tetrahedrite, tennantite, and galena. Leaver and Woolf (*RI 3436*) made an extensive study of the behavior of pure-mineral mixtures of these (exclusive of tennantite and galena) with clean siliceous and with slimy gangues. Their findings were that argentite, polybasite, and tetrahedrite are all readily floated by ethyl xanthates and Aerofloat 15, and that recoveries were not affected by sufficient amounts of lime to depress pyrite. Pyrargyrite floated with the lower sulphydrates in neutral circuit but was depressed by small quantities of lime. Proustite and stephanite required higher xanthates (amyl) for efficient flotation and were both affected adversely by lime. Iron oxide slimes were generally bad, if dispersed, because they lowered concentrate grade unless frothing was decreased, and they lowered recovery when frothing was decreased. Talcy slimes lowered recovery when they were flocculated by lime. Both slimes could be depressed by starch; but such depression lowered recovery with all the minerals except tetrahedrite. Sodium sulphide, which is often used with oxidized gold ores, consistently lowered recovery, even in low concentrations.

Tennantite is similar to tetrahedrite and the Leaver and Woolf tests on the latter may be considered indicative of the probable behavior of the former.

Galena is not appreciably affected in flotation behavior by silver content.

Mill practice with silver sulphides is to use powerful sulphydrate collectors, and lime, and, if necessary, cyanide to depress pyrite. If pyrite depression raises tailing assay, use of a lower xanthate or of a cresyl Aerofloat may raise recovery without floating undue quantities of pyrite. At Eldorado, the collectors are Aerofloats 25 and 208 (*139 #4 J 37*); at Sunshine (*136 J 269*), Aerofloat 25, Minerec A, and Barrett 4 were used. At Lucky Tiger (*128 J 465*), Aerofloat plus ethyl xanthate gave maximum recovery on an ore in which the principal silver-bearing mineral was tetrahedrite.

Sphalerite, in the absence of activating ions, is floatable with fatty-acid collectors in acid pulps but not so well at higher pH; it is not floated by the lower sulphydrate collectors but is floated by xanthates C_8 and upward. Resurfacing is effected by all metallic ions that form less soluble sulphides than Zn does. Such resurfacing, and activation toward ethyl xanthate, are effected by As, Sb, and Pt for flotation in acid solutions ($pH = 4$ to 5), and by Ce, Pb, Cd, Cu, Ag, Hg, Bi, and Au for flotation in neutral solutions (*40 JPC 799; PF 168*). The minimum concentration of copper ion that will activate sphalerite is reported (*112 A 245*) to be 10^{-28} mols per li. It is reported (*38 JPC 13*) that one minute is sufficient for monomolecular filming at usual operating concentrations.

Sphalerite is usually a penalty product in concentrates of metals other than zinc, and zinc concentrates are penalized heavily for extraneous substances. On the other hand the mineral occurs without sulphide associates in very few ores. It must, therefore, be depressed, or floated in pulps containing depressants for other sulphides, in practically every case where it is recovered, and hence its behavior to depressants and activators is of primary importance. Usual procedures are to depress it from copper and lead minerals and to float it away from iron. Since it does not float with the lower sulphydrates without activation, activation is prevented by complexing the usual activating ions (Cu, Ag) by cyanide (Art. 8) and floating the lead and/or copper minerals with a lower xanthate or Aerofloat, then activating the sphalerite with copper ion in excess of that required to complex the remaining cyanide, when it can be floated with a sulphydrate. Lime is preferred for pH control; pH is usually held between 9.0 and 11.5. The floatability of sphalerite is increased markedly by rise in temperature. If iron is to be depressed, this is done by adding high lime, in which case a higher sulphydrate, butyl or amyl, is used for collection, or the lower molecular-weight collector is buttressed by an oil.

Cyanide is not a depressant for unactivated sphalerite in the presence of a collector for the same, such as fatty acid.

Sulphites depress sphalerite in much the same way as cyanide does, but higher concentrations are required and the operation requires close control. The action of sulphite ion is intensified by adding the sulphate or chloride of Al.

The action of cyanide ion is intensified by $ZnSO_4$. Salts of manganese, tin, nickel, etc., which, in the presence of iron, will precipitate insoluble ferrocyanides, are also recommended to be added with cyanide to intensify its action (*U. S. pat. 2,048,369*).

Ferrous sulphate is harmful in sphalerite flotation; the ferrous ion should be removed by precipitation by lime or soda ash, or it may be oxidized as by $CaOCl_2$, or removed by washing.

The iron sulphides are all highly susceptible to oxidation under the conditions prevailing in grinding circuits and flotation pulps. As a result, the pulp loads up with ferrous sulphate, the water is depleted of dissolved oxygen, and has strongly reducing quality. Oxidation is necessary from the standpoint of iron flotation with xanthates, since the insoluble xanthate is ferric. Ferrous sulphate is harmful to the flotation of other sulphides because it holds back the necessary oxidation of their surfaces. Arsenopyrite and pyrrhotite are the worst offenders. When the iron-sulphide content of the ore is high and flotation of sulphides other than iron is desired, it is necessary to oxidize ferrous ion or to remove it from solution. It cannot be oxidized so long as pyrite or SO_2 in solution remains (*RI 3263*). Precipitation is the usual procedure; it is effected by adding hydroxyl and/or carbonate ion to the pulp.

The order of floatability of the iron sulphides appears to be marcasite > pyrite > pyrrhotite. Wark and Cox (*112 A 200*) report that pyrrhotite is not coated by ethyl xanthate without resurfacing by copper sulphate.

Usually the aim is to depress iron sulphides. Cyanide ion is a powerful depressant for pyrite. The most powerful depressant combination which yet will permit flotation of other sulphides is a high-lime alkalinity with a small amount of cyanide ion. The cyanide may be omitted when, as with copper-iron or zinc sulphides, it tends to depress these associated minerals. Wark and Cox (*112 A 220*) postulate that the effect of high alkalinity and of the addition of cyanide ion is to lower the concentration of ferric ion so greatly that the solubility product of ferric xanthate is not exceeded. Sulphite ion is also a depressant. Pyrrhotite may be depressed by starch (*140 #2 J 75*). Pyrite is strongly depressed by *p*-aminophenol, which forms colloidal sols with iron salts; by phenol-sulphonic acids; by gelatin; by tannic acid and similar substances (formation of adhering and water-avid tannates and the like). Ferric sulphate is also a depressant on the acid side, although not so powerful as the ferrous salt; it is speculated that the pyrite particles become coated, even in the presence of collector, with ferric-hydroxy sol or with a layer of basic-ferric-sulphate slime (*RI 3263*), while on the alkaline side the ferric compounds flocculate and precipitate out. Arsenopyrite is reported by Wark and Cox (*134 A 45*) to respond to cyanide in the same way as pyrite when copper ion is present; in the absence of copper, however, cyanide does not affect arsenopyrite. They report a critical *p*H value of 7 for arsenopyrite with 25 mg. per li. of potassium ethyl xanthate. Lime is reported to be a better depressant than cyanide for arsenopyrite (*141 #5 J 40*). Parsons (*123 J 932*) reports that soda ash has a marked depressant effect on pyrrhotite. When flotation of pyrite in alkaline pulps is desired soda ash is used for *p*H control.

Parsons (*123 J 931*) states that soda ash is of use in reactivating pyrite that has been depressed by a cyanide-high lime mixture. Sulphide ion is sometimes used for the same purpose.

Linneite (Co–Ni·CuS) is reported (*135 J 401*) readily floated with soda ash (0.8 lb.), ethyl xanthate (0.5 lb.), and pine oil (0.1 lb.), yielding 26% Co–Ni concentrate and 0.18% tailing from a 2.2% ore.

Molybdenite is the most readily floatable of all the sulphides. It is floated at CLIMAX with a saturated hydrocarbon as the sole collector and can be refloated with the same reagent, even after depression with an organic colloid, such as starch (*U. S. pat. 2,070,076*). It floats with the copper minerals with lower-xanthate collectors and pine oil, and floats preferentially to pyrite in the presence of sodium silicate with starvation amounts of pine oil (0.03 lb. per ton) as the sole added reagent. Gaudin *et al.* (*112 A 319*) report that flotation is not markedly enhanced by xanthates; tests at Columbia University indicate that it is not coated by xanthate at all. It is depressed in copper ores by starch, glue, and other organic colloids added in controlled quantities (*U. S. pat. 2,070,076*). "Condensation products of aldehydic substances (formaldehyde, acetaldehyde, butyraldehyde) with aromatic sulphonic acids (sulphonic acids of alkylated and nonalkylated aromatic hydrocarbons such as benzene, xylene, naphthalene, etc.), and the salts of these products with salt-forming bases" are also recommended as depressants (*U. S. pat. 2,187,930*), but commercial use is not reported. Differential separation from copper is effected by making a bulk float, decomposing the xanthate coatings on both minerals by steaming (*143 #2 J 80*) or by dry heating and refloating the molybdenite with pine oil ± small amounts of kerosene (MIAMI, UTAH, CHINO). Xantho-molybdic acid is recommended as a selective collector (*U. S. pat. 2,148,475*). Marsh (*U. S. pat. 2,316,743*) recommends differential flotation of molybdenite from other sulphides by use of a mixture of C_6–C_{10} aliphatic alcohols, fuel oil, and pine oil (approx. 4 : 4 : 2 respectively). He notes that in such flotation lime in excess of $^1/_2$ lb. per ton is harmful but that soda ash producing even higher alkalinity is not.

Molybdenite, owing to its softness, acts like graphite in coating gangues by smearing, whereupon such coated gangue particles float and lower grade of concentrate; use of

sodium silicate tends to prevent the coating or to detach and disperse the adhering particles, and thus raise grade.

Realgar floats readily with a neutral hydrocarbon oil as collector. It requires activation by a heavy-metal salt for flotation with xanthate; this activation hinders flotation with hydrocarbon collectors. Dextrin is a depressant.

Silver sulphides are argentite; the arsenic- and antimony-sulphur compounds polybasite, proustite, pyrargyrite, and stephanite; and silver-bearing tetrahedrite, tennantite, and galena. Leaver and Woolf (*RI 3436*) made an extensive study of the behavior of pure-mineral mixtures of these (exclusive of tennantite and galena) with clean siliceous and with slimy gangues. Their findings were that argentite, polybasite, and tetrahedrite are all readily floated by ethyl xanthates and Aerofloat 15, and that recoveries were not affected by sufficient amounts of lime to depress pyrite. Pyrargyrite floated with the lower sulphydrates in neutral circuit but was depressed by small quantities of lime. Proustite and stephanite required higher xanthates (amyl) for efficient flotation and were both affected adversely by lime. Iron oxide slimes were generally bad, if dispersed, because they lowered concentrate grade unless frothing was decreased, and they lowered recovery when frothing was decreased. Talcy slimes lowered recovery when they were flocculated by lime. Both slimes could be depressed by starch; but such depression lowered recovery with all the minerals except tetrahedrite. Sodium sulphide, which is often used with oxidized gold ores, consistently lowered recovery, even in low concentrations.

Tennantite is similar to tetrahedrite and the Leaver and Woolf tests on the latter may be considered indicative of the probable behavior of the former.

Galena is not appreciably affected in flotation behavior by silver content.

Mill practice with silver sulphides is to use powerful sulphydrate collectors, and lime, and, if necessary, cyanide to depress pyrite. If pyrite depression raises tailing assay, use of a lower xanthate or of a cresyl Aerofloat may raise recovery without floating undue quantities of pyrite. At ELDORADO, the collectors are Aerofloats 25 and 208 (*139 #4 J 37*); at SUNSHINE (*136 J 269*), Aerofloat 25, Minerec A, and Barrett 4 were used. At LUCKY TIGER (*128 J 466*), Aerofloat plus ethyl xanthate gave maximum recovery on an ore in which the principal silver-bearing mineral was tetrahedrite.

Sphalerite, in the absence of activating ions, is floatable with fatty-acid collectors in acid pulps but not so well at higher pH; it is not floated by the lower sulphydrate collectors but is floated by xanthates C_8 and upward. Resurfacing is effected by all metallic ions that form less soluble sulphides than Zn does. Such resurfacing, and activation toward ethyl xanthate, are effected by As, Sb, and Pt for flotation in acid solutions (pH = 4 to 5), and by Ce, Pb, Cd, Cu, Ag, Hg, Bi, and Au for flotation in neutral solutions (*40 JPC 799; PF 168*). The minimum concentration of copper ion that will activate sphalerite is reported (*112 A 245*) to be 10^{-28} mols per li. It is reported (*38 JPC 13*) that one minute is sufficient for monomolecular filming at usual operating concentrations.

Sphalerite is usually a penalty product in concentrates of metals other than zinc, and zinc concentrates are penalized heavily for extraneous substances. On the other hand the mineral occurs without sulphide associates in very few ores. It must, therefore, be depressed, or floated in pulps containing depressants for other sulphides, in practically every case where it is recovered, and hence its behavior to depressants and activators is of primary importance. Usual procedures are to depress it from copper and lead minerals and to float it away from iron. Since it does not float with the lower sulphydrates without activation, activation is prevented by complexing the usual activating ions (Cu, Ag) by cyanide (Art. 8) and floating the lead and/or copper minerals with a lower xanthate or Aerofloat, then activating the sphalerite with copper ion in excess of that required to complex the remaining cyanide, when it can be floated with a sulphydrate. Lime is preferred for pH control; pH is usually held between 9.0 and 11.5. The floatability of sphalerite is increased markedly by rise in temperature. If iron is to be depressed, this is done by adding high lime, in which case a higher sulphydrate, butyl or amyl, is used for collection, or the lower molecular-weight collector is buttressed by an oil.

Cyanide is not a depressant for unactivated sphalerite in the presence of a collector for the same, such as fatty acid.

Sulphites depress sphalerite in much the same way as cyanide does, but higher concentrations are required and the operation requires close control. The action of sulphite ion is intensified by adding the sulphate or chloride of Al.

The action of cyanide ion is intensified by $ZnSO_4$. Salts of manganese, tin, nickel, etc., which, in the presence of iron, will precipitate insoluble ferrocyanides, are also recommended to be added with cyanide to intensify its action (*U. S. pat. 2,048,369*).

Ferrous sulphate is harmful in sphalerite flotation; the ferrous ion should be removed by precipitation by lime or soda ash, or it may be oxidized as by $CaOCl_2$, or removed by washing.

Stibnite does not float with xanthates without activation (*112 A 319*). It is reported to be activated for such flotation by copper sulphate (*RI 3328*), and when thus activated to have the same standard curve as sphalerite (*40 JPC 799*). Lead is said (*U. S. pat. 2,052,-214*) to activate it for flotation with thiocarbanilid or Aerofloat. Fahrenwald (*139 # 2 J 80*) reports that it is depressed by copper sulphate at *p*H 4 to 7.4, and by cyanide at *p*H 3.5 to 7.

47. DIFFERENTIAL FLOTATION

Differential flotation is the term used to describe flotation operations in which two or more minerals are successively floated from a pulp, or, more rarely, in which a bulk concentrate is first floated and then, after conditioning this concentrate to effect selective depression of one or more of the mineral constituents thereof, is refloated. Choice between the two methods is discussed in Art. 48. Differential flotation has been applied principally to sulphide ores. The usual separations are galena from sphalerite, and copper sulphides from pyrite; less frequently, galena from pyrite, sphalerite from pyrite, chalcopyrite from sphalerite, and galena from copper sulphides.

Certain general procedures are followed in all differential work. So long as the flotation is differential, *i.e.*, so long as one or more sulphides are to remain depressed during the flotation of another, collectors which act with a certain degree of selectivity in favor of the mineral to be floated are chosen; the molecular weight of the collector is kept down; and starvation quantities are added. Conditioning for selective flotation of the first mineral is usually effected during grinding, but Parsons (*123 J 757*) says that as much as 2 1/2 hr. contact time is allowed in some practice before lead flotation and up to one hr. before subsequent zinc flotation; in other ores the required contact times are a few minutes only. Froth is made as fragile and lively as possible without excessive loss of the mineral to be floated. Table 25 shows the comparative behaviors of common sulphides with normal concentrations of various collectors and conditioning agents.

Table 25. Collector coating and the effects of depressants on sulphide minerals, as determined by contact angles (*After Wark and Cox, 112 A 267*)

Collector	Concn., mg. per li.	Chalcopyrite *j*		Pyrite		Galena		Sphalerite *d*	
		Critical *p*H	Critical CN⁻ concn., mg. per li.	Critical *p*H	Critical CN⁻ concn., mg. per li.	Critical *p*H	Critical CN⁻ concn., mg. per li.	Critical *p*H	Critical CN⁻ concn., mg. per li.
Sodium Aerofloat	32.5	9.6	±0.01	4.1 *a*	....	6.5	∞	*e*	....
Ethyl xanthate (K)	25	11.8	0.4	10.5 *b*	0.1	10.4	∞	*e*	....
Ethyl dithiocarbamate (Na,di)	26.7	>13.5	1.8	10.5 *c*	....	>13.5	∞	6.3 *f*	*i*
Amyl xanthate (K iso-)	31.6	>13	2.4	12.3	1.7	12.1	∞	5.5 *g*	*i*
Amyl dithiocarbamate (K,di)	42.3	>13.5	±50	12.9 *c*	17	>13.5	∞	10.4 *h*	*i*

a Copper ion activates at higher *p*H values.
b Raised to 12 by 150 mg. per li. $CuSO_4 \cdot 5H_2O$.
c Response greatly decreased by 5 mg. per li. $CuSO_4 \cdot 5H_2O$ and bubble attachment completely prevented by 150 mg. per li. Probably due to impoverishment of collector by precipitation as the copper salt.
d When activated with copper behaves like chalcopyrite, but slightly more sensitive to depressants.
e No contact, irrespective of *p*H or quantity of collector up to 200 mg. per li.
f Increases to 7.8 as quantity of collector is raised to 200 mg. per li.
g Increases to 6.5 as quantity of collector is raised to 200 mg. per li.
h Increases to 11 as quantity of collector is raised to 200 mg. per li.
i Cyanide an effective depressant.
j The other copper sulphides are more resistant to depression than chalcopyrite.

Critical cyanide-ion concentrations of Table 25 are for the collector concentrations given therein. It has been pointed out that the values vary with collector concentrations, but that with normal and higher collector concentrations the floatability curve for any sulphide mineral (Fig. 59), which has the same general shape, down to the lower inflection point, as the curve of constant cyanide-ion concentration, has the same shape as that for any other sulphide mineral, in other words that this may be designated a STANDARD CURVE.

Wark and Sutherland (*134 A 53*) report, however, that when starvation quantities of collector are used, the presence of heavy-metal salts, addition of sodium carbonate, or low temperature, separately or in combination, produces ISLANDS OF NONFLOATABILITY to the left of and below the standard curve and that aggravation of these conditions causes these islands to so grow and the curve itself to become

so modified in shape and position that all resemblance to the standard condition is lost. Pyrite and pyrrhotite are most markedly affected and chalcocite least. The authors conclude therefrom that susceptibility to departure from the standard curve is a measure of susceptibility to depression, and that those conditions which, in contact-angle tests, produce most marked departure are the ones which should be applied in the cell for depression. They state further that island formation is due fundamentally to exhaustion of collector. If this is true, differential flotation becomes a clear-cut problem of the use of a collector, the heavy-metal salts of which have different solubilities according to the heavy-metal ion; the addition of starvation quantities thereof; with possibly the further addition of a soluble salt of the metal of the sulphide to be collected, and of carbonate ion.

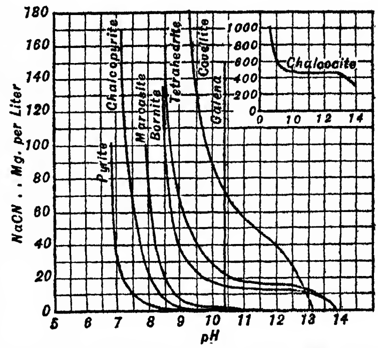

FIG. 59. Floatability curves for sulphide minerals with KEtX in the presence of CN^- and OH^- (*After Wark and Cox*).

Galena-sphalerite separation is usually performed by grinding in the presence of lime or sodium carbonate sufficient in quantity to maintain *p*H of 8 to 9.5, plus 0.1 to 0.5 lb. per ton of sodium cyanide, the amount required depending upon the amount of copper ion to be locked up and upon the alkalinity maintained. Soda ash is normally used for *p*H control, both to buffer below the critical *p*H for galena (10.4 for ethyl xanthate) and to precipitate lead as the basic carbonate and thus prevent activation of sphalerite by lead ion. Ethyl xanthate or a lower Aerofloat or thiocarbanilid is used as the lead collector, normally in very small quantities to minimize coating of sphalerite, and a small amount of wood or coal-tar creosote may also be added, the function of which is probably to smear the lightly coated galena and thereby aid bubble attachment. Occasionally chemical collectors are omitted, the minute sulphydric content of tar oils being depended upon to spread an oil coating on the galena. Frothing is usually kept to a minimum by starvation quantities of frothing agent (0.03 to 0.1 lb. per ton).

If sphalerite tends to float despite the cyanide, zinc sulphate is added; if sphalerite flotation still persists, it is wise first to examine into the lubricants employed in mining and crushing, eliminating those in the mine that are doped with fatty acids and soaps, and protecting in the mill against introduction of grease into the ore stream. At MAMMOTH-ST. ANTHONY (*A TP 1714*) the sphalerite was of two varieties so far as color and depressibility were concerned; one depressed normally, the other would not depress with cyanide or with sulphite ion. Copper minerals were dispersed in both varieties; apparently more coarsely so in the depressible one. The remedy was to float a lead-zinc middling, containing the nondepressible zinc, between the normal lead and zinc stages, and to depress the lead from this (Fig. 58, item 11).

Parsons (*123 J 759*) states that when the iron-mineral content is low, sodium bicarbonate may be preferable to sodium carbonate for lead-zinc separation.

Sphalerite is usually floated by adding sufficient copper sulphate to complex cyanide ion (Art. 7) and to activate the sphalerite. Xanthate, frequently of higher molecular weight than that used for galena, is added as collector. Frothing is made more vigorous. Leady middling may be returned to the lead circuit, but if this is done it should be well conditioned in relatively strong cyanide to deactivate sphalerite, and should usually be reground. High lime is added to keep pyrite down. If pyrite is absent, or substantially so, sphalerite may be floated with oleic acid in substantially neutral or slightly acid circuit without activation by copper, but this treatment is barred when pyrite or lime-bearing gangue is present, because these then float with the sphalerite.

Copper minerals present normally float with the galena, as do also any free silver minerals. If chalcopyrite is to be so floated, however, the cyanide addition must be carefully regulated, since this mineral is materially depressed by relatively small amounts of cyanide at a *p*H above 8 (see Fig. 59).

At CENTRAL MINE, Broken Hill, Australia (*82 Aa 23*), KEtX, 0.03 to 0.05 lb., is used to float galena, and soda ash, 0.6 to 0.8 lb. per ton, to lower concentration of lead ion and prevent activation of sphalerite. This is essentially differential flotation by reason of the relatively high solubility of zinc ethyl xanthate. Laboratory results indicated better grade of lead concentrate with more soda ash, but build-up of some ingredient in circulating mill water with the higher concentrations caused a great decrease in grade. Cyanide as a depressant improved grade of lead concentrate but depressed silver. Zinc was reactivated by neutralization of the pulp (13 to 15 lb. per ton of H_2SO_4 required) and 0.4 to 0.5 lb. copper sulphate, and floated with 0.05 to 0.07 lb. KEtX. An alkaline circuit was harmful in zinc flotation. A similar method is followed at BROKEN HILL SOUTH (*129 J 350*).

At BUNKER HILL & SULLIVAN (*U. S. pat. 2,019,306*) a partially oxidized lead-zinc-iron ore yielded four concentrates and a reject as follows: The ground ore was treated with sodium silicate in sufficient

quantity to disperse slimes thoroughly and was then lightly deslimed. Glue, 0.3 lb. per ton; a frothing agent comprising 10% pine oil and 90% Barrett 4; and 0.005 lb. of ethyl xanthate were added and galena floated. Sphalerite was next activated with 1 lb. of copper sulphate and floated with addition of 0.1 lb. Barrett 4. Pyrite was floated next on addition of 0.2 lb. ethyl xanthate. Finally cerussite was floated with 1 lb. of an oleic soap-cresol gel.

At PECOS (*IC 6605*) it was found that lead recovery and grade of concentrate were improved and zinc grade was improved at the expense of a slight loss in recovery by substituting lime and amyl xanthate for soda ash and ethyl xanthate in the lead circuit. Zinc sulphate only (0.8 lb. per ton) was used with the lime in the 15-min. conditioning for zinc depression; cyanide addition was deferred until zinc began to show in lead roughing (fourth cell) and until pyrite began to appear in zinc flotation, *i.e.*, in the cleaners. The earlier cyanide was added the less the recovery of Ag and Cu in lead concentrate (where they are paid for). $ZnSO_4$ is, similarly, the only depressant used for sphalerite at the HECLA (*IC 6600*), PAGE (*IC 6587*), and MORNING (*IC 6587*) mills.

Parsons (*123 J 931*) generalizes that the separation between lead and zinc with cyanide is easier and more complete the higher the iron content of the zinc mineral. This is probably due to coupling prevention of copper resurfacing of zinc with cuprocyanide depression of iron.

Sphalerite is described as floated preferentially to galena by use of an unsubstituted primary aliphatic amine of at least 6 carbon atoms (*U. S. pat. 2,287,274*). (See also Art. 5.)

Galena-pyrite separation with sulphydric collectors is made with cyanide; alkali is not effective for the reason that the critical pH of the two minerals is close together.

Copper-iron separation is a much more difficult problem than lead-zinc both because the copper is usually present in two or more sulphides having different responses to flotation agents, and because depression of the iron is not simply a matter of prevention of activation, as is the case with sphalerite, but requires the taking of steps that detract from the floatability of the copper minerals as well as of the iron minerals, although to a smaller extent.

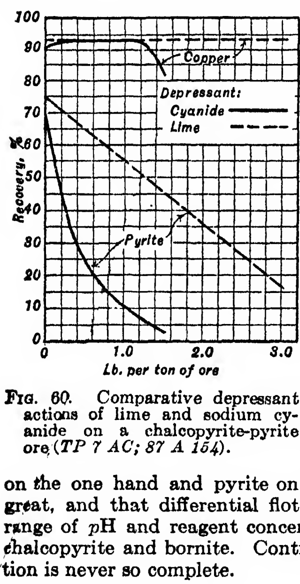

FIG. 60. Comparative depressant actions of lime and sodium cyanide on a chalcopyrite-pyrite ore (*TP 7 AC; 87 A 154*).

The usual copper sulphides are chalcocite and chalcopyrite, the former characteristic of secondary deposits and the latter of primary. Bornite is fairly common in transition zones; covellite is usually present in minor quantities with chalcocite; tetrahedrite, tennantite and enargite are often present in minor amounts in vein-type deposits, particularly in ores containing sensible amounts of precious metals.

The usual iron mineral is pyrite. Pyrrhotite may constitute an important part of the massive copper sulphides, as, for example, at NORANDA and TENNESSEE COPPER.

The relative responses of the copper minerals and of pyrite to sulphydrate collectors and to cyanide, the usual iron depressant, are shown in Figs. 59 and 60. High concentration of lime is also an effective depressant for pyrite (Fig. 60). It is apparent from the curves that while the differences in the responses of chalcocite and covellite on the one hand and pyrite on the other to the collectors and to cyanide are relatively great, and that differential flotation should, therefore, be possible over a considerable range of pH and reagent concentrations, the differences in response are much less with chalcopyrite and bornite. Control must be much closer with these minerals, and separation is never so complete.

In tests on copper-iron separation with ALDERMAC ore, 0.04 lb. per ton was the maximum permissible cyanide addition without affecting chalcopyrite in alkaline (soda-ash) pulp with Aerofloat 25 and cresylic acid. Pyrite was floated subsequently with Aerofloat 25, ethyl xanthate, and copper sulphate (*724 CMB 101*). At HOWE SOUND (*140 #11 J 34*) the maximum permissible cyanide addition was 0.02 to 0.04 lb. per ton of feed. The effectiveness of cyanide to depress pyrite from chalcopyrite is less at 95° F. than at 10° F. (*134 A 48*). Addition of copper sulphate increases pyrite depression at the lower temperature but not at the higher. Sodium Aerofloat shows maximum differentiation between the two minerals in the absence of copper sulphate (*112 A 290*). The Aerofloat reagents are normally used in the mills for the separation, since they are effective at lower alkalinities than xanthates, but pH must be watched closely as the effectiveness of the collector falls off rapidly with excess alkalinity. The dithiocarbamates are highly effective for differentiation in the presence of copper ion.

At ANACONDA (*112 A 413*) an exhaustive series of tests was run, directed toward maximum depression of pyrite. It was found that cyanide plus zinc sulphate was much more effective than high lime, but that, using them, middling could not be returned to the head of the roughing circuit or there was a loss of copper mineral locked with depressed pyrite. A flowsheet was devised in which a high-grade concentrate was made on the primary rougher, using sodium Aerofloat and ethyl xanthate as collectors

and high lime for depression, then a high-pyrite middling was made on the scavenger, which middling was reground and floated in a cleaner-scavenger circuit, making tailing on the scavenger; scavenger froth was sent back to the cleaner. Tailing of the cleaner-scavenger circuit was 0.36% Cu as against 0.14% on the primary scavenger, with a combined tailing of 0.20% Cu. Concentrate was raised from 28% to 41% Cu.

Lime is the usual pyrite depressant. At ANACONDA (*128 J 297*) pH is carried at 12 to 13 (5 to 6 lb. of lime per ton of ore), and ethyl xanthate kept at a minimum; tonnage rate is kept as constant as possible; control is by colorimetric tailing assays at hourly intervals; overfrothing raises tailing loss. At BRITANNIA (*IC 6619*) a bulk float of copper minerals and copper-pyrite middling is made with ethyl xanthate, pine oil, and lime (pH 8 to 8.5); the rough concentrate is reground to break the copper-pyrite bond and then refloated with ethyl xanthate, Aerofloat 25, pine oil, and lime to pH 10 to 10.5. At MIAMI (*IC 6573*) it was found necessary to have a small amount of undissolved lime present for good pyrite depression in chalcocite-pyrite rough concentrate; increase in lime depresses chalcocite also. At UTAH (*IC 6479*) a small amount of cyanide is used with lime.

At INTERNATIONAL NICKEL (*130 J 467*) chalcopyrite is said to be floated from pyrrhotite and pentlandite without use of a depressant, simply by crowding the cells and feeding starvation quantities of collector and frother.

At RIO TINTO, Province of Huelva, Spain (*52 CMJ 97*), treating a high-sulphide chalcopyrite-pyrite ore, the flotation routing (Fig. 58) involves the familiar roughing out of a bulk concentrate, regrinding this, and making a differential float of chalcopyrite and a final tailing therefrom. In both the rougher and cleaner circuits, however, low-grade secondary middling from scavenger cells is cleaned and returned directly to the concentrate cell of its respective circuit. This ingenious variant on the usual one-stage middling counterflow in concentrate-middling routings tends to build up a rich feed to the concentrate cell without as many reflotations of the difficultly floatable fraction of the valuable mineral, and thus tends to decrease tailing loss.

Sphalerite-pyrite separation is effected by first activating the sphalerite with copper sulphate and then depressing pyrite with lime. The collector should be of low molecular weight and added in as small quantity as will just effect sphalerite flotation. Wark and Cox (*134 A 48*) report tests indicating that the copper-cyanide complex is the effective depressant for pyrite in the co-presence of copper ion and a cyanide salt, and that the depressing action of this ion on pyrite is greater at low than at high atmospheric temperatures.

In general in lead-zinc-iron separations the alkalinity in the zinc circuit is kept higher than in either of the others.

Chalcopyrite-sphalerite separation is one of the most difficult. The usual procedure is to add soda ash and cyanide in grinding to prevent resurfacing of sphalerite with copper and then to float with a strong collector, adding a little copper sulphate at the cell, if necessary, to lower cyanide-ion concentration below the critical for chalcopyrite.

At SHERRITT-GORDON (*Q, Tref 1/44*) chalcopyrite is floated from a heavy-sulphide pulp maintained at 0.8 lb. Na_2CO_3 per ton of water, using cyanide to depress sphalerite and thiocarbanilid to minimize iron flotation. Amyl xanthate is used for scavenging copper. Aerofloat 15 is the primary frother. Sphalerite is activated and floated from iron in the usual fashion.

Barthelmy (*134 J 281; U. S. pat. 1,950,537*) describes a process for floating sphalerite from copper minerals in which the ore is first treated with an alkaline ferro- or ferricyanide, forming, according to the patentee, a colloidal coating of copper-iron cyanide at the copper surfaces, then activating sphalerite with copper sulphate and floating with a dithiophosphate. Chalcopyrite requires oxidizing conditions in the pulp for depression. The copper minerals may be floated subsequently by addition of a xanthate, which, according to the patentee, decomposes the copper-iron cyanide complex.

Galena-copper separation is unusual. The method is to make a bulk float and then either depress the galena with a dichromate or depress chalcopyrite with cyanide.

At DUQUESNE (*153 A 619;* see Flowsheet 54, Fig. 58) a bulk lead-copper concentrate is floated from sphalerite using propyl xanthate as collector and zinc sulphate and cyanide to depress zinc; sphalerite is floated from this tailing with lime, copper sulphate, xanthate, and pine oil, with a little further cyanide to drop iron. The bulk concentrate is refloated with high cyanide (11 lb. per ton of bulk concentrate) at pH 9.7 to 10.2, yielding galena as float and chalcopyrite as underflow. Maximum pH must be kept down in order not to exceed the critical pH for galena.

Molybdenite-copper separation is practiced at a number of the porphyry coppers. The usual procedure is to float a bulk concentrate of the two sulphides, depressing pyrite with high lime, roast or steam the bulk concentrate to destroy xanthate coatings, and then float molybdenite with a neutral oil. Rough depression of the sulphides accompanying molybdenite in a bulk concentrate not made with oil may be effected by conditioning with a high concentration of sulphide ion, which displaces sulphydrate ion; the molybdenite is not affected since sulphydrate ion plays no part in its flotation.

Miscellaneous. SIEGENITE (Co, Ni sulphide) can be floated from copper and iron sulphides with diphenyl thiocarbazid (Art. 4). NICKEL-PYRRHOTITE separation is normally made with the same reagents as chalcopyrite-pyrite, hence any chalcopyrite present floats with the nickel minerals. CINNABAR-ARSENIC separation, the arsenic minerals being realgar and arsenopyrite, was made (*153 A 536*) using dextrin as a depressant for realgar,

cyanide as a depressant for arsenopyrite, mercuric chloride as an activant for cinnabar after closure of the surface by H_2S generated in grinding the realgar, xanthate as collector, and pine oil as frother. Herkenhoff (*U. S. pat. 2,342,277*) describes separation of a bulk float of pyrrhotite, arsenopyrite, and pyrite by use of an alkali permanganate as a conditioner. As little as 0.05 lb. per ton is stated to be effective to depress pyrrhotite in the presence of arsenopyrite, whereas a somewhat greater quantity, but usually less than 0.25 lb. per ton, depresses arsenopyrite while permitting pyrite to float. Sulphydrate collectors and frother are added with the depressant to effect flotation; pulp should be alkaline with soda ash, and copper sulphate aids the flotation.

48. BULK DIFFERENTIAL *VS.* STRAIGHT SELECTIVE FLOTATION

Choice between the two methods depends on the kinds of sulphide minerals to be separated, their absolute and relative proportions, the amount of grinding necessary for severance, the precious-metal content and distribution, and the soluble-salt content of the pulp. In general, if the soluble heavy-metal salt content of the ore is high, and particularly if it is high in copper, lead, or silver, the ore must either be washed before any flotation or the first float must be a bulk concentrate; otherwise the consumption of reagents is excessive. In general, also, if the valuable sulphides are coarsely aggregated with respect to the ore as a whole, but fine grinding is required to separate them from each other, bulk flotation with subsequent differential separation is again indicated. With relatively clean ores in which substantially complete severance is effected at ordinary flotation size (<65-m.), lead-zinc and lead-zinc-iron separations are normally effected by straight selective flotation, this method being the more clearly indicated the higher the sulphide content of the ore. Departure from this rule, if any, is the more likely the smaller the ratio of lead to zinc. When precious metals and iron sulphides are both present in a copper ore, the gold being associated with the copper mineral, decision is frequently based on reagent cost. Since high lime, used to depress pyrite, is also a depressant for gold, cyanide and soda ash are indicated as depressant and protector respectively, and as both are relatively expensive, a preliminary bulk float is indicated. This is particularly true when the copper mineral is chalcopyrite, since the copper sulphate also added to aid in reflotation of the chalcopyrite aids the cyanide in depression of the pyrite. Bulk flotation is usually the first step also when depression of one of the sulphides requires prolonged contact or relatively high concentrations of reagents; thus when lead-copper separation is desired, depression of lead requires the expensive dichromates while depression of chalcopyrite requires conditioning with cyanide, in both cases with relatively high concentrations of reagents and prolonged contact. Massive sulphide ores containing chalcopyrite and minor zinc are usually bulk floated under conditions of high lime and a small amount of cyanide to depress pyrite and to depress as much sphalerite as possible and the bulk concentrate treated with cyanide to depress the zinc and further pyrite. If economic, the tailing from the bulk-float cell may be retreated to make zinc concentrate by adding copper sulphate.

FLOTATION OF NONSULPHIDES

The flotation of nonsulphides is, fundamentally, the same kind of operation as that involved in flotation of sulphides, *viz.*, coating of the particles to be floated with a water-repellent oriented hydrocarbon-type film; depression of the accompanying minerals; and control of frothing. But each of these steps is more difficult in nonsulphide flotation, both because of the greater chemical similarities between the desired and undesired minerals in the nonsulphide ores and, in many cases, because of the higher requirements, in the nonmetallic industries, for purity of concentrate.

The nonsulphide minerals may be classified into several groups on the fundamental basis of their chemical composition, which affects and determines the methods of flotation applicable. The classifications adopted herein are: (1) oxidized heavy-metal minerals; (2) nonsilicate minerals of alkali and alkaline-earth metals; (3) silicate minerals; (4) inert minerals.

OXIDIZED HEAVY-METAL MINERALS

The oxidized metallic minerals include the native metals, the oxides of the heavy metals, and the heavy-metal salts. The native metals are easily floated, if the particle size is small enough, using simply sulphydrate collectors, with gangue depressants if the gangue is slimy. The oxides are not readily floatable because they are, in general, so highly insoluble

in water and resist ionization to any appreciable extent in dilute aqueous solutions. The metallic salts other than the silicates are quite readily soluble in water to a sufficient extent for collector reactions; in fact the greatest difficulty with them is to stop the collector reaction while the precipitated coating is still substantially monomolecular and like-oriented. The standard method is stage sulphidization and collector coating with one of the more powerful sulphydrate collectors; fortification of the reaction coating by oil, usually a creosote; maintenance of a dispersed gangue by use of sodium silicate protected by sodium carbonate; and floating with a fragile, evanescent froth. Reconstructed oils (Art. 6) are frequently used as collectors. Their efficacy for such service is probably due to the fact that they tend to hold the sulphydrate compound that makes them active largely in solution in their droplets, and that by spreading over the collector reaction coating as fast as it forms they prevent the formation of noncollecting thick crystalline coatings. Their use is, therefore, equivalent to stage sulphidizing and stage addition of collector.

49. NATIVE METALS

This class comprises gold, silver, and copper. The native metal is the usual form of occurrence for gold; native silver ores are far from common, and native copper is fairly unusual.

Gold is rarely floated when the gold is free and the gangue simple, since amalgamation and/or cyanidation are cheaper and equally or more efficient in the recovery of such values. The gold ores subjected to flotation are usually ores in which the precious metals are enclosed in one or more sulphides, or the more or less oxidized residues of such ores. Graphitic ores are also usually floated, since the graphite tends to reprecipitate gold dissolved by cyanide and/or to coat amalgamating plates.

A remedy reported (*720 CMB 1931*) for such an ore was flotation of the graphite and some gold with lime, kerosene, and pine oil, whereupon cyanidation of tailing yielded 99% recovery of the remaining gold.

The basic principles underlying treatment are easy to state but rather more difficult to follow. Since every ore particle that has gold in it contributes much more to tailing loss than a particle of the same size in base-metal concentration, the primary endeavor is to float every such particle. Hence powerful collectors should be used. Since these are useful also for flotation of oxidized sulphides, two ends are thereby served. But the powerful collectors differentiate poorly, if at all, between the various sulphides. If the ore is complex and any segregation has occurred in the ore genesis, differential flotation must be attempted in order to save after-treatment charges. Thus gold in lead or copper concentrate is worth more per ounce at the smelter than it is in zinc or iron concentrate, and the usual penalties for zinc in lead and copper concentrate or iron in copper and zinc concentrates apply irrespective of gold content. Copper is objectionable in concentrate that is to be cyanided. Arsenic, antimony, and bismuth frequently occur in gold-bearing sulphides and are usually undesirable in the concentrates. Native gold is not easy to float, and the coated gold in oxidized ores is yet more difficult. Freight rates on gold-bearing concentrates are high, so that high ratios of concentration are desirable. As a consequence of these varied conditions and frequently contradictory requirements, the operator puts in a little of this to hold that down, and some of that to bring something else up until his reagent list looks like the menu for a ten-course dinner.

It is a rule of thumb in gold milling generally that the recovery of gold increases with fineness of grinding. Oldright and Head (*134 J 228*) have shown, however, that when the gold in the ore is coarse, fine grinding tends to imbed other constituents of the ore into the surfaces of the gold particles, with the result that their response to flotation or amalgamation is greatly diminished. This fact, coupled with the tendency of the gold to hang up in tumbling mills and mechanical classifiers, the relative difficulty in flotation of gold at a size that would be fine for a sulphide, and the high unit value of lost gold particles, leads to the desirability of concentration in the grinding circuit, and this is usual practice in present-day flotation of gold ores. See ***Unit cells*** (Art. 23), ***Mineral jigs*** (Sec. 11, Art. 7), and ***Gold*** (Sec. 2, Art. 22).

Reagents. What might be considered a stock reagent combination for a sulphide gold ore with clean siliceous gangue, little or no oxidation, and no differential separation of sulphides necessary, is a C_2 or C_4 xanthate or Aerofloat as a collector, ±0.1 lb. per ton; cresol, pine oil, or Aerofloat 15 as a frother, ±0.1 lb. per ton; and sodium silicate as a dispersant, ±0.5 lb. The same ore, if slightly oxidized, would require a C_5 collector, in slightly greater quantity than above, and would need sodium carbonate with the silicate to precipitate soluble iron and to protect the silicate. Excess of soda ash may depress the gold (*IC 7024*). If the oxidation is heavy, hydroxyl-ion addition should increase, a part, at least, normally being added as soda ash (lime is a depressant); sodium sulphide should be added in

stages; more of the soluble collector should be used, preferably added in stages; an oily collector, preferably a coal-tar creosote, 0.2 to 0.4 lb. per ton, should be added also; and frother addition will normally be greater. When differential flotation is practiced, the usual sulphide-flotation and depression requirements prevail, with the exception that collectors are usually stronger than when gold is absent, and especially powerful collecting conditions prevail in the final float. There is no recognized reagent for tarnished gold (*140 #11 J 34*); long time-factor is the best remedy. For reagent combinations used with particular ores see Sec. 2, Art. 22.

At BEATTIE, treating an ore in which gold is finely disseminated in pyrite, which is in turn finely disseminated in silicified porphyry, pyrite is activated with copper sulphate in the presence of sodium carbonate in the grinding circuit and Barrett 4 is added here also for emulsification; ethyl xanthate and pine oil are added at the roughers and Rhodamine B and further pine oil are added at the scavenger to raise a quartz float for regrinding and return to the rougher. At SURCEASE (*141 #8 J 48*), making a mixed sulphide concentrate, Minerec B, pentasol xanthate, soda ash and lead acetate were added in the grinding mill, and pentasol xanthate, secondary butyl thiophosphoric acid, mercapto-benzothiazole, and Aerofloat 15 at the cells. At NORTH CAMARINES (*141 #10 J 49*) pentasol xanthate and Aerofloat 31, with pine oil and lime for depression of pyrite, were used to make a high-copper low-gold concentrate. At WRIGHT-HARGREAVES (*140 #4 J 42*), treating siliceous pyritic cyanide tailing, seeking a high ratio of concentration (100 : 1), the collector used was secondary butyl xanthate (0.04 lb. per ton), DuPont alcohols 23 and 25 were added for frothing, copper sulphate (0.3 lb.) to complex the cyanide, and soda ash (0.15 lb.). At HOG MOUNTAIN (*136 J 608*) hydrated lime (0.4 lb. per ton), amyl xanthate (0.05 lb.), sodium Aerofloat (0.03 lb.), and fuel oil (0.03 lb.) were added to the ball mill, cresylic acid (0.4 lb.) to the first cell, and pine oil (0.1 lb.) staged along later cells. At GOLDEN CYCLE (*136 J 381*), treating custom ores, soda ash, cyanide, and zinc sulphate, with ethyl and amyl xanthates and coal-tar creosote, for lead flotation, are added at the ball mill, cresol and pine oil at the cells, and copper sulphate in the zinc conditioner. For MOTHER LODE ores (*136 J 173*) sodium sulphide (0.4 lb.) and copper sulphate (0.2 lb.) are used for conditioning, amyl xanthate (0.15 lb.) for collection, and cresol (0.33 lb.) for frothing. The Bureau of Mines staff (*RI 3564*) use as a stock testing charge, for preliminary tests, amyl xanthate (0.1 lb. per ton), Aerofloat 15 (0.15 lb.), and cresol or pine oil (0.05 lb.), varying quantities and introducing other reagents as indicated. PLACER GOLD is readily floated, unless too coarse or too badly coated, with ethyl, butyl, or amyl xanthate and Aerofloat 15 with or without soda ash. Lange (*136 J 116*) states generally that gold coarser than 48-m. is hard to float, but that <65-m. gives no difficulty from a size standpoint; that lime and soda ash are definitely depressing, sodium silicate slightly so, and sodium sulphide generally so, but that sulphuric acid is helpful in thin pulps (20% solids) although depressing at higher pulp density; that copper sulphate increases rate of flotation but not recovery; that amyl xanthate, amyl xanthate plus thiocarbanilid, and Aerofloat 31 and 208 are the best collectors for free gold; that free gold, in general, does not float as readily as sulphides; and that high-density pulps are best. Mercury or a mercuric salt in a reducing pulp atmosphere are recommended for difficult ores (*U. S. pat. 2,097,608–9*). Leaver and Woolf (*RI 3275*) made an extensive study of the effects of sodium sulphide in gold flotation. They used an artificial mixture of a gold containing 15% alloyed silver and sea sand. They found sodium sulphide generally harmful to flotation of metallic gold, not helpful for coated gold, bad for flotation of gold-bearing sulphides generally, and bad for silver sulphides, especially when not added in stages, but useful with clayey gangues to raise grade of concentrate although decreasing recovery somewhat. With talcy or iron-oxide slimes both grade and recovery were affected adversely. Long conditioning tended to decrease the harmful effect (probably due to oxidation). Ores containing gold in copper or oxidized lead minerals were both helped to float by the sulphide. Soluble starch was a better depressant for slime than the sulphide. High lime was bad. The collectors used were sodium secondary butyl xanthate and Aerofloat 15 with or without pine oil as a frother. At NORANDA (*112 A 584*) it is necessary to aerate heavily pyritic ore after grinding for periods as great as 40 min. in order to attain optimum flotation of gold, whereupon best gold recovery is made in a high-lime pulp. At SHENANDOAH DIVES (*136 J 395*) it was found that cyanide depression of pyrite and sphalerite caused gold loss; similar depression at GOLDEN CYCLE put 20 to 40¢ soluble gold per ton of water in the tailing. At HOLDEN (*140 #11 J 34*) a 40-min. roughing period is necessary for satisfactory recovery of coated gold. Fahrenwald (*137 J 554*) reports laboratory tests indicating increases in recovery, grade of concentrate and speed of flotation with increasing dilution over the range from 35% to 10% solids. Coke (*U. S. pat. 2,285,394*) describes the use of a heavy metal salt of sulphonated castor oil as an aid in collection of gold and associated sulphides; he asserts that the reagent is particularly effective in pulps made with sea water.

Chapman (*134 A 207*) has proposed a process for gold ores comprising solution with cyanide, precipitation on charcoal and flotation of the latter. Lime, cyanide, and activated carbon are added to the grinding mill, an oily collector and a frothing agent to the cells.

An operation of the method is reported at RIO TINTO (*141 #3 J 43*) in which oxidized gossan carrying $3.25 per ton in gold was treated at the rate of 1,000 tons per 24 hr., being ground to 70% <200-m. Recovery was 90% on the charcoal added, representing 87% of the soluble gold or 70% of the total gold. Silver recovery was low.

Silver (metallic) is treated in the same way as gold, and the same reagents are effective. Improvement in recovery by use of ammonium phosphate has been reported (*IC 6945*).

Copper (metallic) is readily floated in clean ores with small quantities of ethyl xanthate and pine oil; in slimy oxidized ores the collector must be protected by precipitating soluble salts (lime, soda ash) and the gangue should be dispersed (sodium silicate). It has been proposed (*U. S. pat. 2,310,240*) to treat the native-copper ores of the Lake Superior dis-

trict, in which the vein minerals are calcite and epidote, and the country rock mined therewith is highly siliceous, with a collecting mixture comprising xanthate and soap to thereby float a low-grade concentrate containing also the bulk of the locked mineral in a roughing operation, and thereafter to regrind the concentrate and float the copper therefrom with sulphydrate collector at a *p*H high enough to destroy soap flotation of the nonsulphides (Art. 8).

50. OXIDES

The base-metal oxides have, to date (1942), proved to be the most difficult of all minerals to float effectively. The fundamental difficulty is that of producing an ion of the metal at the particle surface by treatment in dilute aqueous solutions at ordinary atmospheric temperatures. The only commercial operations reported so far are for rutile and ilmenite from beach sands, and for manganese; flotation of chromite is rumored. Patent and periodical literature record more or less successful treatment of bauxite, cassiterite, chromite, hematite, molybdite, and arsenic trioxide from flue dusts. In most cases the collector is soap or an analogous chemical, frequently fortified with an oil. The practice is quite definitely that of nonmetallic flotation, involving desliming, substantial elimination of dissolved metallic ions, and careful control of gangue-particle surfaces.

Bauxite may comprise gibbsite, diaspore, or a mixture of the two. Gibbsite is reported (*RI 3586*) as readily floatable from silica in a carefully deslimed pulp, conditioned to *p*H 7.5 to 9 with sodium sulphide, using oleic acid as a collector, and a hydrocarbon distillate of medium boiling range to aid collection and prevent soap overfrothing. Diaspore is more difficult to float but responds to some extent to the same treatment.

Best results with slimes present were obtained by grinding in silica; using meta- or pyro-phosphates to complex Ca, Mg, Fe, and Al ions in solution; adding sodium silicate or sodium sulphide for further slime dispersion, if necessary; conditioning and coating in thick pulp (65 to 75% solids); and floating in a dilute pulp (15% solids). With such treatment silica was reduced from 20% to 5 or 6%. Using dextrin and a higher *p*H reduced Fe_2O_3 from 13% to 6%. Alkyl sulphates and sulphonates with oil produced some separation but were not as effective as oleic acid. Talloel was almost as effective as oleic acid in collection but produced violent overfrothing, particularly at higher *p*H. Quebracho, sodium silicate, or dextrin reduced the phosphorus (apatite) content of concentrate.

Cassiterite has been claimed floatable in several patents; its flotation is reported by the U. S. Bureau of Mines (*RI 3397*); and certain samples of concentrate have been floated at Columbia University. But no commercial flotation of cassiterite ores is reported and Columbia experience indicates that success there was due to a superficial coating, probably of iron oxide, on the cassiterite grains. This postulate is supported by the fact that quartz also present in the concentrate floated excessively. Activation of cassiterite by calcium hydroxide has been reported.

Collectors used in most reported flotations have been fatty acid, usually oleic, or soap, with or without a frother (pine oil, cresol, Ninol), but Vivian (*36 MM 348*) reports some collection by cupferron (ammonium salt of nitrosophenyl hydroxylamine). Kirkland (*CU 1932*) found that cassiterite abstracted the negative radical of this compound, leaving ammonium ion substantially undiminished in concentration in the solution. Activation attempts with tungstic acid, *iso*-polyacids (*U. S. pat. 2,125,631*), $CuSO_4$, or $FeSO_4$ in weak alkali, nascent hydrogen (*Brit. pat. 354,395*/1930), and sodium metaphosphate with a metal salt are reported, as well as the use of a metal salt-silicate mixture (Art. 10) to depress silicate gangue. It is reported that the function of the metal-silicate is to coat quartz with silica gel and that such action has been indicated by staining with a water-soluble dye (*27 ME 527*).

Chromite flotation is reported (*RI 3370, 3397*) as effected by soap and oleic acid, using in one case sodium silicate and sodium carbonate as conditioners and in another sodium metaphosphate plus or minus $FeSO_4$ or $PbNO_3$. Conversely flotation of olivine from chromite with oleic acid in slightly acid pulp is reported (*134 A 87*).

Various patents recommend triethanol amine (*U. S. pat. 2,014,406*), phosphomolybdic or phosphotungstic acids (*U. S. pat. 2,082,817*) and isopolyacids (*U. S. pat. 2,125,631*) as conditioners with fatty-acid collectors. The U. S. Bureau of Mines reports a recovery of 75% with a concentrate containing 42.6% Cr_2O_3 on an ore ground through 200-m. As usual, flotation is easier with deslimed pulp. Coghill and Clemmer (*112 A 459*) report that acid is superior to alkali for depressing silicates in deslimed chromite (and other) nonsulphide soap flotation.

Cuprite floats readily under the same conditions as malachite and azurite, *q.v.*

Ilmenite is reported floated (*RI 3328*) with oleic acid (1.5 lb. per ton), Emulsol X-1-corn oil emulsion (0.25 lb.), and sodium silicate (0.17 lb.) after a silica grind. The same experimenters also report that with soda ash admixed with the pulp a steel-mill grind gave equally good flotation. Soft water was necessary for good results, quartz being the gangue in all cases. Isopolyacids are recommended (*U. S. pat. 2,125,631*) for conditioning with fatty-acid collectors. Cetyl pyridinium bromide is claimed

as a collector (*U. S. pat. 2,132,902*). Flotation of quartz by Emulsol 660 B (cationic), leaving ilmenite depressed, is reported. McMurray (*AIME, Feb. meeting, 1943*) reported flotation of ilmenite with pine oil, Lorolamine and sulphuric acid; $pH < 5.1$ was required for consistent results; concentrate contained 53.8% TiO_2 and represented 90% recovery.

Iron oxides. The problem of flotation rises both in the separation of small quantities of the oxide occurring as an impurity, *e.g.*, as in glass sands, barite, bauxite, etc., and in treatment of low-grade iron ores. The facts are, at present (1942), that while granular hematite and granular magnetite float readily as pure minerals and limonitic slimes are almost impossible to keep down when one seeks to float anything else in a pulp containing them, there are, nevertheless, no commercial operations in which the iron oxides are floated.

Keck *et al.* (*134 A 102*) report experiments on pure-mineral flotation of specular and massive HEMATITES with fatty-acid collectors. Oleic acid was best; optimum pH was 7 to 7.4, an active frother was desirable, and optimum recovery was made over the size range of 20- to 150-μ. Lead nitrate was found to better recovery when added in quantities of 0.4 to 0.6 lb. per ton, but to have a depressing effect over the range of 0.1 to 0.3 lb. Sodium hexametaphosphate aided collection; gelatine, tannic acid, and sodium silicate were powerful depressants. Behavior of MAGNETITE was similar to that of hematite (*134 A 129*). Mesabi log-washer tailing carrying 17% Fe as hematite, in laboratory test, yielded 74% of the iron in a 59% concentrate when ground fine and floated with 1 lb. per ton of sodium oleate, 2 lb. of soda ash, and up to 0.5 lb. of sodium silicate (*132 J 54*). Current wash-ore slime required desliming and flotation in soft water (*139 #6 J 42*); it then yielded satisfactory concentrate with the same reagents, but recovery of >200-m. material was very low. As a result the over-all iron recoveries, counting desliming loss, ranged from 25 to 75%, depending on the amount and tenor of the coarser material present.

Starch is reported as a satisfactory depressant for iron oxide slimes in xanthate flotation (*RI 3436*).

Manganese oxides are floated from siliceous gangue on a commercial scale at CUBAN-AMERICAN MANGANESE (Sec. 2, Fig. 137).

A tremendous amount of experimentation has been done on other ores, the results of which may be summarized as follows: The crystalline oxides float readily from siliceous gangue with fatty acids and their soaps, but the earthy oxides separate from gangue difficultly if at all. Desliming is advantageous but not necessary. Sodium silicate, with or without soda ash, is the usual conditioner. With calcareous and chloritic gangues separation by soap flotation is poor. Iron oxides and phosphorus (probably as phosphate) float with the manganese substantially nonselectively in soap flotation; the iron can be largely removed by a reducing roast and magnetic separation of concentrate. Flotation of quartz from the manganese shows little promise (*RI 3333, 3397, 3419, 3547, 3564, 3600, 3623, 3624, 3628, 3633; 143 #2 J 80*).

Molybdite flotation with soap is reported (*RI 3370*).

Rutile. Flotation from mica and clay, using oleic acid as a collector, is reported (*RI 3473*).

A rutile-quartzite ore containing about 34% TiO_2, ground to <200-m. and thoroughly deslimed, yielded concentrate containing 87% TiO_2, representing 67% recovery, using oleic acid and Emulsol X–1 in small quantities. Attempts to float the slimes and silica with laurylamine hydrochloride left coarse silica in the nonfloated rutile (*RI 3628*). The use of isopolyacids as activators is recommended (*U. S. pat. 2.126,631*). Emulsol X–1 is said to be a collector (*RI 3333*). Flotation of rutile, ilmenite, magnetite, and alumina from glass sand is asserted (*U. S. pat. 2,257,808*) using a reagent combination comprising a wood creosote (*e.g.*, Pensacola Tar and Turpentine 400, 0.5 lb. per ton; or Cleveland Cliffs 1 or 2), a sulphonated oil (Colonial Dipex M, Colonial Beacon Oil Co., a pure sodium sulphate of a mineral oil), 0.4 lb.; and oleic acid or a soap (0.4 lb.). Procedure involves deflocculation with or without subsequent decantation, and flotation in a thick pulp (30 to 50% solids) in a pneumatic cell. Excess fatty acid tends to float silica.

Stainerite is reported (*RI* 3370) to have been floated in the laboratory with 10 lb. per ton of ammonium sulphide, sodium silicate (1 lb.), amyl xanthate (4 lb.), and pine oil (0.05 lb.).

Arsenic trioxide in flue dusts is said (*U. S. pat. 2,257,710*) to float in a pulp neutralized with lime, using kerosene as a collector and the flue gases themselves for "aeration" and frothing-agent supply.

51. HEAVY-METAL OXIDE SALTS

This group comprises principally the nonsilicate salt-type oxidation products of the sulphides. Cerussite, malachite, and cerargyrite are the principal members; the vanadium minerals are floated at one or two mills; the jarosites give great difficulty.

Alunite floats readily from quartz, using fatty acid in pulps made slightly alkaline by sodium silicate (*RI 3610*). Iron was depressed to a considerable extent with the quartz, as were also clay and feldspar. Some flotation of the former with the alunite was effected by co-addition of dibutyl amine.

Anglesite is a minor constituent of oxidized lead ores. It is more difficult to float than cerussite on account of higher solubility. It is reported (*RI 3419*) to sulphidize better when the sulphate-ion concentration in solution is raised by addition of sodium sulphate.

Wark and Cox report (*134 A 10*) that sulphide films are most adherent to it at pH 8 to 10; that bubble contact is induced by ethyl xanthate best at pH 9.5 to 11; that xanthate concentration must be greater than 50 mg. per li.; that more xanthate is required when sodium carbonate is added; that sodium sulphate had no effect; that it is activated for xanthate collection by sodium hydrogen phosphate, but that only a small excess of the salt can be tolerated.

Cerussite is the usual oxidized mineral in the simpler oxidized lead ores. It is readily floatable by step addition of a considerable quantity (up to several pounds per ton) of higher xanthate, or, more economically, by step sulphidization with sodium sulphide and simultaneous step addition of small quantities of higher xanthate. The mechanism of collection in the latter case is light sulphidization, oxidation of the surface film, and substantially monomolecular filming with lead xanthate. Best pH in contact-angle tests was <9 (*134 A 23*). An oil, usually a creosote, is normally used to fortify the soluble collector. Careful dispersion of slime gangue, usually effected by sodium silicate, is important. See Sec. 2, Fig. 127.

Alkaline cyanide in addition to the alkaline sulphide has been suggested for conditioning (*U. S. pat. 2,196,233*). Handy (*U. S. pat. 2,019,306*) recommends, as a collector, a gel made by mixing 57 parts oleic acid and 29 parts cresol, stirring thereinto a 10% aqueous solution of soda ash containing 8 parts, referred to the oil, of the ash, and then stirring in a 10% aqueous solution of sodium silicate, comprising 8 parts of the silicate on the mixture, until the mixture gels. This is to be added as a 10% emulsion in water. It has both frothing and collecting properties and is said to be effective to collect also malachite, hematite, siderite, and scheelite. It is added with sulphide reagents at BUNKER HILL & SULLIVAN (Sec. 2, Fig. 108). Christman and Falconer (*U. S. pat. 2,029,156*) prescribe mercapto-benzothiazoles, in pulps made acid with phosphoric acid, for both oxidized lead and copper minerals.

Cerargyrite is not an uncommon silver mineral in cerussite ores. Leaver and Woolf (*RI 3436*) found that it was readily floated by ethyl and amyl xanthates or by Aerofloat 15, that sodium sulphide depressed it, normal quantities of lime did no harm, but high lime (pH 11) decreased recovery and lowered grade, and that starch could be used as a slime depressant without affecting silver recovery.

Malachite and azurite float readily with either sulphydrate or fatty-acid collectors. Of the former the higher molecular-weight xanthates are best, with stage addition coincident with additions of sodium sulphide. If much copper sulphate is present in the ore it should be washed out; precipitation with Na_2S or Na_2CO_3 is not satisfactory (*RI 3419*).

Large-scale commercial practice at KATANGA (*135 J 401*) uses about 4 lb. per ton of 6 parts hydrolyzed palm oil and one of oleic acid or 12 parts corn oil to one of oleic acid after conditioning with 2.4 lb. soda ash and 1.5 lb. sodium silicate at 95° F. The pH should be 8.5 to 9. With high-talc ores the talc is first floated with 0.03 lb. pine oil alone. This treatment raises concentrate grade from 25% Cu and $>18\%$ insol. to 41% Cu and $<3\%$ insol. Recovery is about 90%, but tailing is high. In general the unsaturated fatty acids and their soaps are superior to the saturated (*136 J 220*). Lightly oxidized copper sulphides can be floated in the usual fashion (Art. 46) with amyl xanthate.

Chrysocolla does not sulphidize on the alkaline side; it can be sulphidized at pH 4, using H_2S or Na_2S with $(NH_4)_2SO_4$. High recoveries on a synthetic ore with sulphidization and xanthate collector are reported (*RI 3419*). Some success in laboratory flotation with animal-fatty acid soaps has been reported (*RI 3357*). At present (1942), however, commercial flotation of copper-silicate ores is not reported.

Rhodochrosite is floated by oleic acid or soap. Siliceous gangue is depressed by sodium silicate and sodium carbonate.

At ANACONDA (Sec. 2, Art. 138) a bulk sulphide float is taken first without harm to the subsequent soap flotation.

Calamine has been floated in the laboratory (*RI 3370*) by sulphidizing, activation with $CuSO_4$, collection by amyl xanthate and Barrett 4, with pine oil for frothing as needed.

Jarosites do not respond to the ordinary methods for treatment of oxidized ores. They respond to sulphidization very slightly, if at all. Flotation of deslimed ore in neutral or slightly alkaline solutions with octyl xanthate (3 lb. per ton) and with lauryl xanthate (1 lb. per ton) are reported (*RI 3419*). The same experimenters report nonselective flotation in the presence of calcite with higher fatty acids and also some recovery with sulphuretted (reconstructed, see Art. 6) pine oil in neutral pulp. Slimes are reported to consume tremendous quantities of reagent.

Siderite is reported (*RI 3333*) floatable with Emulsol K 1031. Siderite rock is reported (*112 A 457*) raised in iron content from 36% to 44% and lowered in silica content from 18% to 5% by soap-oleic acid flotation with the usual dispersants.

Tungsten minerals. The principal ore mineral is scheelite, but hübnerite, wolframite, and ferberite are not uncommon. Their floatability decreases in the order named. Scheelite is readily floated from silicate gangues by soap flotation with sodium silicate ± soda ash (pH 9.5 to 10.5) for conditioning.

Calcite gangues are depressed by metal-silicate treatment (Art. 10). It is reported (*OD Notes 7 AC*) that spraying froth on the cell with a dilute solution of Aerosol OT (sodium salt of dioctyl sulphosuccinic acid) improves grade markedly. This is strongly surface active and a strong detergent and would tend to disperse and drop the less lightly held material in the froth. Ultra-violet light is useful in observing the operation (*112 A 460*). Apatite, which will float with scheelite, can be depressed in the cleaner by a weak organic acid (formic or acetic) or by a low concentration of an inorganic acid (*RI 3239*). Hübnerite flotation is aided by potassium acid dichromate in both rougher and cleaner (*RI 3328*). Ferberite floats best in acid solution, depression thereby being prevented by addition of $MnSO_4$. Wolframite responds to the same reagents and conditions as ferberite. (See also Sec. 2, Fig. 164.)

A 75-ton plant at Nevada-Massachusetts (*TP 585 USBM 19*) treated gravity-plant slimes assaying 0.25 to 0.5% WO_3, by scalping out pyrite with xanthate, Aerofloat 25, cresylic acid, and pine oil in a pulp made alkaline with soda ash, then roughing in a subaeration machine with oleic acid, sodium silicate, Emulsol X-1, and DuPont B 22 (or pine oil). Optimum *p*H was 9.0 to 9.5; lower *p*H lifted calcite and silica, higher tended to prevent frothing. Stage addition of collector and frother was desirable. Rough concentrate assayed 10 to 15% WO_3 with a recovery of 60 to 90%, averaging about 80%. Flotation concentrate was cleaned on slime tables to 50 to 65% WO_3 with a yield of 50 to 80%. Water treating to decrease hardness was necessary, both for conservation of collector and for economic recovery.

Vanadium minerals. The principal ore minerals are vanadinite and the descloizites.

Laboratory flotation is reported by the Bureau of Mines (*RI 3328, 3333, 3370, 3547, 3564, 3628*). The reagents were: soda ash to precipitate soluble salts, sodium sulphide for sulphidizing, $CuSO_4$ for activation, amyl xanthate and Aerofloat 25 step-added for frothing-collection. Recoveries on a feed assaying 1.6% V_2O_5 ranged from 60 to 90%, with concentrates carrying 10 to 17% V_2O_5. In general the conditions for flotation were those that favored flotation of cerussite, but sulphidization was much slower. Vanadinite floated more easily than the descloizites. Sodium naphthyl dithiocarbonate gave better collection than xanthate. Engel and Guggenheim (*RI 3425*) found that high concentrations of earth-metal salts derived from the mill water and the ore were harmful and that by filtering after grinding and throwing out Mg by lime and Ca by soda ash, then repulping, they could make 15% V_2O_5 concentrate and 0.13% tailing from a feed containing 1.55% V_2O_5. See also Mammoth-St. Anthony, Sec. 2, Fig. 65.

Wulfenite responds to the same treatment as vanadinite.

Carnotite is reported easily floatable with soap, but rougher concentrate grade is low and losses in cleaning high (*RI 3370*).

Metal-acid minerals (tungstates, molybdates, etc.) are all apparently collectible by cationic collectors, on the basis of precipitation and contact-angle tests with laurylamine hydrochloride (*CU*).

52. NONSILICATE MINERALS OF ALKALI AND EARTH METALS

These minerals comprise a large group of soluble and relatively insoluble salts of which calcite, fluorspar, barite, halite, and sylvite are typical. Flotation is almost universally effected by soap flotation, the soap being added as such or formed *in situ* by hydrolysis of a fatty acid in the presence of an alkali. The coating reaction is dependent upon the fact that the earth-metal soaps are of very low solubility in water and hence precipitate as reaction products at the mineral surfaces, the soap ion displacing the acid ion of the mineral.

Because of the tendency of soaps to coagulate, and the gelatinous character of the coagules, bubble attachment at soap-coated surfaces is frequently not easy to establish. On the other hand, oil coats a soap-coated surface readily. For these reasons, oil is usually employed as a co-collector in soap flotation.

Conditioning. The mineral associates of a desired earth-salt mineral are frequently other minerals of the same class, or silicates that are floatable with soap. Concentration becomes primarily conditioning to depress the undesired constituents. If the undesired associate carries a different earth-metal, differential flotation may sometimes be effected by close control of *p*H (Fig. 2). The usual way to prevent flotation of silicate associates is to reduce the solubility of the silicate-mineral surfaces by increasing the concentration of silicate ion in the pulp, by addition of a soluble silicate (*e.g.*, sodium silicate) to the point that an anchored ionized surface is formed. The visual test of this condition is a high degree of dispersion of such silicate particles. Under these circumstances the concentration of available earth-metal ions at the particle surface is very low and sufficient soap coating cannot form on the particles to activate them for bubble or oil attachment.

Undesired earth-metal nonsilicate minerals may be depressed by the so-called metal-silicate treatment (Art. 10).

Desliming is necessary when it is impossible to prevent collector coating of gangue (unwanted) slime. It is always desirable from an operating standpoint because it reduces the quantity of reagent necessary and the presence of slime in the froth increases the difficulty in dropping out granular gangue.

Barite floats readily with fatty-acid collectors and with the sulphate and sulphonate salts of the corresponding alcohols. Optimum *p*H for oleate collectors is 10 to 11. Sodium silicate is a sufficient depressant for iron-silica gangues (*RI 3427*), but calcium-bearing gangues require metal salt-silicate treatment or quebracho, and grade of concentrate is improved by dichromate addition in cleaning. Feeds are usually high-grade (>50% $BaSO_4$) so that stage addition of collector is desirable and oily collectors should be emulsified.

Tall oil at *p*H 7.5 to 9, naphthenic acids, sodium and calcium lauryl sulphate, Emulsol X-1, X-2, K-1031, Alphasol, and Shell 795 are also reported as collectors (*RI 3333, 3425, 3397, 3484*). Concentrate containing 90 to 95% $BaSO_4$ with sp. gr. of 4.2 to 4.3, representing recoveries of 70 to 75%, are reported (*RI 3425; 148 A 291*) in laboratory tests. Norman and Lindsey (*153 A 540*) report separation of barite from silica at <325 m. without desliming, using fatty acid (lauric preferred), sodium silicate and pine oil. Oleic acid is not a good collector to employ when concentrate is to be used for oil-well mud, because of resistance of the concentrate to water wetting; Shell 795 is reported to make wettable concentrate. Siliceous gangue is reported as floating with hydrochloric acid (8 lb. per ton), DP 243 (0.25 lb.), and DP 60 (0.1 lb.), yielding 94% barite and 70% recovery, but the reagent cost is excessive. It is reported in the discussion that a 125-ton all-flotation plant is now treating the same ore (*153 A 545*). Barite is also floatable with lauryl and higher amines; recovery is aided by increasing concentration of either amine or sulphate ion. Ba^{++}, added as $BaCl_2$, reduces floatability (*CU*).

Calcite floats readily from siliceous gangue, using fatty-acid collectors with sodium silicate, lignin sulphonate or dextrin for dispersion, at *p*H 8 to 9.5. Use of this fact is spreading rapidly in preparing cement mixes (see Sec. 3A, Art. 2, for performances). U. S. patents *2,161,010* and *2,161,011* to Breerwood are veritable textbooks for the practice. Procedure usually involves light desliming of a finely ground pulp, flotation of carbonaceous material by starvation amounts of a frother, such as the C_7 to C_{10} monohydric alcohols or cresol, dispersion of the remaining pulp with calcium lignin sulphonate or a dextrin, and thereafter either flotation of calcite by step addition of minute quantities (<0.5 lb. per ton total) of fatty acid emulsified with an alkaline resinate and a frother, leaving mica and quartz in the tailing; or flotation of mica and silicates with cationic reagents at *p*H 7.5 to 8, leaving calcite and iron minerals in the tailing. In either case mica may be floated from quartz and other silicates by starvation quantities (0.05 lb. per ton of feed) of medium-weight amines, *e.g.*, dodecyl amine hydrochloride.

Results reported from Lone Star Cement Co., Argentina, S. A. (*31 PQ 52*), are given in Table 26. Table flotation of deslimed calcite-flint cement rock, using fatty acid + soap (1 lb. per ton) and cheap fuel oil (4 lb.) with soda ash (0.5 lb.), yielded concentrate assaying 99.5% lime rock and 1.7% SiO_2 and recovery of 97.6% (*136 J 221*).

Table 26. Flotation of calcite from cement rock at Lone Star Cement Co.

Material	Percentages				
	Feed	Rough concentrate	Clean concentrate	Combined concentrate	Tailing
SiO_2	30.9	3.4	3.0	3.4	75.7
Fe_2O_3	2.4	0.6	0.8	0.6	3.9
Al_2O_3	2.9	0.3	0.3	0.3	5.9
CaO	33.5	53.9	53.9	53.9	5.2
$CaCO_3$	59.8	96.2	96.2	96.2	9.2
MgO	0.9	0.3	0.6	0.3	1.0
Loss	28.7	41.2	41.0	41.0	9.4
Total	99.3	99.7	99.5	99.5	101.1
Ratio *a*	5.8	3.9	2.8	3.7	7.7

a $SiO_2/(Fe_2O_3 + Al_2O_3)$.

Calcite is also floated by laurylamine hydrochloride; the amount required for good collection is reduced from 80 mg. per li. of solution to 40 mg. by co-addition of 10 mg. of Na_2CO_3, and to 20 mg. by 5 mg. of sodium silicate. In the first case the phenomenon is simple common-ion effect; in the second, silicate coating of the calcite precedes the common-ion phenomenon (*CU*).

Celestite is reported (*RI 3628*) as floated from calcite and strontianite at <200-m. and 30% solids using quebracho, oleic acid, and a higher-alcohol frother.

Cryolite is reported floated with fatty acids (*RI 3397*).

Dolomite can be floated by soap flotation (*RI 3314*). It is depressed in soap flotation by metal salt-silicate treatment or by acid dichromate. Selective activation to xanthate ion by treatment with zinc sulphate is reported (*28 ChA 2305*). No commercial operation has been reported (1942).

Fluorspar was floated commercially at 10 plants in the U. S. in 1941 (*143 #2 J 80*). Treatment of sulphide-free feed usually involves light desliming, soap and oleic acid as a collector, and use of a dispersant depressor fitted to the gangue. Optimum *p*H is 8 to 9.5.

Silicate gangue is depressed by sodium silicate or quebracho; calcite and barite require metal salt-silicate treatment (*RI 3437*).

A laboratory test to make acid spar from gravity concentrate containing 90% CaF_2 is reported (*RI 3547, 3564*) to have yielded concentrate, after calcination, carrying 98.5% CaF_2 and 0.86% SiO_2, recovery being 82%; reagents were: oleic acid (0.9 lb. per ton), DP 23 (0.25 lb.) and quebracho extract (1 lb. per ton in the rougher and 0.1 lb. per ton in each of four successive cleaning stages). Water should be soft and iron precipitated or complexed (*RI 3437*). Good concentration from calcite gangue without desliming has been reported (*RI 3239*). Mitchell *et al.* (*134 A 100*) found that in floating fluorspar from calcite and quartz with oleic acid as collector, optimum results were obtained at temperatures upward of 140° F. at pH = 8.5, with a small amount of sodium silicate added. Sized feeds in the range of 65- to 150-m. gave best grades and recoveries, but good results were obtained on 65~0-m. material.

Gypsum is floatable with the soap-type anionic reagents, preferably oleic acid, with low alkalinity and a controllable frother. Slime feed is difficult to handle, and both it and the fact that the percentage to be floated is high dictate stage addition of the organic reagents. Flotation of siliceous gangue with the cationics Emulsol 660B or DLT 699 has been reported (*RI 3553*), but other cationics (DP 243, Armour 1180, Emulsol 903L) floated gypsum as well as quartz.

Magnesite floats readily with oleic acid, but is not thus separable from calcite, dolomite, talc, and serpentine, which are common associates.

For treatment of such a mixture in WASHINGTON ORES Doerner and Harris (*Bul P-1 SCW*) floated silicates first with cationic reagents (DP 243 > Emulsol 660B >DPQ) in neutral pulp (pH = 7.8), using DP B-23 as a frother and tannic acid as a depressant, then graded up the magnesite underflow by stage addition of oleic acid and sodium silicate. Recovery of MgO was 80% in the cationic float, in the form of an underflow assaying 82% MgO. The first anionic float from this underflow was substantially pure magnesite; continued flotation brought up increasing dolomite. High-grade magnesite rock was treated in a pilot plant by Clemmer *et al.* (*153 A 547*), also to float silica; they found that DLT 699, Emulsol 903L and DP 243 were about equally effective as collectors, that about 1 lb. per ton yielded about 85% of the magnesite in a product containing less than 1% SiO_2 and 2% CaO, and that either tannic acid or caustic starch aided separation.

Phosphates are both froth-floated and table-floated on an extensive commercial scale (Sec. 3, Art. 30). Fatty acids at a pH of 8 to 9 obtained with sodium silicate, soda ash or caustic soda, fuel oil, and a rosin or turpentine frother are the usual reagents, the frother being omitted, of course, in table flotation. Cheap carriers of fatty acid, *e.g.*, fish-oil fatty acids, or talloel, are used. Reagent consumption in table flotation is about 1 1/2 to 2 lb. fatty acid, 2 to 4 lb. of a light fuel oil, and 1/2 lb. of caustic soda (*129 A 295*); consumption is materially lowered by re-use of water. Florida feeds are invariably deslimed before conditioning, but Russian apatite ore with nephelite gangue is treated in the presence of the slimes produced by grinding (Sec. 3, Fig. 56). Birch tar is a satisfactory substitute for fatty acids in the Russian practice, but a larger quantity must be used. The phosphate minerals apatite, podolite, staffelite, and kurskite are said to float decreasingly in the order named; their solubilities increase in that order.

Phosphates are depressed by mineral acids and short-chain organic acids. Amine soaps (*U. S. pat. 2,084,413*), aliphatic alcohol esters of higher fatty acids (*U. S. pat. 2,312,466*), and the reaction products of polyethylene polyamines with fatty acids and/or fatty oils (*U. S. pat. 2,321,186*) as collectors; flotation of feeds sized hydraulically (*U. S. pat. 2,156,245*); use of C_{12} and higher xanthates (*U. S. pat. 2,162,495*); preflotation of clay with short-chain amines followed by quartz flotation with long-chain cationics (*U. S. pat. 2,185,224*); prewashing of the feed with caustic alkali solution and draining before flotation with a long-chain amine (*U. S. pat. 2,313,360*); and similar treatment except that the prewash is with alkali and fatty acid (*U. S. pat. 2,288,237*), are a few of the variants from standard practice that have been suggested.

Strontianite is floatable with oleic acid.

Soluble Salts

All flotation is carried out in aqueous solutions substantially saturated at the time of the flotation operation with all of the chemical species comprising the suspended solids. Flotation of the so-called soluble salts depends on similar saturation of the flotation liquor. Flotation of sylvite from halite and the reverse operation are both being practiced commercially in the recovery of potash from its ores. Laboratory flotation of borax minerals and of ammonium chloride from alkali-metal nitrates have been described (*RI 3333*). Best feed size is <35-m. Conditioning with oily reagents should be effected in thick pulps. Stepwise addition of frothers and collectors is desirable.

Halite is floated from sylvite by fatty acids in a brine saturated with both minerals.

Naphthenic and tar acids (*RI 3397; U. S. pat. 2,222,332*); soaps soluble in salt water, *e.g.*, palm-kernel oil soap or coconut oil soap, resin soaps and alkali resinates (*U. S. pat. 2,188,933, 2,222,331*); and the alkylamine soaps and Turkey-red oil (*RI 3271*) are also described as collectors. Sodium silicate may aid (*RI 3397*). Clayey slimes usually go with the halite. Starvation quantities of soap or fatty acid ± sodium silicate are suggested to float such slimes preferentially (*U. S. pat. 2,175,178*). Alizarin oil and turf tar have been used experimentally in Russia for flotation of earthy impurities from halite (*PC* from N. Vishnevsky). Weinig (*U. S. pat. 2,188,933*) states that lead or bismuth salts in the solution (*e.g.*, 1.5 gm. dissolved Pb per li. of brine) reduces the amount of collector required and increases speed of flotation. He says further that the use of an independent frother, such as cresol, in amounts ranging from 0.5 to 1 lb. per ton of solid, increased selectivity and decreased the amount of collector required from 4 lb. to 1.6 lb. Halite is floated from sodium nitrate by capric or oleic acid or betaine hydrochloride and lead nitrate. Use of oleic acid or oleates with a frother such as cresol or C_7-C_{14} alcohols to float calcium sulphates from halite in saturated brines is described by Perkins (*U. S. pat. 2, 340,613*).

Sylvite is floated from halite and from small amounts of clay by the sulphates of the C_8 to C_{12} aliphatic alcohols in amounts of 1 lb. or less per ton; shorter-chain products require larger quantities, and longer-chain compounds are too insoluble for rapid and effective use (*RI 3271; U. S. pat. Reissue 21,566*).

The process was used at Potash Company of America. Feed should be at least <35-m. and better <48-m. and pulp density about 25% solids. Recovery of 93.6% KCl in a concentrate containing 96% KCl is reported on a feed assaying 43% KCl. Table flotation using 20 lb. fuel oil in addition to the sulphate gave about the same yield but concentrate of about 10% lower grade on 10~48-m. feed of about the same assay. Fatty acids, fatty-acid soaps, and aromatic sulphonates were investigated and found unsatisfactory. Amine salts C_6 to C_{12} range *e.g.*, octylamine hydrochloride, are reported to give good recovery and good grade of concentrate (*U. S. pat. 2,088,325*). Water-soluble salts of straight-chain acyl derivatives of ethylene diamine, in which the acyl group derives from a single fatty acid of 10 to 18 carbon atoms, or from mixtures of fatty acids such as occur in natural oils and waxes, are also recommended as sylvite collectors in the presence of halite (*U. S. pat. 2,329,149*). Tartaron (*U. S. pat. 2,330,158*) recommends desliming before final grinding. Cole *et al.* (*U. S. pat. 2,322,789*) recommend the use of dextrin as a conditioning agent with amine collectors.

Gangue minerals accompanying sylvite and halite, *e.g.*, clays, gypsum, anhydrite, iron and manganese oxides, polyhalite, langbeinite, leonite, and glaserite, are said to be floated from sylvite and halite in saturated brines thereof by an alkali resinate (*U. S. pat. 2,222,330*).

Langbeinite is reported (*RI 3300*) as having been floated from halite with sodium octadecyl sulphate. Tartaron *et al.* (*U. S. pat. 2,297,664*) recommend sulphonates of the higher fatty acids for langbeinite and sylvite.

Borax and boric acid are reported as floated from halite by oleic acid or with an aromatic amine (*40 CIMM 691*); flotation of boric acid with pine oil and cresylic acid is described (*RI 3488*); Shelton (*U. S. pat. 2,317,413*) asserts that boric acid is AUTO-FLOATABLE, *i.e.;* floats without a collector or frothing agent, in saturated solution of boric acid, and that depression of clayey slimes and the like is aided by use of metallic salts, the cations of which form insoluble borates, *e.g.*, Al and Cu, or of colloidal depressants (Art. 10), or of both jointly, or of sodium silicate. Shelton points out also that the boric acid may be formed by reaction of other borax compounds with inorganic acids.

Potassium sulphate is said to float readily with fatty- and naphthenic-acid collectors.

Sodium bicarbonate is reported readily separated from halite by capric or oleic acid or by betaine hydrochloride.

Sodium sulphate is claimed (*U. S. pat. 2,310,315*) to be separated from sodium chloride in a brine made alkaline with sodium hydroxide, using a fatty acid or an oil containing fatty acid and a salt containing Ba, Cu, Sr, Ti, or Fe^{+++}.

53. SILICATE MINERALS

Silicate minerals comprise quartz and the silicate salts of both earth and heavy-metal minerals. In general the latter are too insoluble to free surface ions in sufficient quantities for effective collector coating. Most of the silicates containing earth metals are sufficiently soluble, however, to free ions at the surface and are, therefore, amenable to flotation. Furthermore, since the silicate salts of the cationic collectors are, in general, exceptionally insoluble, they, as well as the soaps, are available for collection.

Choice of collector depends, from the technical standpoint, upon the relative quantities of silicate and nonsilicate minerals present in the feed. From the standpoint of cell operation and collector consumption, that ingredient should be floated which is present in the cell in smaller quantity. On the other hand, the cationic collectors are more expensive, in general, than the anionics, and more securely protected by patents, whence economic factors are, at present (1942), frequently controlling, and anionic collectors are used where technology alone would indicate cationic flotation.

In soap flotation of silicate minerals the procedures and techniques are much the same as those already discussed for nonsilicate earth salts; control of pH and depression of unwanted minerals are the primary problems. In cationic flotation the problem is selection of the proper cationic reagent, there being quite definite differences between the floatabilities of the various silica-containing minerals with different cationic collectors. Water should be soft and free of heavy-metal ions; surfaces should be free of slime coating and pulps preferably deslimed; quantity of collector used should be a minimum, particularly if concentrate is to be cleaned.

Patek (*112 A 486*) rates the relative floatabilities of 20 silicates by oleic acid in acid pulps, on the basis of flotation tests on 80∼200-m. thoroughly deslimed artificial mixtures, as follows: zircon > tourmaline > almandite > topaz > olivine > kyanite > epidote > tremolite > titanite > rhodonite > augite > anorthite > spodumene > biotite > muscovite = labradorite > nephelite > albite > orthoclase = quartz. Separation could not be effected satisfactorily between minerals adjacent in the list, but could, in general, between those three or more places apart, *e.g.*, muscovite and anorthite.

Andalusite floats with soaps. Norman *et al.* (*134 A 76*) report flotation of this mineral and corundum from quartz, in a mixed concentrate, in acid pulp (2 lb. H_2SO_4), using tetrasodium pyrophosphate (1 lb. to complex soluble iron), sodium silicofluoride (3 lb. to complex soluble aluminum), and naphthenic soap (3 lb.) as frother and collector. Quartz was floated from the andalusite by laurylamine hydrochloride.

Beryl ore in a deslimed pulp, with oleic acid and DP 23, yielded concentrate assaying 6% BeO with 87% recovery. Beryl is depressed by sodium silicate, soda ash, or caustic soda (*RI 3547, 3564*).

Brucite, olivine, and other magnesium minerals are said to be floated from cement rocks by the use of cresylic acid and a hydrocarbon with an alkaline earth soap in conjunction with a salt of the lead-thallium class and a xanthate, or with the reaction product of these latter substances (*U. S. pat. 2,208,143*).

Clays differ widely in the kind and proportions of clay minerals present, in the degree of dispersion, and in the amount of included impurities such as quartz, feldspar, mica, etc. They can be floated with amines and with the ammonium and pyridinium compounds.

Selective flotation of clay from other silicates is asserted (*U. S. pat. 2,185,224*) using short-chain amines ($<C_5$); also with 25 lb. per ton of raw waste liquor from sulphite treatment of spruce and hemlock pulps (*U. S. pat. 2,249,569*), leaving quartz, mica, etc., depressed. Depression of clay and flotation of mica, using DP 243 as collector and Calgon and HCl for conditioning, has been described (*RI 3427*). Removal of limonite, pyrite and such "speck" material from clays in Macquisten tubes, presumably with anionic collectors, is also recorded (*138 #2 J 93*).

Corundum is floatable with soaps (see Andalusite).

Feldspar is reported floatable by both soaps and cationic reagents.

Lead nitrate is a strong activator with soap; copper salts also activate; $Al(NO_3)_3$ depresses in acid solutions, if the feldspar is clean, and activates in slightly alkaline pulps; iron salts act like aluminum; acid depresses altered feldspars (*RI 3558*). With cationic collectors quartz tends to float selectively in slightly alkaline pulps, but in acidic pulps generally, especially in those acidified with fluorine-bearing acids, feldspar floats selectively. In general, also, feldspar floats more readily with the cationic collectors, under conditions where quartz and feldspar will both float, so that use of cationics of lower hydrocarbon weights or in relatively starvation quantities favors selective flotation of feldspar. O'Meara *et al.* (*Bul 18 ACerS 286*) and Smith *et al.* (*23 ACerS 339*) describe extensive laboratory and pilot tests both by froth-flotation at <48-m. and table-flotation at 20∼48-m. Smith tabled a feed containing iron-contaminated silicates and quartz, first conditioning with oleic acid (2 lb. per ton) and Diesel oil (4 lb.) and tabling to remove iron, then with hydrofluoric acid (4 lb.), laurylamine hydrochloride (2 lb.), and Diesel oil (4 lb.) to take off feldspar. Feed containing 0.87% Fe_2O_3, 76% feldspar, and 19% quartz yielded 10 parts iron concentrate assaying 4.1% Fe_2O_3, 29% feldspar, and 16% quartz; 73 parts of feldspar concentrate assaying 98% feldspar, 2% quartz, and 0.52% Fe_2O_3; and 16 parts of quartz tailing containing 95% quartz. Flotation of <48-m. from the same feed was done in three stages: Tributylamine, 0.33 lb. per ton, was used to float off slime and save on quantities of subsequent reagents; an iron float was next made with oleic acid (2 lb.); a final feldspar float required 4 lb. hydrofluoric acid and 2 lb. laurylamine hydrochloride. Feed assayed substantially as above; combined iron-slime floats comprised 19 parts and carried 2.8% Fe_2O_3, 75% feldspar, and 7% quartz; 63 parts of feldspar concentrate assayed 99% feldspar, 1% quartz, and 0.41% Fe_2O_3; tailing carried 98.6% quartz. Tabling a clean feed carrying about 3% mica with the balance about 50–50 quartz and albite, O'Meara (*ibid.*) made concentrate assaying 19.2% Al_2O_3 and tailing containing 0.89% Al_2O_3 from feed carrying 9.1%, representing 95% recovery, using 2.3 lb. per ton HF, 0.24 lb. laurylamine hydrochloride, and 5.4 lb. fuel oil. Results by flotation on <48-m. feed were slightly better. On a badly weathered potash feldspar containing about 2% mica and a 50–50 quartz-feldspar ratio, conditioning with 3 lb. per ton HF, 0.48 lb. laurylamine hydrochloride, and 10 lb. fuel oil, table concentrate contained 18.6% Al_2O_3 and tailing 0.1% from 13% feed. Flotation of <48-m. material, using 3 lb. HF and 0.8 lb. of the same amine, gave concentrate assaying 19.2% Al_2O_3 and tailing carrying 1.4% from 15.5% feed. Cleaning was unnecessary. Tests with varying amounts of hydrofluoric acid in flotation with the laurylamine showed peaks of both recovery and grade at about 3 lb. per ton.

With hydrochloric acid, grade of concentrate rose from 10 to 16% Al_2O_3 and recovery fell from 95 to 50% over the pH change from 6 to 2. The more extensively altered the feldspar was, the greater was the tendency for quartz to float, even in acid pulps. This was attributed to coating of quartz by the slimes and to activation of quartz by iron and aluminum salts. For satisfactory feldspar separation it was necessary to disperse the slimes with dispersion agents ± attrition mixing, and to add salts or acids that would form complex or slightly ionized salts with iron and aluminum, this being the supposed principal function of the fluorine-bearing conditioners. Reagent consumption by mica and other feldspar decomposition products is excessive; such materials should be dispersed, and decanted, floated with short-chain amines, or tabled with the same conditioner plus fuel oil. Such treatment reduced consumption of laurylamine in subsequent feldspar flotation from 6 lb. per ton to 0.2 lb. in one instance.

Kyanite is floated with anionic reagents, using sodium silicate or a phosphate salt for dispersion, ± sodium carbonate or hydroxide for protection and ± an auxiliary frother, *e.g.*, pine oil.

At CELO MINES (*RI 3473*) sulphides and biotite are floated first with Aerofloat and laurylamine hydrochloride; then kyanite is floated with oleic acid and Calgon, and cleaned with further addition of Calgon. Concentrate is about 97% kyanite and 0.8% Fe_2O_3 with recovery about 90%. Feed size is 2% >65-m. and 60 <200-m.

Acid may be useful in cleaning. Tartaron (*U. S. pat. 2,305,502*) recommends a short pre-treatment of deslimed kyanite pulp with strong acid and subsequent washing out of the acid before flotation with fatty acid and a frother. Tartaron (*U. S. pat. 2,289,741*) recommends analogous pre-treatment with caustic alkali. Dean and Hersberger (*134 A 85*) report the use of a slightly acid circuit to depress iron minerals as well as quartz when using oleic acid as collector. Use of a cationic reagent (Emulsol 660B) to float siliceous gangue and leave enriched kyanite is reported (*40 CIMM 691*).

Mica may be floated by either anionic (fatty acid) or cationic collectors. It is depressed by lactic acid, starch, and by organic colloidal substances such as glue, tannic acid, etc. (*RI 3239*). Flotation with cationics should be with short-chain amines or with starvation quantities of the longer-chain amines, using depressants, *e.g.*, acid ± aluminum sulphate for depression of granular silicates. Lead nitrate is reported (*40 CIMM 691*) as an activator.

Tartaron (*U. S. pat. 2,226,103*) recommends flotation of mica from quartz, feldspar, and kaolin with an alkaline resinate in a dilute pulp. Tartaron and Cole (*U. S. pat. 2,303,962*) recommend activation of the mica with alkaline earth compounds. Norman *et al.* (*134 A 68*) report flotation of vermiculite from granular silicates by thorough desliming, either by attrition or hydrofluoric acid, conditioning with a small amount of a long-chain amine and oil in the presence of aluminum sulphate and sulphuric acid, and tabling. They assert this to be a general method for separation of the micas other than biotite from other silicates. Desliming is highly desirable; if the mica is slime coated, an alkaline dispersant and attrition mixing should precede desliming. Tabular shape permits tabling at as coarse as 10-m. (4- to 6-m. for vermiculite) and floating at 35-m. maximum, but tabling at coarse sizes requires 2 to 4 times as much oil (14 to 28 lb. per ton) as at finer sizes (*RI 3558*). Biotite is less floatable than muscovite.

At PECOS (*IC 6605*) mica was removed before lead flotation using 0.15 lb. per ton of pale cresylic acid as the only organic reagent added. The operation required that the quantities of lime and zinc sulphate be held down in the lead conditioner as both depressed mica, the lime seriously. When attempt was made to depress mica with lime, the amount required was so great that galena also was depressed.

Quartz is more resistant to flotation than the earth silicates, but floats directly with the more powerful cationics (long-chain amines, pyridinium, and substituted ammonium compounds). It may be activated for anionic flotation by heavy-metal ions, by Ba ion in alkaline solutions, and by Al ion over a wide pH range. Oil aids bubble attachment with either type of collector. Depression is aided by acid and by precipitation or complexing of dissolved activating ions; also by argol, citric acid, and the organic colloids of the glue-tannic acid group (*RI 3397*). Dispersion is readily effected by the alkaline silicates and phosphates.

Betaine N (Art. 5) has been recommended for flotation of quartz from nonmagnetic iron minerals (*U. S. pat. 2,217,684*). Norman *et al.* (*134 A 72*) assert the general rule that the quaternary ammonium bases and their salts should be used for flotation of quartz and granular silicates from nonsilicates. Kirby (*U. S. pat. 2,341,046*) describes the use of carbohydrate colloids of the type of tannic, pectic, and alginic acids and their water-soluble salts, and gums containing them, in conjunction with amine-type collectors, in flotation of quartz from carbonates and oxides. Lontz (*U. S. pat. 2,337,118*) describes the use of acids of the type of tartaric and citric, and their water-soluble salts and amides, in the same way, in the same service.

Sillimanite was floated from schist in a deslimed <65-m. pulp, using soda ash and oleic acid, yielding 95% sillimanite in concentrate and 90% recovery on the sands (*RI 3564*). Flotation by cationics is reported (*140 #3 J 42*).

Slimes comprise generally a heterogeny of secondary silicates, usually more or less hydrated, plus, in many instances, considerable quantities of iron oxides. Nearly all of the

components of such slimes are susceptible to coating by fatty-acid collectors, with the result that they consume large quantities of collector because of their great surface, they show up in the froth, and they largely exclude granular material therefrom so long as they are present in the pulp. Fortunately they contain little or nothing of value in most nonsulphide flotation and can, therefore, be discarded with considerable economy. They do not float (become water-repellent) with sulphydrate collectors, hence, if they are dispersed, as is readily done with sodium silicate or low concentrations of hydroxyl ion, they do not enter the froth except under over-frothing conditions or as they are classified upward by excessive aeration. Quebracho is a common, cheap, and useful dispersant in nonsulphide flotation (*RI 3437*). The silicate constituents float very easily with cationic collectors, and must be removed both for economy of reagent and in the interest of high-grade concentrate before the powerful cationics are added; desliming or flotation with short-chain amines effects this. They tend to coat granular materials and thereby affect their responses to collectors. Their flocculation in sulphide flotation tends to entrap and enclose sulphide values in the floccules and to cause coating of sulphides.

Carbonaceous slimes are depressed by soluble starch (*40 CIMM 691*) or by lignin sulphonates (*U. S. pats. 2,161,010–1*). At FLIN FLON talcy and micaceous slimes are floated, prior to sulphide flotation, using starch as a depressant for granular materials, by lubricant, accidentally introduced, as the collector (*RI 3397*).

Spodumene usually occurs with feldspars, mica, and quartz plus small amounts of iron and manganese oxides. If unweathered, it is floatable from the other silicates by soap flotation, but if weathering has proceeded to any considerable extent, the weathered spodumene coats the other minerals, either in the ground or in preparation for flotation, to such an extent that all of the ore floats alike with soap.

Norman and Gieseke (*148 A 347*) report tests in which heavily weathered rock was attrition-cleaned at 50% solids with 6 lb. NaOH for 1 hr. in an agitation-froth beater box, deslimed, washed, and floated with oleic acid (0.8 to 1.5 lb.) and pine oil, making concentrate assaying 5.4% LiO_2 and tailing of 0.49%. Optimum *p*H was between 6.5 and 8.5. Concentrates assaying 90 to 95% spodumene and tailing containing about 1% spodumene were said to be easy to obtain. Naphthenic soap with sodium silicofluoride in acid pulp gave somewhat lower recovery but a slightly higher grade of concentrate. Other collectors effective with the cleaned feeds were sodium and ammonium oleates, paper-mill soaps, and fatty acids, in neutral and slightly alkaline pulps; also naphthenic acids, sulphonated and phosphorated castor oils, and ammonium sulphoricinoleate, in acid pulps. Mica could be thrown into the spodumene concentrate by adding about 0.1 lb. of C_{18} amine; it was thereafter removed by cleaning in acid pulp, wherein the spodumene was depressed. Clean feldspar was floated from mica-free tailing with laurylamine hydrochloride or C_{18} amine; feldspar was floatable with the spodumene and mica by adding more of the C_{18} amine in the roughing float, in both cases using HF as a conditioner (5 to 10 lb.). Aluminum nitrate is reported as a depressant for spodumene at $pH < 7$ (*40 CIMM 691*).

Talc is so readily contaminated with fatty-acid collectors that it is activated in almost any ore before it gets to the flotation machines and is, therefore, floatable by the addition of frothing agent alone. It is also readily coated by cationic reagents (*e.g.*, DP 243), yielding a good grade of concentrate and good recovery (*RI 3484*).

Separation from magnesite with kerosene emulsified with Emulsol X-1, using sodium silicate and soda ash for dispersion, is reported (*RI 3314*). At EASTERN MAGNESIA TALC Co. (*Tref. 2/40*) 0.1 lb. per ton of a sulphonated petroleum fraction (C_{14} aver.) is used as the sole reagent for the same separation. Talc is depressed by starch (*RI 3436*), and by organic colloids (*U. S. pat. 2,070,076*). Norman *et al.* (*Bul 18 ACerS 292*) report on laboratory separations respectively from tremolite ± serpentine; limestone; and quartz, feldspar, and tremolite. They found pine oil sufficient for flotation of foliated talc, and amines better for fibrous talc. Quartz did not require special depressants; tremolite and dolomite required acid or alkali. A "mixture of nitrogenous bases from recovered oil" was the best collector; diamyl amine next. None of the talc concentrate was of high purity. Sodium carbonate was the best dispersant and yielded cleanest concentrate; grinding with 2 lb. per ton, settling 30 min., decanting, and floating the sand was the best operation. Norman and Ralston (*134 A 73*) assert the general rule that the short-chain amines will float silicates containing more than 5% water of hydration (*e.g.*, talc, pyrophyllite, sericite, clays, and weathered mica) but do not float those less hydrated.

Tourmaline floats with soap (*40 CIMM 691*).

Wollastonite is collector-coated by laurylamine hydrochloride (*CU*).

Zircon is floatable, after a fashion, from mica and kaolin with oleic acid (*RI 3473*).

Zircon is said to be separable from rutile with sodium oleate plus oleic or other unsaturated fatty acid plus a frother, or with soap plus sodium oleyl sulphate, in alkaline pulps (*40 CIMM 691*). Order of floatability is said to be zircon > monazite > rutile > ilmenite with soap collector; these differences are accentuated by draining after conditioning, subjecting the sand to an acid wash, and refloating in slightly acid or neutral pulp with a small amount of frothing agent.

54. INERT MINERALS

The minerals in this class comprise a small group, unrelated chemically, which are substantially chemically inert in dilute aqueous solutions at atmospheric temperatures. The best known are coal, graphite, and sulphur; others are the solid hydrocarbons, *e.g.*, gilsonite, ozokerite, etc. These minerals have the outstanding property, from a flotation standpoint, that they are preferentially wetted by neutral hydrocarbon oils, and by certain other oily substances, in the presence of water. Gilsonite and ozokerite attach to air bubbles in clean water, through a wide pH range, and can, therefore, be froth-floated with a frothing agent only, and can be table-floated with preparation directed solely to depression of the accompanying minerals. The other minerals require oil filming, but the oil may, in the case of graphite and the fat coals, be largely or entirely supplied by contamination in mining or by the minute amounts of insoluble oil carried in the frothing agent.

Graphite, particularly the flake variety, is readily floated; the difficulty in treatment is to keep down gangue which is smeared by the graphite in crushing. Pine oil, which is the preferred frother, is usually the only organic reagent needed; kerosene or other hydrocarbon aids recovery and is necessary for coarse flake but decreases grade of concentrate because it tends to float graphite-smeared gangue. Tar oils float entirely too much gangue. Smeared gangue may be depressed by effecting dispersion of the smearing graphite with sodium silicate in slightly alkaline pulp, but the usual procedure is to acidify to pH 3 to 5 and work up grade by three or four cleanings. The froths with acid pulps are more easily cleaned than the relatively tough, small-bubble floats obtained in alkaline pulp. Cyanide is effective to depress pyrite (*RI 3225*). Field experience is that the large-bubble, brittle, evanescent froth induced by high acidity is not well handled in pneumatic cells, so that subaeration machines predominate.

Clemmer *et al.* (*Bul 49 GSA*) found that soda ash, sodium silicate, caustic soda, or cyanide could be used for depression of coarse gangue, if addition was carefully controlled, and that they had the additional advantage over acid of dispersing clay slimes and keeping them out of concentrate. The writers state that the graphite floats over the pH range 3 to 9 and that grade of concentrate and recovery were equally good in laboratory runs at pH 4 and 7.5 on four different and presumably random samples.

Depression of graphite and of so-called carbonaceous gangues is important in some ores. Starch, glue (*U. S. pat. 1,906,029, RI 3397*), and other organic colloid-type depressants, and lignin sulphonates (*U. S. pat. 2,161,010*) are all more or less effective. Use of a reducing gas such as SO_2, H_2S, CO, or natural gas has been proposed (*U. S. pat. 2,154,092*).

Flotation of carbonaceous material from electric furnace waste containing cryolite and alumina, using pine oil (0.08 lb. per ton), hardwood creosote (0.24 lb.), and kerosene (0.12 lb.), has been described (*U. S. pat. 2,183,500*). Flotation of coke and other carbonaceous residues in crude ultramarine pigment using a hydrocarbon collector and a frothing agent is also described (*U. S. pat. 2,144,115*).

Coal floats readily with a neutral collector and a frother; in general the floatability increases with increase in volatile content except that the trend is reversed when the low-rank earthy sub-bituminous coals and lignites are reached. Freshly mined coal is uniformly more easily floated than dump coal; the latter tends to dull either through the formation of oxidation products or deposition of scale from soluble salts leached out of material accompanying the coal.

The problem in coal flotation is normally economic rather than technical. Flotation is applicable only when the finished coal is required to be fine, as in coke-oven feed, gas making, or for powdered fuel; or where a market for the fine coal can be developed, *e.g.*, anthracite briquettes. For this reason the principal use of flotation in coal washing has been in treatment of the fines of coking coals. Here the process clearly more than pays its way in reduction of ash, sulphur, and phosphorus, and in the reduction in porosity and increase in strength of the coke that flows from the admixture of the fine floated coal with crushed slack. In general it may be predicted that raw coking-coal fines carrying 10 to 15% ash can be separated into a concentrate of 3 to 6% ash content, a steam-coal middling of 10 to 20% ash, and a refuse containing 70 to 80% ash.

Dewatering concentrate is a serious item of expense. The floated coal holds moisture obstinately, up to as much as 30% with feeds that have not been deslimed. Dewatering costs may run up to 25¢ per ton for filtration and an additional 10¢ per ton for heat drying of filter cake. At one plant (*26 JCM 126*) the float concentrate was air flocculated by overoiling and heating, whereupon gravity filtration on coco mat was feasible.

Maximum size readily floatable in a froth is 10-m.; 6-m. can be froth floated but flotation conditions must be so intense that fine bone and carbonaceous refuse are also carried up. Table flotation is to be preferred for coarse feeds.

Yield and concentrate grade vary inversely, as is usual in all concentration. The best procedure is to rough out the finer high-grade coal with a small quantity of frother and very little or no collector, making finished concentrate on the primary rougher; scavenge fines in the second cell, and clean once,

with return of cleaner tailing to the scavenger; scavenge coarse material in the final cell, and clean in a separate cleaner, discharging tailing from this cleaner and from the second scavenger. Some plants treating coal in which impurities are largely in the fines have fed <3/8-in. material to the rougher and screened final tailing to recover the coarse coal, thus obviating the screening of a considerable tonnage of fine material (*67 IME 374*).

When elimination of pyrite, phosphorus, and clay are important, best results will be obtained by use of a petroleum or neutral tar oil as a collector and a relatively pure cresylic acid as a frother. This eliminates carboxylic and sulphydric collectors except in so far as the former are introduced with lubricants. Step addition of both collector and frother is desirable. Total requirement of organic reagent should not exceed 1 to 2 lb. per ton of feed. Sodium silicate is a satisfactory dispersant for clayey slimes. Lime is the usual pyrite depressant, but its use is limited by the fact that pH greater than 8.5 tends to decrease recovery and drop grade. Cyanide may be used, but considerable quantities are required on account of the pH limitation. Ferrous sulphate has been recommended as a pyrite depressant (*RI 3263*). Pyrite may be floated preferentially from the less floatable coals, if they are not contaminated with too much oily lubricant, by the use of xanthate and pine oil, using sodium silicate or an organic colloid (*e.g.*, glue or starch) as depressants. Fusain is depressed by starch under gentle collecting conditions, as with cresol alone.

Various procedures suggested in patents are: to emulsify the oily collector and cause frothing by a salt of a sulphonated alcohol, preferably in the C_{12} to C_{18} range (*U. S. pat. 2,112,362*); for a long-range anthracite culm, first float a high-grade concentrate with an alcohol in the C_7 to C_{10} range, deslime the residue with sodium silicate and float the sandy material with 5 lb. per ton of kerosene (*U. S. pat. 2,136,341*); or size the culm into two or more grades and float each separately (*U. S. pat. 2,136,074*); for raw coal, stage addition of up to 1 gal. per ton of a mixture of coal-tar creosote, fuel oil, and kerosene (*U. S. pat. 2,028,742*).

Costs reported range from 15 to 60¢ per ton of feed, but could undoubtedly be lowered.

Sulphur is floated at OLLAGUE, Chile, with creosote, using sodium silicate for dispersion; 90% recovery in an 80% S concentrate from a feed containing 40% S is reported.

SECTION 13

ELECTRICAL CONCENTRATION

REVISED BY

M. D. HASSIALIS, ASSOCIATE IN MINERAL DRESSING,
SCHOOL OF MINES, COLUMBIA UNIVERSITY

Electrical concentration is effected by utilizing the differential responses of minerals to electrical forces. The methods are classed as magnetic or electrostatic, according to the particular form of electrical force employed.

MAGNETIC SEPARATION

Magnetic separation utilizes the force of a magnetic field, coacting with some other force, to produce differential movements of mineral grains through the field. Fundamentally, differences in magnetic permeability of minerals constitute the basis for separation, but practically separation is influenced by the specific gravity, size, and purity of the mineral grains, and by mechanical and electrical attributes of the separator.

1. INTRODUCTION

A magnetic field exerts a force on a permeable particle within it only if the field varies in uniformity. The magnitude of the force exerted, all other things being equal, depends upon the uniformity gradient of the field, and upon the departure from uniformity caused by the particle. The force is invariably directed from a region of low magnetic intensity toward an adjacent region of higher intensity. The steeper the intensity gradient between these regions the greater the force.

Magnets are uncharged bodies which, under suitable electrical conditions, attract or repel one another. The alignment of a freely suspended magnet in the magnetic meridian (roughly north-south in middle latitudes) is a familiar result of the magnetic forces exerted by the earth, itself a vast magnet, upon the suspended magnet. The POLES of a magnet are the points of convergence of lines so drawn as to have everywhere the direction assumed by a magnetic needle when suspended at different points in the neighborhood of the magnet. By convention, a NORTH or POSITIVE pole is one which turns toward the north geographical pole, and a SOUTH or NEGATIVE pole toward the south geographical pole.

Magnetic permeability is a measure of the ease with which magnetic properties may be induced in a substance by the action of a magnetic field. All substances are permeable to some extent; they are classified as PARAMAGNETIC or DIAMAGNETIC, respectively, when more or less permeable than free space. Very strongly paramagnetic materials are called FERROMAGNETIC. The magnetic force exerted on a particle in a given magnetic field depends upon the relative permeabilities of the particle and the surrounding medium; when the permeability of the particle exceeds that of the medium, the force is attraction; conversely repulsion occurs. Since air is the usual test medium, substances attracted to

the poles of a magnet are rated as paramagnetic, those repelled as diamagnetic. A better classification for ore-dressing purposes is STRONGLY MAGNETIC (corresponding to ferromagnetic), WEAKLY MAGNETIC and NONMAGNETIC, as in Table 1. The position of a given mineral in this list may be altered by small amounts of impurities, either chemically or mechanically held.

Table 1. Relative magnetic attractability of minerals. (*After Davis, Bul 7 MSM*)

	Substance	Relative attractability
Strongly magnetic..	Iron (taken as standard)...	100.00
	Magnetite....	40.18
	Franklinite....	35.38
	Ilmenite......	24.70
Weakly magnetic..	Pyrrhotite....	6.69
	Siderite.......	1.82

	Calcite.......	0.03
	Witherite.....	0.02

Mixtures susceptible to magnetic separation are normally those in which valuable mineral and gangue fall in different classes in Table 1. Theoretically, it should be possible to separate materials whose permeabilities are in the ratio of 5 or 10 : 1 (magnetic separation of atomic mixtures of even lower ratios have been performed successfully), but practically success usually depends on other factors. Impurities in natural minerals may so alter permeabilities as to render published indices of susceptibility unreliable. Thus iron-stained quartz and iron-bearing muscovite mica are sometimes separated from other nonmagnetic minerals, iron-bearing sphalerite is separated from pyrite and quartz, iron-bearing garnet from quartz and other acid silicates and corundum, rutile (probably ilmenite-bearing) from apatite, and a magnetic galena occurs at one of the Coeur d'Alene mines. Hence, except for such separations as of strongly magnetic from clearly nonmagnetic substances, the safest procedure in determining whether a mixture is separable by magnet is to test.

Most important magnetic separations in practice are those of the iron ores, *e.g.*, magnetites from quartz, feldspars, hornblende, garnet, and apatite; roasted hematite and limonite from silica; roasted siderite from siliceous and carbonaceous gangue; roasted pyrite from blende unaltered in the roasting; pyrrhotite from blende, and from quartz and basic silicates. Other commercial separations of metallic minerals are: franklinite from willemite, zincite, and calcite; pyrolusite and psilomelane from siliceous gangue and limonite; chromite from silicates; rutile from apatite; copper carbonates from siliceous gangue; wolframite from cassiterite; magnetite and ilmenite from monazite sands; ilmenite from cassiterite concentrate; rutile, brookite, and ilmenite from orthoclase feldspar; wolframite from a tungsten-bismuth concentrate; and tramp iron from ores and ashes. In the field of industrial minerals magnetic processes are used to remove magnetic materials from concentrate, *e.g.*, iron introduced in mining and grinding from body slip or glaze, China clay, or fireclay; iron and magnetic pyrite from coal; siderite from cryolite; iron, and such iron-bearing minerals as biotite, garnet, tourmaline, and some muscovites from feldspar; iron, magnetite, and pyrrhotite from garnet; garnet and mica in a gravity concentrate from kyanite; magnetite and muscovite from nepheline; iron from salt; magnetite and ilmenite from glass sand; iron from sillimanite or andalusite; burnt magnesite from lime and alumina; garnets and basic silicates from diamondiferous sands; garnets from metamorphic silicates; garnet from corundum; and lava from leucite.

2. MAGNETIC THEORY

Units. Great confusion exists in the literature of electricity owing to multiplicity of systems of units and to lack of uniformity in nomenclature and symbolic representation. Electric and magnetic systems of units superimpose on the fundamental mechanical units of length, mass, and time certain units of electrical measurement. When the added units

are themselves fundamental, the system is ABSOLUTE (see ***CGSM system***, below). When the system is modified in order to bring the numerical value of some derived unit to one, when the fundamental units in the derivation equation have unit values, the system is said to be RATIONALIZED. A rationalized system of electromagnetic units is one wherein a unit electric charge emits unit electric flux (instead of 4π units of electric flux) and a unit magnetic pole emits unit magnetic flux. Two methods of achieving this end exist; one changes the size of the units, the other injects the constant 4π into the values of the space constants ϵ_0 and μ_0 (see Table 2 for meaning of symbols). The latter method is sometimes termed SUBRATIONALIZATION.

The following are the systems of electrical units most commonly used.

Electromagnetic (CGSM) system of units (see Table 2) is an absolute, consistent, unrationalized system based on the centimeter, gram, second, and space permeability ($\mu_0 = 1$) as fundamental units. A rationalized form is sometimes used in physics literature. These units were developing in the days when low-voltage, heavy-current phenomena were the center of interest; consequently the units are now of inconvenient magnitude. The unrationalized CGSM system will be used throughout this section.

Electrostatic (CGSS) system of units (Table 2) is absolute, consistent, and unrationalized. It uses the centimeter, gram, second, and space permittivity ($\epsilon_0 = 1$) as fundamental units.

Heaviside-Lorentz (HLU) system of units is an absolute, consistent, rationalized system based on the centimeter, gram, and second. In this system both space permeability and permittivity are taken as unity. This scheme greatly simplifies the fundamental relations; more important, it exhibits the symmetry existing between electric quantities on the one hand and magnetic quantities on the other, *e.g.*, in CGSM,

$$D = E/4\pi c^2 + P = \epsilon E/4\pi c^2 \quad \text{and} \quad B = H + 4\pi I = \mu H$$

while in HLU

$$D = E + P = \epsilon E \quad \text{and} \quad B = H + I = \mu \mathrm{H}$$

This system is primarily used in basic physics; it is also used in engineering literature dealing directly with Maxwell's field equations.

Giorgi (MKS) system of units is an absolute, consistent system based on the meter, kilogram, and second. It was adopted by the International Committee of Weights and Measures, of which this country is a member, in October 1935. No choice was made as to the fourth fundamental unit, preferences being divided between the ampere, ohm, permeability, and coulomb. Similarly, no decision was reached as to rationalization. The rationalized system using Q as the fourth fundamental unit is given in Table 2. This system possesses the symmetry advantages of rationalization and the advantage of utility since it includes all the practical units (see below).

Practical system is an incomplete system of units of magnitude convenient for measurements. Originally these units were designed to be decimal multiples or fractions of the CGSM units. Fortunately, although the units differ somewhat from the International units, the differences are so small as to be negligible for most practical purposes.

International system of units is based on standards set up in accord with the definitions and specifications adopted by the International Electrical Congresses of 1893, 1908, and 1910. The most recent determinations of these units are given in Table 2.

Pole strength is measured in poles. The more common measure, the INTENSITY OF MAGNETIZATION I, gives the distribution of pole strength per unit area, *i.e.*, poles per square centimeter (GAUSS). The more precise definition of I is based on the physical realities of magnetism rather than on the abstractions. Poles cannot be isolated; the finest subdivision of a magnet yields a magnetic particle possessing two equal and opposite poles separated by a distance l. The product of pole strength and the distance between poles is called the MAGNETIC MOMENT M and is measured in pole-centimeters. More precisely, therefore, the intensity of magnetization is defined as the magnetic moment per unit volume. Although this definition gives a unit of I having the dimensions of poles per sq. cm., it makes I a directed or vector quantity. The force F exerted by magnetic pole m_1 upon another m_2 is $m_1m_2/\mu r^2$, where μ is a constant depending on the intervening medium and r is the directed distance in centimeters between the poles. In free space, $\mu = 1$; hence $F = m_1m_2/r^2$. A positive force indicates repulsion and a negative force attraction, since like poles repel and unlike attract. The force H (MAGNETIC FIELD INTENSITY) exerted by a magnetic pole m upon a unit north pole in free space is m/r^2.

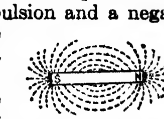

FIG. 1. Lines of force surrounding a bar magnet.

Magnetic field (or force) of a magnet is the surrounding space through which its influence extends. The magnetic field is mapped by lines of force (see Fig. 1) obtained as follows: A unit positive pole is placed in the magnetic field, the direction of the magnetic force exerted on it is determined, and the unit pole is moved an infinitesimal distance in this direction. By repetition of this process at each new position of the unit pole a line of force is traced; the sense of the line is denoted by an arrowhead pointed in the direction of the field intensity. Although through every point of the field there passes one and only one line of force, the desire to associate the magnitude of the field intensity as well as its direction with the mapped field led early investigators to assume that one line of force

Notes for Table 2:

a Or electric charge or quantity.
b And electromotive force, or potential difference.
c Or electric field strength, electric intensity, or potential gradient.
d Or electric displacement, electric induction.
e Or dielectric constant, or inductive capacity.
f Or dielectric coefficient; $\kappa_e = \epsilon/\epsilon_0$ (where ϵ = permittivity of the medium).
g Or dipole moment.
h Or intensity of polarization, density of electric moment.
i Or capacity.
j Or pole strength.
k And magnetomotive force.
l Or magnetic field strength, magnetic intensity, magnetic force.
m Or magnetizing force, magnetic induction.
n $\kappa_m = \mu/\mu_0$, where μ is permeability of the medium.
o Or intensity of magnetization, density of magnetic moment, or magnetic polarisation.
p Bold face italic symbols denote vectors; the corresponding scalar magnitudes are denoted by the ordinary italic symbol.
q Or maxwell/4π.
r Adopted in 1930 by International Electrochemical Commission, oersted sometimes used for unit of reluctance, alternative name gilbert/cm.
s Also maxwell/cm.^{2}.
t Or abhenry/cm.
u Or pragilbert, most often used for unit of unrationalized MKS system.
v Or praoersted, usually used for unit of unrationalized MKS system.
w Q is chosen as the fourth fundamental unit.
x Ratio of size of unit to size of CGSM unit; to obtain equivalent number of CGSM units multiply by F, *e.g.*, 10 amperes = $10F$ abamperes = 1 abampere.
y Ratio of size of international unit to practical unit.
z Practical units incorporated in MKS system.
aa $c = (2.99796 \pm 0.00004) \times 10^{10} \doteqdot 3 \times 10^{10}$.
ab Pure number.

crosses each unit area perpendicular to the line when the field intensity is unity. In the CGSM system, one line of force would cross one square centimeter of surface when the field intensity is one oersted. A magnetic field is said to be UNIFORM or HOMOGENEOUS when the lines of force are parallel and equally spaced; otherwise it is NONUNIFORM or INHOMOGENEOUS. More precisely, a field is uniform when the rate of change of the field intensity with position, in any direction, vanishes; in some instances the field may be uniform in one direction but nonuniform in another, *e.g.*, the wedge-shaped pole piece of a Wetherill separator (Fig. 34) gives rise to a uniform field parallel to the width of the pole piece and a nonuniform field in all other directions.

Magnetic potential, A, at a point of the magnetic field is the work required to bring a unit positive pole from outside the field up to the point in question, *i.e.*, it is the potential energy of a unit pole placed at the point. The magnetic potential depends only upon the position at which it is to be evaluated and not upon the path followed by the unit pole, in contradistinction to the magnetomotive force (see p. 09) which depends upon the path.

Electromagnetic field is produced by any moving, electrically charged body; the magnetic field is transient, *i.e.*, the direction and magnitude of the force exerted on a unit pole vary with time. A steady stream of moving charges, *e.g.*, a current (of electrons) carried by a long straight conductor gives rise to a stationary magnetic field (see Fig. 2)

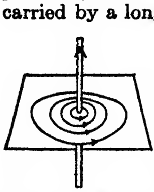

FIG. 2. Magnetic field of a linear current.

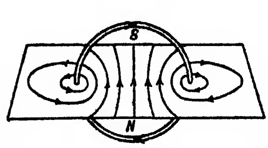

FIG. 3. Magnetic field of a circular current.

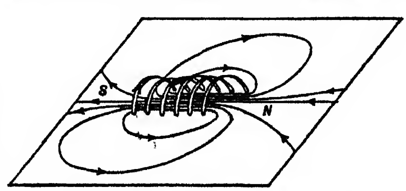

FIG. 4. Magnetic field of a solenoid.

whose lines of force are concentric circles. The sense of the lines of force of the electromagnetic field bears a definite relation to the direction of the moving charges; it is that of the rotation of a right-handed screw advancing in the direction of motion of the charges. The lines of force of a ring-shaped conductor (Fig. 3) are the "circles" of two linear conductors, displaced eccentrically toward the outside and somewhat deformed. For a cylindrical coil (SOLENOID), the lines of force are similar to those of a permanent bar magnet (*cf.* Fig. 4 with Fig. 1). By analogy with the poles of magnets, the areas of convergence

of the lines of force (the openings of the coil) are called the POLES OF THE ELECTROMAGNET, the south pole being the opening through which the lines enter and the north pole the opening through which the lines leave the coil.

Field intensity of a solenoid at any point along its axis is

$$H = 2\pi ni (\cos \theta_1 + \cos \theta_2) \tag{1}$$

where θ_1 and θ_2 are the angles included between the axis and the lines drawn from the point to the near and far edges of the solenoid respectively, and n is the number of turns per cm. At the center of the solenoid, Eq. 1 becomes

$$H = 4\pi ni(l/\sqrt{l^2 + 4r^2}) \tag{2}$$

where l and r are the length and radius of the solenoid expressed in centimeters. In the case of a coil whose length is large compared to its radius, Eq. 2 reduces to $H = 4\pi ni$. For a solenoid wound with n turns per centimeter in a number of layers extending from a distance r centimeters from the axis to a distance R and carrying a current of i abamperes, the field intensity in oersteds at an axial point distant l_1 and l_2 centimeters from the two ends is

$$H = \frac{2\pi ni}{R - r}\left(l_1 \ln \frac{R + \sqrt{l_1^2 + R^2}}{r + \sqrt{l_1^2 + r^2}} + l_2 \ln \frac{R + \sqrt{l_2^2 + R^2}}{r + \sqrt{l_2^2 + r^2}}\right) \tag{3}$$

when ln is the Napierian logarithm.

Induced magnetism is observed whenever matter is placed in the magnetic field of a permanent magnet or electromagnet; thus a rod of iron placed in the core of a solenoid becomes magnetized in the direction of the impressed magnetic field and magnetic poles form at the end surfaces of the rod.

Magnetic flux density, B, that is, the magnetic force at a point inside a magnetic material, is the resultant of the externally impressed magnetic field and the force due to the induced poles at the ends of the rod. If the strength of the induced magnetism is equivalent to I dipoles per cc., the number of lines due to the induced magnetism is $4\pi I$; the number due to the impressed field is H, hence the total number of lines crossing each sq. cm. is

$$B = H + 4\pi I \tag{4}$$

Magnetic flux, ϕ, is the number of lines crossing total section of rod, or

$$\phi = BS \tag{5}$$

where S = surface area of section in sq. cm.

Intensity of magnetization induced depends upon the impressed field intensity, the temperature, chemical composition, physical structure and previous magnetic history of the magnetized body, and upon the time characteristics of the magnetizing field.

Susceptibility of a magnetic medium, k, is defined as the ratio of the induced magnetization to the impressed field, *i.e.*,

$$k = I/H \quad \text{or} \quad I = kH \tag{6}$$

Susceptibility as defined by Eq. 6 is sometimes called the VOLUME SUSCEPTIBILITY to differentiate it from the SPECIFIC SUSCEPTIBILITY $\psi = k/\rho$, where ρ = density. Substances having positive susceptibilities, *i.e.*, those in which the induced field augments the impressed field, are paramagnetic; substances of negative susceptibility, for which the induced field cancels a part of the impressed field, are diamagnetic. The direction of the magnetization is parallel to the impressed field for isotropic materials (antiparallel for isotropic diamagnetic substances) and the susceptibility is a constant independent of the orientation of the body. For anisotropic materials the induced magnetization is at an angle to the impressed field and the susceptibility varies with the orientation. In general, anisotropic materials possess three magnetic axes such that fields impressed along these axes produce parallel magnetization. The susceptibilities along the magnetic axes may vary considerably; with some materials, *e.g.*, graphite, it is possible to prepare a specimen that is paramagnetic in one direction and diamagnetic in another.

Table 3 gives figures on susceptibility of minerals collected from various sources; several discrepancies were evident, and the warning given in connection with Table 1 should be remembered.

Permeability, μ, of a magnetic substance is the ratio of the magnetic flux density to the impressed field, *i.e.*,

$$\mu = B/H \quad \text{or} \quad B = \mu H \tag{7}$$

Permeability is related to susceptibility, since substitution of Eqs. 6 and 7 in Eq. 4 gives

$$\mu = 1 + 4\pi k \tag{8}$$

Hence substances of permeability greater than unity are paramagnetic; less than unity, diamagnetic. Owing to the linearity of the relation between μ and k, it follows as above that B is parallel or inclined to H according to whether the material is isotropic or anisotropic, the latter possessing three magnetic axes along which B and H are parallel.

Magnetization *vs.* impressed field. The ratio of magnetization and, therefore, of magnetic flux density to the magnitude of the impressed field is constant for all known diamagnetic substances at presently available field intensities, and for most paramagnetic substances. However, μ and k vary with H for ferromagnetic substances. Fig. 5 shows a typical B–H curve and the corresponding μ–H

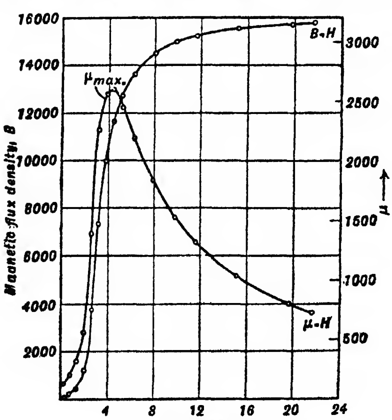

FIG. 5. B–H and corresponding μ–H curve for a ferromagnetic material (*after Ewing, 176 Phil. Trans. Roy. Soc. 523*).

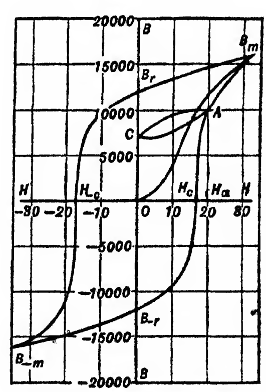

FIG. 6. Hysteresis loops.

curve for iron. The B–H curve shows a varying increase of B with an increase in H, the maximum rate of increase $\mu_{max.}$ coming at the inflection point of the curve; as H increases past the value corresponding to $\mu_{max.}$, B increases less rapidly and finally approaches a steady rate of increase; here the material is said to be MAGNETICALLY SATURATED and the flux density is designated MAXIMUM FLUX DENSITY B_m (or more precisely the SATURATION FLUX DENSITY). If, after magnetic saturation, the impressed field is decreased to zero, the B–H curve is represented by the curve B_mB_r of Fig. 6; B_r is

called the REMANENCE (remanent induction or retentivity) and is a measure of the permanent magnetism acquired by the magnetised body as a result of the magnetic treatment. With an increase of H in the reverse direction, B decreases along the curve B_rH_{-c} until it finally vanishes; H_{-c} is called the COERCIVE FORCE and is equal to $4\pi I$. Materials with a high coercive force are said to be magnetically hard or rigid; with a low coercive force, magnetically soft or elastic. These descriptive terms are loosely used, and their implications are not founded on facts. For further increases of H in the negative direction, B increases negatively to a negative maximum value B_{-m}; further changes of H as indicated by Fig. 6 trace the curve $B_{-m}B_{-r}H_cB_m$, where B_{-r} ($= B_r$) and H_c ($= H_{-c}$) are the negative remanence and positive coercive force respectively. The entire cycle is known as a HYSTERESIS LOOP. If, when the point A on the H_cB_m branch is reached, H is decreased to zero and then increased to H_a, a MINOR LOOP ACA is obtained. This procedure may be repeated for any point of the major hysteresis loop, hence an infinity of minor loops may be obtained. Thus for each value of H there are an infinite number of values of B and consequently an infinite number of values of μ. Hence the value of μ for ferromagnetic substances is significant only when the previous magnetic history is known.

Dependence of permeability upon temperature is of practical importance only in the case of ferromagnetic materials. In general, the value of μ increases slowly at first and then more rapidly until

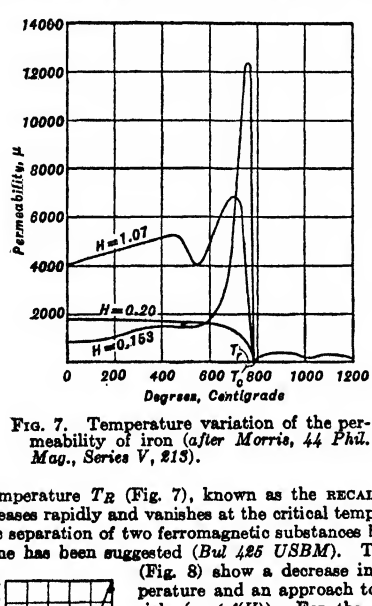

FIG. 7. Temperature variation of the permeability of iron (*after Morris, 44 Phil. Mag., Series V, 213*).

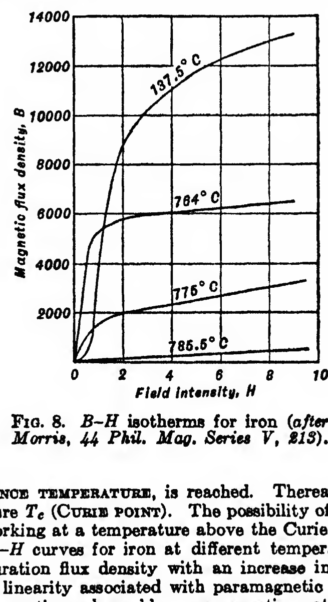

FIG. 8. B–H isotherms for iron (*after Morris, 44 Phil. Mag. Series V, 213*).

a temperature T_R (Fig. 7), known as the RECALESCENCE TEMPERATURE, is reached. Thereafter μ decreases rapidly and vanishes at the critical temperature T_c (CURIE POINT). The possibility of magnetic separation of two ferromagnetic substances by working at a temperature above the Curie point of one has been suggested (*Bul 425 USBM*). The B–H curves for iron at different temperatures (Fig. 8) show a decrease in saturation flux density with an increase in temperature and an approach to the linearity associated with paramagnetic materials ($\mu \neq f(H)$). For the diamagnetic and weakly paramagnetic materials, permeability is independent of temperature; for the stronger paramagnetics the permeability varies inversely as the absolute temperature (Curie's law).

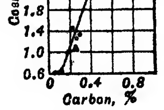

FIG. 9. Coercive force vs. carbon content (*after International Critical Tables, vol. 6, p. 379*).

Effects of physical structure and chemical composition on permeability are too varied to permit of generalization. Substances existing in more than one crystalline state invariably exhibit different permeabilities in these states. In general, the different allotropic states of a substance show different magnetic properties; thus of the four allotropic states of pure iron (α, to 800° C.; β, 800 to 920° C.; γ, 920 to 1,410° C.; δ, 1,410° C. to melting point), only the α-state is magnetic. The decrease in magnetization at saturation with increasing temperature is proportional to the percentage of α-iron. Physical changes produced by the action of mechanical, electrical, or optical forces are invariably accompanied by changes in magnetic properties. Some indication of the effect of chemical composition may be had from the B–H curves (Fig. 9) for steels of varying carbon content. The regular increase of coercive force with carbon content has been suggested as the basis for a rapid method of plant-control analyses (*24 #1 ASM 175*). The unpredictability of magnetic properties of alloys from the properties of the constituents is well known; of practical importance is the low permeability of the higher manganese-iron alloys (>5% Mn) on the one hand, and the high permeability of the alloy, 23.7% Mn with Ni, on the other.

Time characteristics of the magnetizing field intensity have a negligible effect upon the magnetization curves of some materials and a very marked effect on others. In general, magnetization lags behind the imposed, uniformly maintained field intensity (Fig. 10). Similarly magnetization lags behind the removal of the magnetizing field (Fig. 11). This time-lag is a function of size, increasing with diameter of a solenoid iron core, and is also a function of the field intensity. On account of these

time-lags, the hysteresis cycle may vary markedly with the rate at which field intensity is varied. For fields with alternating characteristics, the maximum permeability is at first independent of frequency, then decreases rapidly as frequency is increased, finally becoming unity at frequencies above 3×10^{10} per sec. Hysteresis loops obtained with alternating magnetic fields generally show an increase in coercive force.

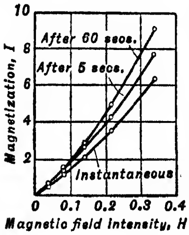

FIG. 10. Time lag of magnetization for annealed wrought iron (*after Ewing, 46 Proc. Roy. Soc. A, 269*).

Magnetic circuit is a useful fiction which conceives of a flow of hypothetical magnetic substance (FLUX) in a manner analogous to the flow of current in a conductor, the magnetic flow resulting from a difference in magnetic pressure or potential, called the MAGNETOMOTIVE FORCE (m.m.f.), by analogy with electromotive force, and resisted by the RELUCTANCE of the circuit (analogous to resistance). The relation of these quantities of the magnetic circuit is

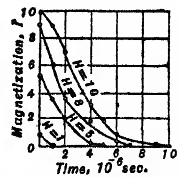

FIG. 11. Time rate of decrease of magnetization of a hard steel wire (*after Wvedensky, 66 Ann. Physik 110*).

$$\phi R_m = \text{m.m.f.} \tag{9}$$

Magnetomotive force is the work done by the magnetic field when a unit positive charge is carried around the current producing the electromagnetic field in the sense of the lines of force; it is independent of the path provided the path is closed, otherwise it is dependent thereon. In a magnetostatic field due solely to permanent magnets the m.m.f. is identical with the magnetic potential. For a toroidal solenoid with an iron core

$$\text{m.m.f.} = \oint H dl = 4\pi N i \tag{10}$$

where l = mean length of torus and N = total number of turns. Since $\phi = BS$ (Eq. 5) and $H = B/\mu$, $H = \phi/\mu S$, whence

$$\phi \oint \frac{dl}{\mu S} = 4\pi N i = \text{m.m.f.} \tag{11}$$

Reluctance. The circular integral of Eq. 11 is the reluctance. In the case of a magnetic circuit consisting of several distinct parts, in each of which μ and S are constant

$$\oint \frac{dl}{\mu S} = \frac{l_1}{\mu_1 S_1} + \frac{l_2}{\mu_2 S_2} + \cdots \tag{12}$$

Thus if the iron-ring core is cut by a narrow gap of width w (Fig. 12) the reluctance of the magnetic circuit becomes (taking $\mu_{\text{Air}} = 1$)

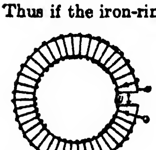

FIG. 12. Cut-ring electromagnet.

$$R_m = \frac{l - w}{\mu_{\text{Fe}} S} + \frac{w}{\mu_{\text{Air}} S} = \frac{l + w(\mu_{\text{Fe}} - 1)}{\mu_{\text{Fe}} S}$$

Thus the original flux has been decreased by a factor $l/[l + w(\mu - 1)]$. Assuming a permeability of 300 for iron, a gap as small as $l/300$ reduces the flux by one-half; which shows the tremendous effect of even small gaps in a magnetic circuit. In the case of an electromagnet with a keeper so located in the magnetic circuit (Fig. 13) as to form two air gaps, the reluctance is

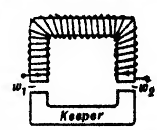

FIG. 13. U-magnet with keeper.

$$R_m = \frac{l - (w_1 + w_2)}{\mu_{\text{Fe}} S} + \frac{w_1}{S} + \frac{w_2}{S} = \frac{l + (w_1 + w_2)(\mu_{\text{Fe}} - 1)}{\mu_{\text{Fe}} S} \tag{13}$$

Inductance. When the magnetic flux in a substance is changing, a current is induced therein which lasts as long as change continues. The magnitude of the induced e.m.f. is proportional to the time rate of change of flux. If the flux is decreasing, the sense of the induced current is that of the rotation of a right-handed screw advancing in the direction of the flux, whereas if the flux is increasing, the induced current is in the opposite sense. In either case the induced e.m.f. acts in the sense to oppose the change in flux. If the changing magnetic flux is due to changes in current flowing in a conductor, a counter e.m.f. is induced in the circuit. This phenomenon is known as SELF-INDUCTION, and the ratio of flux to current is the self-inductance $L = \phi/i$.

Energy stored in a magnetic field is the energy expended in producing the flux against the counter e.m.f. induced by the changing flux. This is

$$W = \int \text{e.m.f.} \times i dt \tag{14}$$

where e.m.f. = induced counter e.m.f. in abvolts. For a coil of n turns the time rate of change of total flux is $d(N\phi)/dt$ = e.m.f. where ϕ is the flux linked per turn. Eq. 14 becomes

$$W = \int_0^{\phi} iN d\phi = iN\phi = NL_i = Li^2 \tag{15}$$

where L and L_t are the inductances of the coil and each winding respectively. If the magnetic circuit includes iron (*e.g.*, iron core in an electromagnet), Eq. 15 becomes

$$W = \int \frac{d(BSN)}{dt}\, i dt = SNi \int_0^B dB$$

But $H = 4\pi ni$ (p. 06) $= 4\pi Ni/l$, whence

$$W = \frac{1}{4\pi} \int_0^B HlSdB \text{ ergs} = \frac{1}{4\pi} \int_0^B HdB \text{ erg/cc. of iron} \tag{16}$$

This integration cannot be performed unless the hysteresis loop relating B to H is known. In the case of a nonmagnetic medium, $\mu = 1$; hence $B = H$ and Eq. 16 becomes

$$W = \frac{1}{8\pi} B^2 = \frac{1}{8\pi} BH = \frac{1}{8\pi} H^2 \tag{17}$$

The energy stored in an air gap w cm. wide between two pole faces S sq. cm. in area is

$$W = \frac{1}{8\pi} BHSw \tag{18}$$

Since Hw is the work done in carrying a unit positive pole from one pole face to the other, $Hw = A$ (magnetic potential) and $BS = \phi$ (assumed uniform over gap), the energy of the air gap may be written as $W = (1/8\pi)\phi A$ ergs.

The energy loss due to hysteresis is, from Eq. 16, $1/4\pi$ times the area of the hysteresis loop, the latter being determined by graphical integration of the loop. In addition to the power loss represented, the conversion of the hysteresis loss into heat, with subsequent reduction in maximum flux densities with rising temperature (see p. 08), is a problem of prime importance in the design of alternating magnets. For maximum flux densities, B_m between 2,000 and 12,000 lines per sq. cm., the empirical equation, $W = \eta B_m^c$ ergs per cc. per cycle, may be used, where η (HYSTERESIS COEFFICIENT or constant) and c are constants of the material. Another empirical equation giving results which are somewhat too high at B_m less than 10,000 and too low at greater values of B_m, is $W = (1/\pi)\eta B_m H_c$ ergs per cc. per cycle.

3. PRINCIPLES OF MAGNETIC SEPARATION

Magnetic forces acting on a body in a magnetic field may be determined by application of Coulomb's law, *i.e.*, $F = m_1 m_2/\mu r^2$. However, if the body in question is not a point pole or a small magnetic dipole, and is not located at distances from the magnets of the field sufficiently great relative to its linear dimensions that it may be so considered, the summations or integrations resulting from application of Coulomb's law are extremely complicated and often impossible. A more fruitful and less difficult method of obtaining the force exerted depends upon the fact that the energy stored in the magnetic field is energy of position, *i.e.*, potential energy, and is, therefore, available to do external work.

If, in any magnetic system composed of permanent and/or induced magnets, a particular body is moved an infinitesimal distance dl, the magnetic energy changes by an infinitesimal amount dW from the energy W_1 of the initial state to the energy W_2 of the final state. The work done in moving the body against the force F acting on it is $Fdl = -dW$, whence the force acting on the body is

$$F = -\frac{dW}{dl} \tag{19}$$

Thus in the case of two magnetized iron surfaces of area S separated by a gap w, the energy stored in the gap is given by Eq. 18. The rate of change of this energy in the direction of w and therefore the pull in dynes is $B^2S/8\pi$. Similarly for a rotation, the torque T is given by Eq. 20.

$$T = -\frac{dW}{d\theta} \tag{20}$$

For the magnetic system specified, the X-component F_x of the force per unit volume is given completely by

$$F_x = -\rho_m \frac{\partial A}{\partial x} - \frac{H^2}{8\pi}\frac{\partial \mu}{\partial x} + \frac{\partial}{\partial x}\left(\frac{H^2}{8\pi}\rho \frac{\partial \mu}{\partial \rho}\right) \tag{21}$$

where ρ_m is the density of magnetic poles and ρ is the mass density. The first term is the force due to the permanent magnetism of the body, whereas the others arise from the induced magnetism. The second term is of importance in dealing with bodies wherein the permeability varies with position within the body. The third term accounts for potential energy stored within the magnetized body as a result of a change in shape of the body (usually a lengthening or shortening in the direction of the magnetization known as MAG-

NETOSTRICTION). The force arising from this internally stored energy depends upon the space rates of change of the field intensity, the permeability, and the mass density. In the problems of interest in this section it is assumed that $\mu - 1 = c\rho$, where c is a constant, and that $\partial\mu/\partial x = 0$. Although neither of these assumptions is correct, the errors introduced by their use are relatively small. Eq. 21 may now be written

$$F_x = -\rho_m \frac{\partial A}{\partial x} + \frac{\mu - 1}{4\pi} H \frac{\partial H}{\partial x} \tag{22}$$

Example. The force exerted by one magnetic particle upon another requires the preliminary evaluation of the potential which was given by Maxwell (II *Electricity and Magnetism 11*) as

$$A = \frac{M_1 M_2}{r^3} (\cos \phi - 3 \cos \theta_1 \cos \theta_2) \tag{23}$$

where M_1 and M_2 are the magnetic moments of the particles, r is the distance between their centers, ϕ is the angle which the axes of the particles make with each other, and θ_1 and θ_2 are the angles which the axes make with r. Although the variables r, ϕ, and θ are sufficient to specify completely the relative disposition of the particles, ϕ is a dependent variable. This difficulty is removed by expressing Eq. 23 in spherical polar co-ordinates using r as the polar direction, θ as latitude, and ψ as azimuth, when Eq. 23 becomes

$$A = \frac{M_1 M_2}{r^3} [\sin \theta_1 \sin \theta_2 \cos (\psi_1 - \psi_2) - 2 \cos \theta_1 \cos \theta_2] \tag{24}$$

Differentiating Eq. 24, the force acting on the second magnetic particle along the line of centers is given by Eq. 25

$$F_r = -\frac{\partial A}{\partial r} = -\frac{3M_1 M_2}{r^4} [\sin \theta_1 \sin \theta_2 \cos (\psi_1 - \psi_2) - 2 \cos \theta_1 \cos \theta_2] \tag{25}$$

When the magnets have their axes in a straight line and in the same direction, $\theta_1 = \theta_2 = 0$, $\psi_1 = \psi_2$, and an attractive force $6M_1M_2/r^4$ is exerted. When the axes are perpendicular to the line of centers and parallel in the same direction, $\theta_1 = \theta_2 = \pi/2$, $\psi_1 = \psi_2$, and a repulsive force $-3M_1M_2/r^4$ acts. If the axes are parallel in opposite directions, $\psi_1 = \pi + \psi_2$, and the force is an attractive force of the same magnitude.

The couple tending to increase, say, the angle ψ_1 is found by applying Eq. 20 to Eq. 24, giving

$$T = -\frac{\partial A}{\partial \psi_1} = \frac{M_1 M_2}{r^3} \sin \theta_1 \sin \theta_2 \sin (\psi_1 - \psi_2) \tag{26}$$

When the axes are perpendicular to the line of centers and to each other, $\theta_1 = \theta_2 = \pi/2$ and $\psi_1 = \psi_2 + \pi/2$. The couple is M_1M_2/r^3.

The force exerted on a sphere, say, of soft iron possessing no permanent magnetism is given by

$$F_x = \frac{\mu - 1}{24} D^3 H \frac{\partial H}{\partial x} \tag{27}$$

Tractive force exists only when the space rate of change of the field intensity does not vanish, *i.e.*, when the field is nonuniform; it has components only in the directions of inhomogeneity and is positively oriented in the direction of maximum inhomogeneity providing $\mu > 1$. For diamagnetics, $\mu < 1$, the direction of the tractive force is that of decreasing inhomogeneity of field, *i.e.*, diamagnetic spheres move toward the more uniform part of the field. Looked at from the point of view of lines of force, a paramagnetic spherical body placed in a uniform field (Fig. 14, item *a*) concentrates the lines of force over the hemispherical surfaces facing the poles. Lines of force may be considered as being in tension; hence each half of the particle is subject to a pull whose magnitude depends upon the orientation and number of lines, and, since this is the same for the two halves, the resultant force vanishes; however, in the case of a paramagnetic particle in an inhomogeneous field (Fig. 14, item *b*), although the number of lines crossing each half of the particle is the same, the orientation is such that the particle is pulled toward the focus of inhomogeneity. If the particle possesses any permanent magnetism and is presented to the field in such fashion that its axis is not collinear with the lines of force, it is also acted on by a couple which turns the particle until its axis parallels the field; if the particle was originally nonmagnetic the axis of the induced polarity is parallel to the field. In the case of a diamagnetic sphere the lines of force are dispersed (Fig. 14, item *c*); the axis of the induced polarity is parallel to the field and the couple acting tends to align the axis therewith. However, if a diamagnetic needle is placed in a field it aligns itself with its axis perpendicular to the field when the dimensions of the needle are comparable to those of the magnet, and with its axis parallel to the field when these dimensions are small.

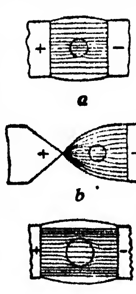

FIG. 14. Effect of permeable bodies on magnetic fields.

Faraday (*Experimental Researches*, § *2418*) observed this behavior of long diamagnetic needles and correctly interpreted it as the result of the tendency of the induced poles to move toward the region of greater uniformity; his published reports on this subject have been rather generally misread and misinterpreted down to the present.

The direction of the motion produced by the magnetic force, as noted above, is that of maximum rate of change of field intensity, and in general does not coincide with the direction of the lines of force. Thus if a sphere of soft iron is placed symmetrically with respect to the two poles of a U-magnet (Fig. 15) and at some distance therefrom, the maximum rate of change of intensity is in the direction perpendicular to the lines of the poles, hence the particle moves in this direction toward the poles generally, but not directly toward either.

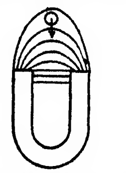

FIG. 15. Motion of a paramagnetic sphere in the field of a horseshoe magnet.

Direction of motion, other things being constant, is determined by the sign of $\mu - 1$ as noted above; this should be written more correctly as $\mu_{\text{solid}} - \mu_{\text{medium}}$, from which it follows that a paramagnetic particle can be made to move in the direction of increasing uniformity of field by surrounding it with a more paramagnetic medium. This principle may be utilized to separate a mixture of paramagnetic particles whose permeabilities are very close, by placing the mixture in a medium of intermediate permeability.

Example: In order to apply Eq. 27, it is necessary to have the equation relating H to position, and this is the chief problem in application. To illustrate the method, an idealization of the Wetherill pole-pieces (Fig. 16) is used. The wedge-pole magnet is assumed to be a line magnet of length $2a$ with positive poles distributed at the rate of $2am$ per unit length. The flat-pole magnet is assumed to be a square $2a$ units on a side with a surface distribution of negative poles of $-m$ per unit area. The contribution H_2 of the line magnet to the resultant field intensity H at a point $P(0,0,z_0)$ is given by Eq. 28, where $r_2 = [y^2 + (z_0 - b)^2]^{1/2}$

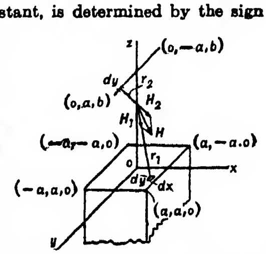

FIG. 16. Sketch of idealized Wetherill pole pieces.

$$H_2 = 2am\int_{-a}^{a}\frac{1}{r_2^2}\,dy \tag{28}$$

From symmetry considerations the x- and y-components vanish, the z-component H_{2z} is given by

$$H_{2z} = 2am\int_{-a}^{a}\frac{(z_0 - b)}{r_2^3}\,dy = \frac{4ma^2}{(z_0 - b)[a^2 + (z_0 - b)^2]^{1/2}} \tag{29}$$

The contribution H_1 of the square-pole magnet at P is given by Eq. 30, where $r_1 = (x^2 + y^2 + z_0^2)^{1/2}$

$$H_1 = -m\int_{-a}^{a}\int_{-a}^{a}\frac{dx\,dy}{r_1^2} \tag{30}$$

The x- and y-components vanish, the z-component H_{1z} is given by

$$H_{1z} = -m\int_{-a}^{a}\int_{-a}^{a}\frac{z_0\,dx\,dy}{r_1^3} = \frac{8mz_0}{\sqrt{2(a^2 + z_0^2)}} - 2\pi m \tag{31}$$

The resultant field intensity of the magnet combination at the point P is

$$H_z = \frac{4ma^2}{(z_0 - b)[a^2 + (z_0 - b)^2]^{1/2}} + \frac{8mz_0}{\sqrt{2(a^2 + z_0^2)}} - 2\pi m \tag{32}$$

and the rate of change of H_z along the z-axis is

$$\frac{dH_z}{dz_0} = \frac{4ma^2[a^2 + 2(z_0 - b)^2]}{(z_0 - b)^2[a^2 + (z_0 - b)^2]^{3/2}} - \frac{16ma^2}{[2(a^2 + z_0^2)]^{3/2}} \tag{33}$$

Assuming a square-pole magnet 6 in. on a side, a wedge-pole magnet 6 in. long, a gap of 3/4 in., and a value of 40 for m (calculated to give a field intensity of 1,000 oersteds at the point in question), the space rate of change of the intensity at a point 1/8 in. above the square pole is 472 oersteds per cm. If a 10∼14-m. magnetite particle is placed at this point, it is acted on with a magnetic force of 55 dynes or 0.055 gm., the gravitational pull on it being 0.0088 gm., assuming a density of 6.0. A 150∼200-m. magnetite particle similarly located is magnetically attracted with a force of 1.4×10^{-5} gm., the gravitational force being 0.22×10^{-5} gm. If the gap is shortened to 1/2 in. and the field intensity at the point 1/8 in. above the lower pole is still assumed to be 1,000 oersteds, the magnetic pull on the 10∼14-m. particle is now 0.103 gm. On the other hand, if a value of $m = 40$ is assumed when the gap is 1/2 in., the pull on the 10∼14-m. particle is 0.234 gm.

The dependability of the above results, considering the number and nature of the assumptions made, is not great; however, it is believed that they show the order of the magnitudes involved. A com-

parison of the forces at constant field intensity, 0.055 and 0.103 gm., acting on the 10~14-m. particle, when the gaps are 3/4 and 1/2 in. respectively, shows the tractive effect of increased inhomogeneity of field. In general, a decrease in gap is accompanied by an increase of field intensity as well as inhomogeneity; the increased pull of 0.234 gm. when $m = 40$ and gap $= 1/2$ in. is due to both factors. It should be noted that ratio of the magnetic forces acting on two particles of different diameters, similarly located in the field, is equal to the third power of the ratio of the diameters and that the ratio of magnetic to gravitational force is independent of particle size.

Magnetic Forces in a Separator

Magnetic concentration is based upon the differences in paths followed by particles of different permeabilities in passing through a magnetic field under the simultaneous action of magnetic and other forces. Determination of the paths is essentially a problem in dynamics, requiring for its solution complete specification of the ore grains, *i.e.*, location, size, shape, density, permeability and initial velocity, and a knowledge of the magnetic and other forces as functions of position and time. Assuming ability to specify the problem, the mathematical difficulties of obtaining a solution are almost insurmountable. However, by stripping the problem of those factors related to the mutual interaction of particles it is possible to obtain an idealized problem more susceptible to attack, the solution of which exposes the interplay between the factors determining the differences in paths. Thereafter by removing the idealizing conditions one by one and modifying the solution accordingly, it is possible to obtain a useful picture of the actual process. In the following example, this method is applied to the Wetherill separator; it is equally applicable, with less difficulty, to drum, pulley, and belt-type separators, and, with greater difficulty, to wet magnetic concentrators.

Particle paths in a Wetherill separator. A single spherical grain of magnetic substance moving with the uniform velocity v of the feed belt of a Wetherill separator (Fig. 34) is acted upon by a balanced system of forces until it comes within the effective range (wherein magnetic exceeds gravitational force) of the magnetic field. Here it is subject to the resultant of the following forces: (*1*) a magnetic force, $\frac{\mu - 1}{24} D^3 H \frac{\partial H}{\partial z}$ varying in direction and magnitude with position; (*2*) a constant gravitational force $\frac{\pi}{6} D^3 \rho g$; (*3*) a negligible, transient, frictional force which acts only at the time the grain leaves the belt, provided the relative motion has a component parallel to the belt. The path of the grain is completely determined by these forces and the velocity v. The force equation along the co-ordinate axes is given by (see Fig. 16, belt is parallel to x-axis)

$$\text{(a)} \qquad \frac{\pi}{6} D^3 \rho \frac{d^2 z}{dt^2} = \frac{\mu - 1}{24} D^3 H \frac{\partial H}{\partial z} - \frac{\pi}{6} D^3 \rho g = F_z$$

$$\text{(b)} \qquad \frac{\pi}{6} D^3 \rho \frac{d^2 x}{dt^2} = \frac{\mu - 1}{24} D^3 H \frac{\partial H}{\partial x} = F_x \qquad \text{(34)}$$

$$\text{(c)} \qquad \frac{\pi}{6} D^3 \rho \frac{d^2 y}{dt^2} = \frac{\mu - 1}{24} D^3 H \frac{\partial H}{\partial y} = F_y$$

Solution of Eqs. 34 requires a knowledge of H as a function of the co-ordinates; information is generally lacking and difficult to obtain. Nevertheless, it is possible to discuss the form of the solution qualitatively with the aid of certain plausible assumptions. If the particle is symmetrically disposed relative to the length of the collecting pole-piece, F_y may be set equal to zero and Eq. 34(*c*) is solved by $y = 0$. F_x, on the other hand, does not vanish; it represents a force of varying magnitude (Fig. 17) whose direction is parallel or antiparallel to the direction of motion of the feed belt when the grain is located to the left or right of the y-axis, taking RR' as the effective magnetic range. The magnitude of F_x depends upon the field intensity, the inhomogeneity of the field in the X-direction, the permeability, and upon the diameter of the particle. In the event that $F_x = 0$, Eq. 34(*b*) is solved by $x = vt +$ constant, *i.e.*, the projection of the trajectory of the particle in the XY-plane is that of a particle moving in the direction of x with constant velocity v (Fig. 18, curve A). The effect of F_x upon this horizontal motion is an acceleration when the particle is located to the left of the Y-axis, and a deceleration when located to the right (Fig. 18, curve B). When the initial velocity v is great, the effect of F_x upon the horizontal motion is almost negligible (Fig. 18, curve C). The solution of Eq. 34(*a*), giving the projection of the motion in the XZ-plane, is obtained in finite terms only when $H \frac{\partial H}{\partial z}$ is given in extremely simple form; otherwise the solution is given by a convergent infinite series, or by a series of successive approximations. If it is assumed that $H \frac{\partial H}{\partial z} = C$ (constant), Eq. 34(*a*)

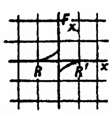

FIG. 17. Variation of the horizontal component of the magnetic force.

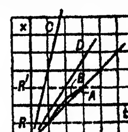

FIG. 18. Projection of particle trajectory in xy-plane.

is solved by $z = \frac{1}{2}\left[\frac{(\mu - 1)C}{4\pi\rho} - g\right] t^2$, *i.e.*, the motion is that of a particle uniformly accelerated (Fig. 19, Curve A). The assumption of a constant F_z is not valid for the fields used in magnetic separators, the Frantz Isodynamic separator (Sec. 19, Art. 22) being the sole exception; in general the product of field strength and inhomogeneity increases as z increases. The effect is to dip the z-t curves more and more toward the Z-axis (Fig. 19, curves B, C, D). The magnitude of this effect may be gaged by comparing solutions obtained by assuming that $H\frac{\partial H}{\partial z}$ varies linearly with z, in which case a solution of the form $z = at^2 + bt^4 + ct^6 + \cdots$ is obtained; and that $H\frac{\partial H}{\partial z}$ varies as z^2, in which case the form of the solution is $z = at^2 + bt^6 + ct^{10} + \cdots$. The shape of the z-t curves also depends on the permeability of the particle, being more steeply inclined as μ increases.

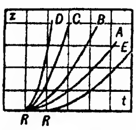

FIG. 19. Projection of particle trajectory in xz-plane.

The trajectory of the particle is obtained analytically by eliminating t between the solutions of Eqs. 34(a) and (b), and graphically by plotting z *versus* x for equal values of t from the curves of Figs. 18 and 19. The resulting curves are shown in Fig. 20. Curve B is the result of eliminating t between curve A of Fig. 18 and curve B of Fig. 19, and curve A results from C of Fig. 18 and D of Fig. 19, from which it appears that the effect of an increase in the value of v is to decrease the steepness of the trajectory; the same effect results from decrease in permeability. The trajectory of the particle is also affected by its vertical position when it comes within the effective magnetic field. Thus if the feed belt were closer to the square pole-piece, the effective magnetic range would be smaller; consequently the z-t curve is simply shifted toward the right (curve E, Fig. 19), it being assumed that the lower initial value of $H\frac{\partial H}{\partial z}$ has negligible effect upon the shape. The resulting trajectory is also shifted toward the right (curve A, Fig. 20).

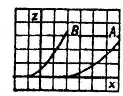

FIG. 20. Trajectory of a particle in Wetherill separator.

Separation of particle elevated by the action of the magnetic force depends upon the interception of its trajectory by the surface of the collecting pole-piece (actually the cross-belt). The factors favoring steeper trajectories and therefore increased probabilities of separation are: increases in permeability, field intensity, inhomogeneity, and particle diameter, and a decrease in speed of feed belt. In practice, inhomogeneity is increased by bringing the wedge-shaped pole-piece closer to the square pole, *i.e.*, by decreasing air gap. This also increases field intensity and in effect brings the particle closer to the collecting pole. When it is desired to increase field intensity alone, the current to the electromagnets is increased. These conditions are opposed by economic requirements; thus, although a zero feed-belt speed insures separation of a magnetic particle placed within the effective magnetic range, capacity requirements necessitate the maximum belt speed compatible with high probability of separation. Similarly infinitely large field intensities are opposed by the economic demand for minimum power consumption.

Removal of idealizing conditions reveals new factors affecting the shape of the trajectory and therefore the probability of separation. If a closely sized mixture of magnetic and nonmagnetic grains is spread over the feed belt in a closely packed single-grain layer, F_z acting on a magnetic particle will be opposed by a frictional force, owing to contact with neighboring nonmagnetic particles, and F_x will be increased by a force resulting from contact with material moving with the belt. Both factors tend to produce a flatter trajectory, and hence to decrease chances of separation. If a closely sized mixture is presented in a closely packed layer two particles deep, a magnetic particle in the bottom layer completely surrounded by nonmagnetic particles is almost completely shielded from the magnetic field, resulting in a decrease of F_z; moreover, its resistance to rise is effectively increased by frictional contact with neighboring particles and by the weight of the overlying nonmagnetic particles. The net effect is a marked decrease in F_z, with consequent flattening of the trajectory and a decrease in probability of separation. The adverse effect of layering may be partially overcome by suitable changes in the factors which tend to steepen the trajectory, *e.g.*, by increasing permeability, field intensity, or inhomogeneity, and by decreasing belt speed. If the particles of a closely packed, single-grain layer are of different sizes, a small magnetic particle surrounded by larger nonmagnetic neighbors is partially shielded from the full action of the magnetic field; hence the value of F_z acting to elevate the particle is decreased. Further decrease is due to the greater distance of the particle from the collecting pole, and to the force resisting passage through the interstice among neighboring particles. When the magnetic particle is small enough to pass through the interstice unopposed, it is small enough to be completely shielded by a contiguous particle; then, as before, F_x is increased by a force resulting from contact with material moving with the belt. The net effect of these additional forces is to flatten the trajectory to such an extent that the probability of separating fine particles is greatly reduced; the probability decreases with increasing size range. There exists, therefore, some CRITICAL SIZE RANGE beyond which the loss of fine magnetic material is too great for economic operation. The critical range is affected by the same factors that affect F_z and F_x; hence increases in permeability, field intensity, and/or inhomogeneity, and decrease in belt speed increase critical size range. If the mixture possesses a long size range, and is presented in the form of a closely packed, multiparticle layer, the adverse effects of shielding and resistance to vertical penetration of the layer by a magnetic particle increase. If the mixture contains a sufficient amount of moisture to impart slight coherence, resistance to exit penetration increases and particle weight is increased by the adhering particles.

Magnetic interaction between magnetic particles is more difficult to assess since it depends upon the geometric arrangement of the magnetic particles. Grouping increases F_z for the group; nonmagnetic material trapped within the grouping reduces the increase in F_z, and the magnetic product

is diluted with nonmagnetic material. The larger the ratio of magnetic to nonmagnetic particles, the greater the probability of levitation as a group, and the greater the chances of entrapment of nonmagnetic particles.

Summary. To separate material of given permeability the maximum usable belt speed depends upon $H \frac{\partial H}{\partial z}$, *i.e.*, upon the field intensity and air gap, increasing as $H \frac{\partial H}{\partial z}$ increases. On the other hand, for a given air gap and field intensity, belt speed increases with the permeability of the material, an upper limit being set by the permeability. Keeping current to electromagnets and permeability constant, belt speed increases with a decrease in air gap; keeping current and belt speed constant, air gap decreases with decrease in permeability; keeping belt speed and air gap constant, current increases with a decrease in permeability. In so far as presentation of feed is concerned, the size range and depth of layer are critical; a broad range requires increase in current, decrease in air gap, decrease in belt speed, or an increase in permeability; the requirements for multiparticle layers are the same. In both cases there exists an upper limit which may not be exceeded if economic recoveries are desired. A decrease in maximum size of feed requires increase in current, decrease in air gap or belt speed, or increase in permeability.

Forces normally acting in magnetic concentrators, in addition to the magnetic force, are gravity, friction, centrifugal, fluid resistance, electrostatic, and capillary. Momentum is of equal importance in determining particle trajectories. Air resistance, electrostatic attraction, and capillary forces are unavoidable; usually they are beyond control and act to decrease the effectiveness of the separation. The air currents created by moving belts, falling material, and the like, and the force required to pull magnetic particles through an air-water interface may be reduced somewhat but not completely eliminated. The nonmagnetic forces that are used deliberately to assist in the separation may act either with or against the magnetic force. When centrifugal force or fluid resistance is the nonmagnetic force, the magnitude and direction of the resultant force can be varied by varying either these or the magnetic force; when gravity or friction is the nonmagnetic force, control lies in the magnetic force alone. When momentum is active in determining the resultant force, it is usually subject to control.

MAGNETIC SEPARATORS

Separators differ greatly according to whether the feed is coarse or fine, wet or dry, and of low, medium, or high permeability. Types have been classified on several bases: (*a*) Intensity of the magnetic field, as low-, medium-, and high-intensity; the same machine often falls in two of the classes and in some cases in all three. (*b*) Medium, in which separation takes place, as wet or dry; some machines fall in both classes. (*c*) Mechanical devices used in the presentation of material to the magnet, as on a belt, pulley, drum, shaking tray, or by free fall through a fluid, etc. (*d*) Mode of disposal of products, as by gravity, cross and longitudinal belts, sprays, scrapers, etc. (*e*) Current characteristics, *i.e.*, alternating- or direct-current separators. (*f*) Nature of the magnetic phenomena utilized, as induced attraction, hysteretic repulsion, coercive-force reaction, etc. (*g*) Motion of magnets, *e.g.*, stationary or moving. (*h*) The classification adopted herein is based on the method used to get the magnetic material onto the collecting surface. When an attempt is made to introduce the feed directly onto the collecting surface, the separator is classified as of HOLDING TYPE; when the collecting surface must attract particles from a feed stream moving in close proximity, as of PICK-UP TYPE.

4. HOLDING-TYPE SEPARATORS

Material is usually fed directly onto the collecting surface, where a component of gravity acts to hold both magnetic and nonmagnetic material. Nonmagnetic material is removed either by flowing water across the collecting surface (in this case usually inclined), a component of gravity aiding, the balance developing an opposing frictional resistance; or by suspension in a fluid; or by transportation by the collecting surface to a region where gravity has no component normal to the surface, discharge being aided by the momentum acquired as a result of such movement. Magnetic material is removed either by mechanical scraping across the collecting surface to a point beyond the action of the magnetic field followed by gravity discharge, or by movement of the material on and with the collecting surface to a point beyond the effective range of the magnetic field where the material discharges by gravity (which may now oppose the magnetic field), momentum aiding.

Drum separators of the holding type consist of rotating horizontal cylinders of nonmagnetic material, ordinarily brass or bronze, surrounding magnet banks conformed to the inner surfaces of the drums. Magnet banks may be either stationary or rotating.

They are built up of individual flat magnets, arranged radially around the drum axis and wound to produce opposite polarities in adjacent poles. Electrical connections are made through a hollow shaft supporting one end of the drum.

Stationary-magnet drum separator (Fig. 21) has a magnet bank fixed to cover between $1/2$ and $2/3$ of the drum circumference as shown. Feed is distributed along the top element of the drum. Magnetic material, under the coaction of the magnetic field and the frictional force exerted on it by the drum surface, moves with the drum so long as the particles remain in the magnetic field. Magnetisation of this moving material persists from the field of one magnet to that of the next; as a result the magnetised particles, which orient themselves along the lines of magnetic force, turn end-for-end in adjusting to the curved lines of force between adjacent poles. In going from one pole to the next nearest pole of like polarity, the magnetised particle executes one complete rotation; thus it travels along the drum surface in its direction of its own rotation a distance $\pi Dn/2$, where D = diameter of particle and n = number of poles. Nonmagnetic material that may have been mechanically held among or under magnetic particles is freed by this winnowing action. The bulk of the nonmagnetic material rolls or slides along the downward-curved downcoming forward face of the drum and falls off as shown, separated from discharged magnetic material by a divider.

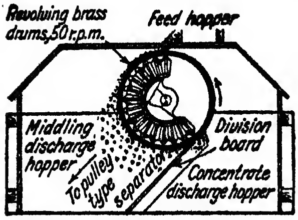

Fig. 21. Drum separator with stationary magnet.

Rotating-magnet separator (Fig. 22) has a full-circle magnet bank *a* which is rotated counter to drum *b* by an independent drive. It requires a take-off roll *c*, of ferromagnetic material, likewise independently rotated. Magnetism is induced in the latter by the main magnet, and its surface is corrugated to accentuate inhomogeneity of field and cause traction toward it from the drum. The magnet rotates much more rapidly than the drum, so that the winnowing travel of magnetized material is not only counter to that of the drum surface, but is more rapid, resulting in a net movement counter to the gravity flow of the nonmagnetic material.

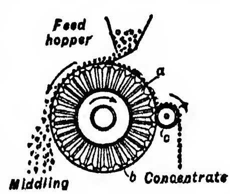

Fig. 22. Drum separator with counter-rotating magnet.

Operation of drum machines. Drums range from 8 to 60 in. in width, 12 to 30 in. in diameter, and are run at peripheral speeds of 150 to 2,000 f.p.m. Power requirements range from 0.25 to 5 hp. for mechanical operation, and from 150 to 2,500 watts for magnet activation. The activation requirement varies with permeability and feed size. At Mt. Hope (*99 J 562*), 6 amp. at 250 v. is used for 1 $1/2$- to 2-in. material, 4.5 amp. for $1/2$- to 1 $1/2$-in., and 3.75 amp. for $1/4$- to $3/4$-in. Feed size ranges from 3-in. to about 100-m. limiting. Fairly close sizing is practiced when concentration is the object; a wider size range is permissible when drum acts as a guard. Spacing of magnets depends on feed size, a closer spacing being used for finer feeds. Capacity varies from about 650 cu. ft. per hr. per ft. of width for the smaller machines at 40 to 50 r.p.m. to about 3,000 cu. ft. per hr. per ft. of width for the larger machines at 25 to 40 r.p.m.; capacity varies with feed size, being considerably smaller on the fine sizes.

Double-drum separator (Fig. 23) is an attempt to make finished concentrate on a drum-type machine. The first drum is run slowly with a strong field in an attempt to make a low-grade concentrate and clean tailing. The second drum (*G*) is fed by centrifugal force with the rough concentrate from the first. It is run at higher speed and with a weaker field; as a result low-grade material is dropped into middling compartment (*M*) and only high-grade concentrate is carried around to be thrown over into hopper (*C*). This machine is intended for finer feed than the single-drum machine, the size recommended by the makers being below 2.5-mm. On such material a capacity of 15 to 20 tons of magnetite ore per hour is claimed on drums with 24-in. face, running the first drum at 40 r.p.m. and the second at 50, drawing 10.5 amp. and 13 amp. respectively. Power required for driving is 0.5 to 0.75 hp.

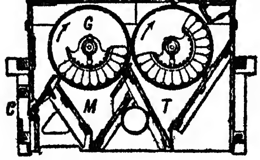

Fig. 23. Double-drum separator.

A double-drum separator (Fig. 24) of local design was used at Witherbee Sherman (*IC 6624*). The magnets were mounted as in the standard type except that 14 were used, the upper 6 being stronger than the lower 8. The upper drum drew 9 amp. at 125 v. while the lower drum took 12 amp. at 125 v. Peripheral speed of drums was 340 f.p.m. Feed to the upper drum was separated into a concentrate and middling; the latter went to the lower drum, where a clean tailing and middling were made. Concentrate assayed 66% Fe (by magnetic determination) and tailing 1.2%. Feed assay was probably between 40 and 52% Fe.

Double-drum separators arranged with one drum above and to one side of the other are used to remove magnetic particles of high reluctance. The upper drum subjects the feebly magnetic particles to an intense magnetic field and thus makes them more susceptible to the second drum, which receives the discharge from the first. This separator has been especially designed for the removal of very fine iron and iron oxide from nonmetallic minerals.

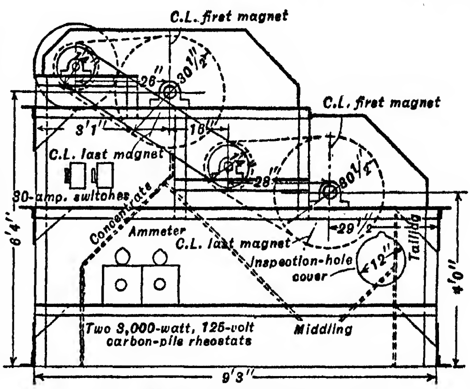

Fig. 24. Mineville double-drum separator.

Performance. Single-drum separators at Witherbee, Sherman Co. (*96 J 959*) were 30-in. diam. by 18-in. face, made of brass, rubber covered. Each contained 16 magnets. They ran at 50 to 56 r.p.m., and were used to treat sized feed $^3/_4$~$^3/_8$-in. and $^3/_8$~$^1/_4$-in. Capacity was about 10 t.p.h. on the finer feeds (*IC 6624*). In one mill treating coarsely crystalline ore, material 2~0.75-in. was also treated on drum machines. They made concentrate assaying about 60 to 65% Fe and a middling assaying about 18% from feeds ranging between 25 and 45% Fe. About 4 amp. at 125 v. was used on the coarse feeds, 7 amp. on finer feeds. From 0.5 to 0.75 hp. was required for driving. One man attended 17 separators of drum and pulley types. At Replogle Steel Co. 2-drum machines with drums 36-in. diam. by 28-in. face with 14 magnets per drum were run at 49 r.p.m.; feed rate was 14.9 t.p.h. Sizing test of feed and products is given in Table 4. Average assays: Feed, 33.4% Fe; concentrate, 62% Fe; tailing, 22.4% Fe. Iron in tailing was mostly hematite. Similar drum machines were used to treat reground middling from belt separators. Sizing test of feed was about the same as given in Table 4. Average assays: Feed, 26.8% Fe; concentrate, 57.4% Fe; tailing, 20.6% Fe (mostly hematite, went to gravity mill). One of the separators in retreatment service had 30×42-in. drums with 27 magnets in the upper drum and 45 in the lower. Average tonnage on retreatment machines was 17 each.

At Mesabi Iron Co. a 30×30-in. drum drawing 7 $^1/_2$ amp. at 110 v. was fed with deslimed <4-m. sand (58.2% water) at the rate of 8.7 t.p.h. Assays (magnetic Fe, %) were: Feed, 36.7; concentrate, 48.2; tailing, 9.5.

At Mt. Hope manganese-steel shells were substituted for brass on the drum. These shells, $^1/_8$-in. thick, lasted four times as long as the brass drums and the cost per ton was one-quarter as much. Roche substituted pure rubber bands for manganese steel at the Richard mine and found that the life of $^3/_{16}$-in. rubber was three times that of the steel, with a further saving in installation time and power consumption. Roche used four bands on a 24-in. drum and found that the bands could be readily snapped on drums by merely lifting one end of the shaft out of its bearings.

Table 4. Sizing tests of feed and products of drum-type separators, Replogle Steel Co.

Screen, mesh	Weights, per cent.		
	Feed	Concentrate	Tailing
20	14.6	15.5	10.2
40	37.5	50.1	37.4
60	30.4	14.5	23.7
80	7.6	3.8	5.1
100	3.1	1.4	3.4
<100	6.8	14.8	20.1

Wenstrom separator is a drum-type machine for coarse feeds, used in Swedish mills in the same position as the drum separator. The flanged drum is built up of alternate lamellae of wood and soft iron. The electromagnet is circular in cross-section but has annular grooves containing the winding and is wound in such a way that alternate poles have opposite polarity. It is placed eccentrically within the drum. Projections from the inner face of the iron drum lamellae are so arranged that those of alternate lamellae approach opposite poles of the magnet during their downward travel and are thus magnetized by induction; during their upward travel they are out of the effective field of the primary magnet and lose their induced magnetism. The effect is somewhat the same as in the drum machine, except that the magnetic agitation of pulp on the drum is not so active in the Wenstrom machine. A 30×24-in. drum is said to require about 15 amp. at 110 v. and to treat from 5 to 10 tons of 1- to 2-in. magnetite ore per hour at 30 r.p.m.

Use. The magnetic drum is essentially a low-intensity roughing machine. In concentrating iron ores it is used to make a clean concentrate and a middling for retreatment. In treating industrial minerals it is used to remove iron and iron-bearing impurities, also to remove magnetite prior to a high-intensity separation of two nonmetallic products. Drums are also used to remove tramp iron from the feed to crushers, grinders, etc.

Magnetic-pulley separators (Fig. 25) consist essentially of a belt conveyor with a magnetic head pulley, a feeder to deliver a thin layer on the carrying portion of the belt, and a divided receiving chute to take the two products. The magnetic pulley consists of a number of circular, horseshoe electromagnets, cast integrally or in sections, of highly permeable, homogeneous, electric steel (usually dynamo steel) properly annealed, the

whole assembled on a common shaft. The magnet is energized by direct current, and is so wound or assembled that adjacent poles are of like polarity, electrical connection being made through slip rings on the pulley shaft. As the ore passes over the pulley, the nonmagnetic portion discharges by gravity or acquired momentum in a parabolic path; the magnetic portion is held by the magnet against the belt until it is carried out of the field at the underside of the pulley, where it is discharged by gravity.

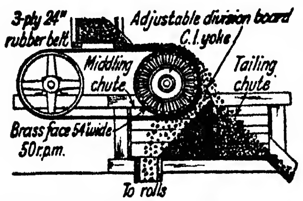

FIG. 25. Magnetic-pulley separator.

Pulley diameters range from 12 to 30 in., belt widths from 12 to 90 in. Belt speed is 125 to 500 f.p.m. CAPACITY varies with field strength and feed size; manufacturers' average figures range from about 800 to 1,850 cu. ft. per hr. per ft. of belt width. POWER required for mechanical operation increases with belt width and ranges from about 1/2 hp. for a 12×12-in. pulley to 10 hp. for a 30×60-in.; for magnet activation, power increases with pulley diameter and width; average manufacturers' figures are 415 watts for a 12×12-in. pulley, 3,080 watts for a 24×48-in., and 7,850 watts for a 48×60 in.

Performance. At WITHERBEE, SHERMAN Co. (*96 J 959*) 20-in. pulley machines treated 2~0.75-in. crude ore at the rate of 300 tons per machine per day and also treated the sized middling from drum machines. Each pulley had 25 magnets and drew about 25 amp. at 125 v. Feed was practically dry. Pulley speed, 40 to 50 r.p.m., giving a belt speed of 250 to 320 f.p.m. Feed assayed 35% Fe and tailing 6 to 8%. Rough concentrate was sent to drum machines. Pulley machines were also used to rough out tailing on drum rejects sized to 2~1 1/4-in., 1 1/4~3/4-in., 3/4~1/2-in., and 1/2~5/16-in. Tailing averaged 4.2% Fe on the 2~1 1/4-in. and 1.85% Fe on the 1/2~5/16-in. material. One man attended 17 separators of the drum and pulley types.

At INTERNATIONAL NICKEL Co. a capacity of 75 t.p.h. is reported for a 36×36-in. pulley cobbing nickeliferous pyrrhotite from a low-grade nickel ore crushed to <3 1/2-in. At CLIMAX 1,000 t.p.h. is reported for a pulley with a 54-in. belt, removing tramp iron from cone feed.

Uses. Magnetic pulleys are used to remove tramp iron from the feed to crushers and grinding machines, to remove magnetic contaminants, usually iron, from finished nonmetallic products, and to concentrate minerals from their associated gangue. In the latter capacity they function best on coarse or lump material, although material as fine as 48- or 65-m. has been handled. Pulleys produce clean tailing and a concentrate requiring further treatment, hence they are used in magnetite milling to retreat reject from drum machines, producing a discardable tailing and thus reducing load on regrind machines.

Drum-pulley machine (Fig. 26) is a combination of the two machines just described, designed to economize floor space and headroom and deliver, from one machine, finished concentrate and tailing, and middling for retreatment. Construction and operation of each part are the same as in the separate machines.

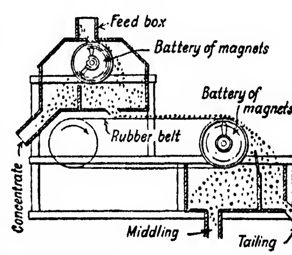

FIG. 26. Drum-pulley machine.

Induced-roll separator (Fig. 27) consists essentially of a number of high-intensity drums in series. Transversely laminated rolls A made of alternate sheets of a highly permeable material such as soft iron and of a nonmagnetic material such as zinc are located between the poles C of an electromagnet and the induced poles B of a bridge-bar or keeper, and are rotated in the directions indicated. Keeper poles B are accurately machined to conform to the rolls, which are placed in close proximity to them to minimize air gap and consequently the reluctance of the magnetic circuit. Primary poles C are machined as shown, located with apices substantially in the 45° diametral planes of the corresponding rolls, with an adjustable gap. The curvilinear contour below the apex is said to conform to the trajectory of the nonmagnetic material delivered from the roll. The primary poles induce, over a short length of arc of each lamination of the corresponding roll, a magnetic pole of opposite polarity, the lines of force being more concentrated over the arc than over the primary pole; the keeper provides the magnetic circuit with a magnetic conductor of low resistance and thus insures maximum concentration of flux lines over the roll surface. Air gaps are adjusted so that field intensity is progressively higher as the material proceeds from top to bottom; on the roughing roll A_1, the field may also be weakened by not bringing the primary pole piece C to as sharp an apex as for the other rolls and by not providing a keeper. Feed is introduced from a hopper feeder onto the upper surface of the roughing roll at the same rate as the peripheral speed thereof. The less susceptible portion is discharged from the brow of the roll in a parabolic trajectory determined by gravity and acquired momentum; the more susceptible material is attracted to the magnetic lamina-

tions and there held until, by rotation of the holding lamina out of the magnetic field, attractive force is reduced, when discharge takes place by gravity. An adjustable knife edge D_1 is set to make a cut at any desired point of the discharge stream. Magnetic fractions fall directly into discharge spouts; the less magnetic fractions are treated further on lower rolls. Number of rolls depends upon the feed; separators with seven rolls are reported. A roughing roll is indicated when the separator has an odd number of rolls; it is optional, used for treating materials containing a small amount of abraded iron or other strongly magnetic material which must be removed before material reaches the high-intensity rolls, since these would otherwise be fouled. A duplex-type machine consists of two standard separators placed back to back, with one coil serving four instead of two poles.

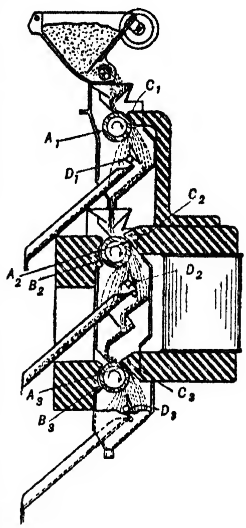

FIG. 27. Stearns induced-roll separator.

Roll width ranges from 4- to 90-in.; diameter usually about 5-in.; speed is 100 to 200 r.p.m. POWER required for driving ranges from 1/8 to 15 hp.; for energizing the magnets from 100 to 22,000 watts is required, depending on roll width, number of rolls, and material to be treated. CAPACITY depends upon the permeability and size of material treated, width of rolls, number and speed of rolls, and the completeness of separation required; it is estimated at about 10 times that of the high-intensity pick-up separators (*Bul 425 USBM 198*). CAPACITIES of 2 t.p.h. for four separations and of 3 t.p.h. for five separations, requiring respectively 100 and 300 watt-hr. per ton, are reported.

Uses. This separator is used primarily for the separation of weakly magnetic materials, to produce one or more concentrates, one or more middlings, and tailing. Feed must be clean (*i.e.*, washed), dry, finer than about 8-m. but not finer than about 200-m.; the lower limit is imposed because of dusting and sticking to the roll surface.

Performance. Successful use in the following services is reported: biotite, garnet, tourmaline, and muscovite from run-of-mine pegmatite (*IMR 262*); tourmaline and biotite from feldspar (*17 MM 441*); iron from feldspar (*IC 6488*); limonite after roasting from barite (*IMR 106*); abraded iron, pyrite, magnetite, limonite, garnet, biotite, and some muscovite from kyanite (*138 J 45*); magnetite and muscovite from nepheline syenite (*18 Glass Ind. 204*). At the WARWICK mine the ore containing 45% ilmenite and 20% apatite, together with micaceous minerals, is ground, deslimed, dried, and separated into a salable magnetic ilmenite, a weakly magnetic micaceous material, and a salable nonmagnetic apatite concentrate (*43 CME 24*). Other reported applications are cleaning gangue from manganese ores, separation of wolframite from tin and silica, and of molybdenite from scheelite. At COLONIAL SALT CO. (*Bul 425 USBM 303*), iron specks introduced into salt by contact with iron vessels are removed from the hot, dry material by two-roll machines fed at the rate of 3 t.p.h. At BRIDGETON SAND CO. (*ibid.*) a white sand analyzing 99% SiO_2, 0.1% iron oxide, and some ilmenite and clay is washed, piled, drained, dried, and then screened on a 22-m. screen; the warm undersize goes to a 3-roll separator which makes a product containing 0.018 to 0.02% Fe. Cost of the magnetic operation is 15¢ per ton. At MAGNET COVE mill orthoclase feldspar carrying about 5% TiO_2 in the form of rutile, brookite and ilmenite, and some iron-bearing minerals, such as limonite, magnetite, goethite, etc., is first concentrated by tabling. Table concentrates are then given both an oxidizing and reducing roast which cracks fine particles of iron from the surface of the titanium crystals. The cool product is sized into five fractions, *viz.*, >30-, 30~40-, 40~55-, 55~70-, and <70-m, then the three finer fractions are each passed through a low-intensity roll which makes a magnetic product assaying 6% TiO_2 and a tailing which passes through 3 @ 3-roll separators in series. The composite assay of the magnetic product of the first two separators is 60% TiO_2, the assay of the third 80% TiO_2, and of the nonmagnetic 93% TiO_2.

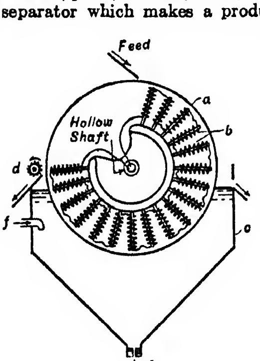

FIG. 28. Wet drum cobber.

Wet drum cobber (Fig. 28) comprises a standard rotating brass drum *a*, with stationary magnets *b* extending through about 245° of arc, submerged to approximately 1/3 of its diameter in a spitzkasten *c*. Wet pulp is fed at the top of the drum in the direction of rotation; some of the nonmagnetic portion is washed off the drum by the feed water, the balance is discharged by gravity under water in the spitzkasten; the magnetic portion, held to the drum surface, is carried out of the water on the rising side of the drum and is removed by a counter-rotating longitudinally ribbed induction roller *d*. Sand tailing discharges through spigot *e*; slimes are overflowed with water introduced at *f*. Drum is 36 in. diam., 6 in. wide, and is rotated 40 r.p.m.; the take-off roller runs at 400 r.p.m. The machine is said to work best in the range from 8- to 100-m., but can treat sizes up to 1/2-in. (*Bul 425 USBM 301*).

Roche wet belt machine (Fig. 29) consists of an endless rubber vanner belt *a*, 30 in. wide, 2-ply with 2-in. flanges, set on a slope of 10 to 80°, usually 30°; and a battery of 20 electromagnets 30 in. long, spaced 3 in. center to center, having alternating poles of opposite polarity, enclosed in a properly ventilated, waterproof copper box *b*, all set underneath the upper run of the belt as shown. Feed is introduced at *f;* the magnetic portion, held against the belt by the action of the magnets, is carried up slope against a stream of wash water supplied through spray pipes *c;* the nonmagnetic material, acted on by wash water and gravity, flows downslope and discharges over the tail roller. Washing of concentrate is aided by the winnowing motion caused by the alternating polarity of the magnet poles. Concentrate is discharged by immersion of the belt in water box *d*, aided by spray *e*.

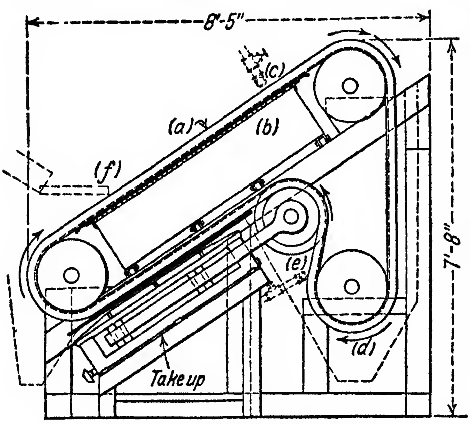

FIG. 29. Roche wet belt separator.

Maximum SIZE OF FEED is 1/4-in. but the best results are obtained with material passing 1/8-in. or 1/16-in. screen. Current supply should be up to 20 amp. at 125 v. One hp. is required for running a 2-belt unit. Belt SPEED is 200 f.p.m. Roche (*115 J 971*) states the CAPACITY on magnetite ore to be 3 t.p.h. per ft. of belt width with a total water consumption of 2 g.p.m. per in. of belt width. CURRENT draft is 5 to 10 amp. at 125 v. Table 5 gives comparative results obtained by this machine and a dry belt-type machine treating ore from the RICHARD MINE.

Table 5. Comparison of concentrate made by Roche wet separator and dry belt separator (*a*)

Screen size, mesh	Belt separator, per cent.		Roche separator, per cent.	
	Weight	Fe	Weight	Fe

Total.....	100	56.56	100.00	63.25

a Feed to both machines all through 8-m. (0.084-in.) screen and on 300-m.; assay, 48% magnetic Fe. Dry belt machine: tailing, 17.93% magnetic Fe; ratio of concentration, 1.28; recovery, 91.8%. Roche machine: tailing, 2.19% magnetic iron; ratio of concentration, 1.33; recovery, 98.9%.

Performance. At the SCRUB OAK plant (*134 J 241, 273*) ore containing 33% Fe, of which 18% was nonmagnetic martite, 0.075% P, and 36% SiO_2, was crushed through 6-m., concentrated by gravity, and the gravity tailing treated as follows: 6 @ 36-in. separators fed at 16.5 t.p.h., run at 200 f.p.m., drawing 14 amp. at 125 v. produced a primary rough concentrate assaying 45% Fe, and a finished tailing containing 1.2% Fe, from a feed assaying 24.6% Fe; rough concentrate went to 6 @ 36-in. primary finishing machines fed at 11 t.p.h., run at 200 f.p.m., drawing 6 amp. at 125 v. (current decreased to increase grade), making a finished concentrate of 60% Fe and a middling of 30% Fe, which was reground in a rod mill, the discharge of which went to four secondary roughers making finished tailing assaying 1.2% Fe and a secondary rough concentrate containing 45% Fe; this was cleaned by four finishing machines making finished concentrate (60% Fe) and a 30% middling which was returned to the rod mill.

Magnetic log washer (Fig. 30). As originally designed, this machine was similar to the ordinary two-log washer (Sec. 10, Art. 4) but had, additionally, a bank of primary magnets underneath the tank as shown in Fig. 30. In the later design, similar to that of an Akins classifier (Sec. 8, Art. 3), the logs were replaced by two helical-screw conveyors made from copper-ribbon spirals which form a four-thread worm of relatively long pitch. Ore pulp is fed into the trough about one-fourth the way from its lower end; the magnetic portion, usually of higher density, under the combined action of gravity and magnetic attraction, falls to the bottom of the trough, along which it is worked uphill by conveyor action until it is forced over the top end of the trough; the nonmagnetic portion is kept in suspension by water currents and flows over a tailing weir. Concentrate is washed by sprays directed at the point where concentrate emerges from the pulp.

Use. This is essentially a slime machine, not suited to treatment of feed coarser than 48-m.; treatment increases in efficiency as the feed is finer. All >48-m. material goes into the concentrate, with resulting lowering of grade.

Performance. Machines installed by MESABI IRON Co., 14 ft. long and 2 ft. wide, with two spirals per tank, treated <150-m. feed containing about 35% magnetic Fe at the rate of 50 to 75 tons per

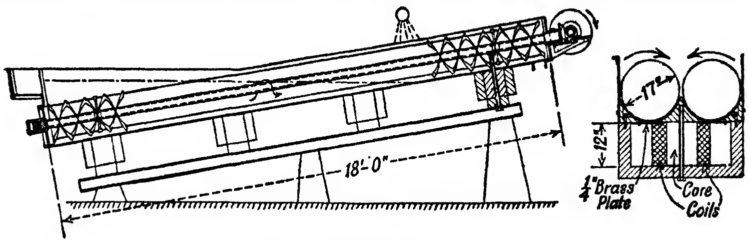

FIG. 30. Magnetic log washer.

24 hr. and produced 65% concentrate and a tailing containing from 1 to 2% magnetic iron. The machines for the final installation at Mesabi were 18 ft. long and 6 ft. wide, equipped with four spirals; produced from 50 to 125 tons of concentrate per 24 hr., the amount depending on the difficulty experienced in washing concentrate. W. G. Swart stated that the machine required about 0.25 hp. for excitation and the same for mechanical operation and that it recovered 95 to 98 per cent. of the magnetic iron fed. Character of concentrate depended upon the extent to which mineral was freed, fineness of grinding, and amount of washing. With grinding fine enough to permit gangue to be kept in suspension, and to free mineral with substantial completeness, concentrate assaying 65 to 70% Fe as magnetite was readily made. Wear with fine feed was negligible.

Frantz Ferro-filter (Fig. 31). Pulp is flowed through a tube containing a set of screens *A* magnetized by an electromagnet *B;* in this manner a magnetic particle repeatedly passes close to the magnetic edges of the screens until it is finally acted upon by a magnetic force sufficiently great to overcome the viscous drag; it is held at the edge until screens are demagnetized. The screens, made from steel of high permeability, are stacked between two spiders *D* and centrally located by means of a center tube *C*. The material to be separated is passed through the screens, either by gravity feed from above or by forced feed from below; the cleaned product passes out either through a discharge pipe in the bottom or over a discharge lip at the top. Pulp level is regulated by a discharge valve operated by float *E*. The separator may also be equipped with a magnetic safety valve *F*, made of magnetic tubing, which falls and closes the discharge in case of current failure, thus preventing contamination of cleaned product.

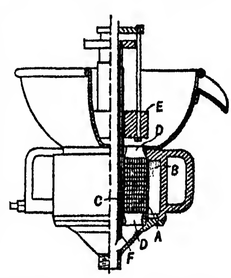

FIG. 31. Frantz Ferro-filter.

Sizes are rated to handle from 50 to 2,000 g.p.h., with different screen openings; lineal feet of screen collecting edges ranges from 260 to 5,000 ft. POWER requirements range from 115 to 275 watts. In a recently reported model, screens were made of a permanent magnetic material. Operating cost averages between 2 and 4¢ per ton.

Use. Removal of magnetic impurities from slurries, slips, glazes, enamels, lubricating oils, etc. Particles of ilmenite as small as 1-μ may be removed (*45 #5 CME 274*). At LENOX, INC. (*425 Bul USBM 292*), ceramic body composed of clay, flint, and feldspar, weighing 31.25 oz. per pint (67° Baume), and of such viscosity that 1 lb. of slip flows through a 3/8-in. opening in 1 hr., is cleaned of abraded iron by large Ferro-filters having a capacity of 1,000 lb. per hr.

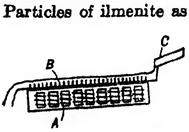

FIG. 32. Trough separator.

Magnetic trough separator (Fig. 32) consists of a magnet battery *A*, housed in a waterproof copper casing, over which is placed a removable tray, having the bottom studded with rectangular auxiliary pole-pieces *B*, appropriately staggered. Pulp fed from a pipe or launder *C* flows downhill and discharges into a suitable receiver; during its run it is subject to the magnetic field induced in the auxiliary poles, magnetic contaminants being attracted and held thereto. This machine is used primarily to remove small amounts of magnetic material from clay slip and the like.

5. PICK-UP SEPARATORS

With this type, feed does not come into direct contact with the collecting surface but is conveyed through the magnetic field by suitable means and therein magnetic particles

are attracted, gravity usually opposing, and are moved through a short distance to a moving collecting surface, which then transports them to a point beyond the magnetic field, where they are discharged by the action of gravity, scrapers, sprays, etc. Nonmagnetic material follows the path of the feed means and is discharged by gravity, momentum aiding, at a suitable point. With wet machines of this type, owing to eddy currents, some nonmagnetic material does come in contact with the collecting surface and is mechanically entrained. Except for materials of high permeability, the ratio of magnetic to gravitational force required to effect separation is greater for this type than for the holding type (p. 15), since the range of the effective magnetic force must be greater.

Belt separator (Fig. 33) consists essentially of a feed belt *b* which carries material into the magnetic field of a battery of d-c. electromagnets *c*, and a take-off belt *d*, running directly under the magnets, which removes attracted magnetic particles. A suitable feeder *a* regulates feed to belt *b*. The battery consists of 8 to 12 magnets wound so that poles alternate in polarity. In one variant the pole-pieces are arranged in herringbone pattern to produce vibration of belt *d*, thus assisting in cleaning. As material comes into the magnetic field the magnetic portion is lifted to the underside of belt *d*, which runs at a higher speed than belt *b*; lifted material is carried forward by friction against *d*. Magnetic particles, aligning with the lines of force, form depending loops, which break and reform as the belt carries material forward; this enables weakly magnetic middling and entrained nonmagnetic material to be dislodged and fall into hopper *M*. Strongly magnetic material is carried forward until it passes out of the field and is discharged into hopper *c*. Nonmagnetic material remaining on the feed belt is discharged over the head pulley, usually into the same hopper as the middling.

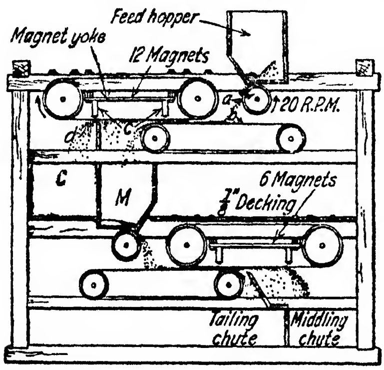

Fig. 33. Belt separator, series type.

This low-intensity machine is used primarily in treating dry sized ores ground finer than 1/2-in., and containing a strongly magnetic mineral.

Usual belt speeds are 100 to 250 f.p.m. for the feed belt and 200 to 400 f.p.m. for the take-off belt, the lower speeds corresponding to the more weakly-magnetic material, such, for instance, as magnetite middling, and coarser sizes. In treating magnetite ore passing 1/4-in. screen, the current requirement for a 12-pole machine is from 4 amp. at 250 v. when lifting concentrate, to 8 to 10 amp. when lifting middling. The machine shown in Fig. 33 is a 2-deck machine of the series type in which middling from the first belt is retreated on a second belt that makes a true middling and a tailing that can be rejected.

In the 2-deck parallel machine, used for fine material that does not contain suffisufficient middling to justify regrinding and retreatment, clean concentrate and finished tailing are made on each deck, and the use of multiple decks is resorted to only in order to increase capacity per unit of floor space. Where both series and parallel types are used in a mill, as at Witherbee, Sherman Co., the series type is used on coarser feeds, say >1/16-in., and the parallel type on the <1/16-in. material. Usual belt widths are between 18 and 30 in. Capacity of a 24-in. machine on <1/4-in. crude magnetite ore is 20 to 25 t.p.h.; Roche (*115 J 972*) gives the capacity on magnetite ores crushed to pass 8-m. as 1 long ton per ft. of belt width per hour but this is undoubtedly low. Capacity varies nearly in proportion to diameter of feed within the range of sizes treatable. Capacity is increased and grade of products is bettered if feed is closely sized. At Mt. Hope (*99 J 563*) the sizes treated are: 5/16~3/16-in., 3/16~1/8-in., 1/8~1/16-in. and <1/16-in. At Reploglе Steel Co. double-deck separators are of the parallel type, with 26-in. 2-ply belts and 10 magnets per deck. Speed of feed belts is 209 f.p.m.; magnet belts, 335 f.p.m. Average feed rate, 15 t.p.h. Sizing tests of feed and products are given in Table 6. Average assays: Feed, 31.4% Fe; concentrate, 61.1% Fe; tailing (middling), 27.0% Fe. Iron in tailing is mostly hematite.

Table 6. Sizing tests of feed and products of belt-type separators at Replogle Steel Co.

Screen	Coarse feed, weight, %			Fine feed, weight, %		
	Feed	Concentrate	Tailing	Feed	Concentrate	Tailing
1/8-in.	10.3	....	....	....	....	....
10-m.	8.0	25.6	33.4	....	....	....
20	42.4	31.8	44.9	....	....	....
40	20.3	28.0	11.8	33.0	26.6	32.9
60	8.1	6.8	5.5	27.8	48.2	40.0
80	3.3	2.0	1.1	10.7	4.4	8.1
100	1.8	1.5	0.5	5.9	4.4	5.8
<100	5.8	4.4	2.7	22.6	16.4	13.2

The same-sized separators at the same belt speeds are used to treat <20-m. product at the rate of 10 t.p.h. Sizing tests of feed and products are given in Table 6. Average assays: Feed, 32.7% Fe; concentrate, 59.1% Fe; tailing, 19.9% Fe (hematite; to gravity mill).

Wetherill separator (Fig. 34) consists essentially of a feed belt *c*, which carries material through convergent magnetic fields produced between flat and wedge-shaped pole-pieces, and a cross belt *d* for removal of concentrate. Both magnets are of the horseshoe type, energized by regulated direct current and wound so that opposite poles are of opposite polarity. The lower flat poles *a* are fixed, the upper wedge-shaped poles *b* may be raised or lowered to give an interpole distance of about 1 $^1/_4$- to $^3/_8$-in. The cross belt runs over a series of two or three pulleys and directly under the upper pole in a direction at right angles to the feed belt. Magnetic particles lifted toward the upper pole come in contact with the cross belt and, owing to friction, are carried off toward the front of the pole, which is horn-shaped to reduce field intensity and thus facilitate discharge. A feeder located near the tail pulley of the feed conveyor regulates feed thereto; tailing is discharged over the head pulley. The action of this separator is discussed on p. 13.

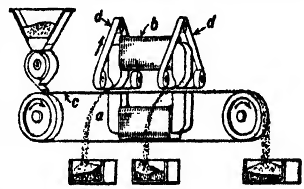

Fig. 34. Wetherill magnetic separator.

This machine is made with one, two, three, or four pairs of poles and with feed-belt widths of 6- to 18-in. Table 7 gives manufacturers' data on various mill sizes for machines with 18-in. pole widths. Current regulation of each pair of electromagnets is made with a rheostat, an ammeter indicating change. Speed of feed and cross belts is adjustable.

Use. The Wetherill, being a high-intensity machine, is used primarily for the separation of weakly magnetic minerals and of mixtures of minerals whose difference in permeability is small.

Effect of adjustments. Current strength varies the strength of the magnetic field and consequently, if the pole distance remains constant, the character and amount of products lifted from the feed belt. Too great current strength causes concentrate to cling under the upper poles and fail to discharge uniformly, with the result that clusters of concentrate build up and are scraped off by the feed belt or crowd material off the feed belt. The current drawn varies from about 5 amp. on the first magnet of a 6-pole (3-magnet) machine to 35 amp. on the last magnet. Variation in pole distance is an important adjustment. If the pole distance is too great, current strength must be increased in order to make the desired recovery and difficulty in discharging concentrate results, as explained above. With too small pole distance the cross stream of concentrate brushes gangue off the feed belt into the concentrate receiver and thereby lowers the grade of concentrate. Pole distance depends upon the permeability of the concentrate and upon the size of feed particles. It may be as great as 1 in. plus the thickness of the feed belt (usually $^1/_4$ in.) on coarse material of relatively high permeability, whereas it may need to be as small as $^1/_8$ in. if the permeability is low and the feed fine. Thickness of feed belt is preferably less than $^1/_4$-in. if the concentrate is very feebly magnetic; $^1/_8$-in. is, however, the practical minimum. The take-off belt should be and is made as thin as possible, usually about $^1/_{32}$ in. thick. Speed of belts affects capacity and recovery. The feed belt is run as rapidly as possible, in order to make capacity as large as possible, but if ore is fine, dusting limits the speed to between 200 and 300 f.p.m., while on coarser material a limit is imposed by the inability of the magnetic field to overcome the momentum of the particle. From this point of view, of course, the speed for feebly magnetic materials must be least and feed must be fairly uniform in size, whereas greater speed and less uniformity in feed size are allowable with more permeable substances. Effect of size of feed on speed is shown in Table 8. The usual speed of the feed belt is from 50 to 100 f.p.m. on feebly magnetic materials and from 100 to 300 f.p.m. with material of medium permeability. Width of

Table 7. Sizes of Wetherill separators

8 *a*	20,000	30,000	60,000	7,000	3

a A fourth magnet is wound for 100,000 ampere turns.

FEED BELT also affects capacity, but is practically limited to 18 in. because of the fact that with greater width the mass of material on the take-off belt is so great that it scrapes gangue off the feed belt unless the pole distance is made impossibly great. Ratio of concentration affects width of feed belt, a low ratio with the correspondingly great bulk of concentrate requiring a narrower belt than a high ratio. SPEED OF TAKE-OFF BELT is limited by the kind of material removed and the size of particles. It may be higher with strongly than with weakly magnetic material and higher with fine than coarse particles.

a The 36 machines of Cols. 1 and 2 are arranged in twelve similar groups, each consisting of one primary separator (Col. 1) and two final separators (Col. 2). Both poles of the primaries and the first two poles of the final separators produce franklinite for shipment. The last two poles of the final separators produce a mixed low-grade product, also for shipment. Tailings from each group constitute feed to tables for willemite-calcite separation (see Sec. 2, Fig. 106).

b Feed is composite of new feed and reground middlings from separators in Cols. 3 to 7.

c These machines make a franklinite concentrate for shipment, middlings for regrind, and a tailing which constitutes feed to jigs for willemite-calcite separation (see Sec. 2, Fig. 106).

Speed of take-off belt is the limiting factor in the capacity of a machine when the ratio of concentration is low, while speed of feed belt limits when ratio is high. Young (*106 J 868*) recommends not more than 50 to 100 lb. per hr. per cross belt for a 6-in. machine. Capacity on wolframite-cassiterite ore is as low as 0.75 ton per 24 hr. on account of fineness and necessity for clean products (*120 P 379*). The feed must be perfectly dry in order to permit free movement between particles and not too fine or slime will stick to the feed belt.

Performance. At NEW JERSEY ZINC Co., Franklin mill, 6-pole 18-in. Wetherill-Rowand machines (Fig. 35) treat an ore containing franklinite, willemite, zincite, and calcite and make franklinite as

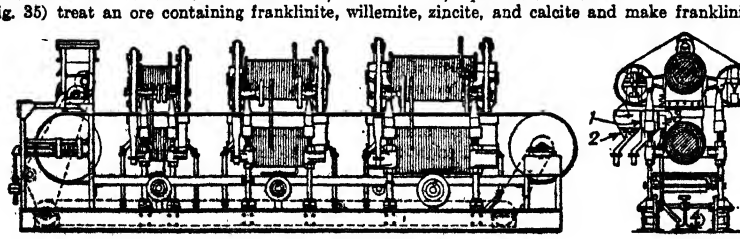

FIG. 35. Wetherill-Rowand separator.

concentrate. Two or more products are taken from each cross belt by means of the hoppers (1), (2), the most highly magnetic material being thrown farthest. Gangue swept off falls into (3) and

thence by conveyor (4) back to the feed end. Adjustments are shown in Table 8. An approximate mineralogical analysis of the products of one separator is shown in Table 9. At ALGONQUIN MINE, Philipsburg, Mont. (*116 J 181*), pyrolusite and psilomelane occur in a siliceous gangue. A Wetherill 6-pole machine (see Table 7) took 5~10-m. feed. Speed of feed belt, 95 f.p.m.; take-off belt, 250 f.p.m. Concentrate from the first pole contained 10% Fe and was rejected; other poles delivered concentrate assaying 75 to 80% MnO_2; tailing assayed about 10% MnO_2. A second machine of the same type treated 10~100-m. material and made similar products except that the product of the first pole contained about 20% Fe. At S. AND M. SYNDICATE (*120 P 379*), feed was gravity concentrate containing wolframite, bismuthinite, and cassiterite; a four-pole separator with weak current on the first two poles removed magnetite and pyrrhotite; later poles with strong current removed a wolframite

concentrate assaying 73% WO_3, 0.7% Sn, and a trace of Bi; nonmagnetic product contained 63% Sn, 4% Bi, and upward of 2% WO_3, depending on the amount of scheelite (nonmagnetic) present. Recoveries were about 97% WO_3 and 99% Sn.

At AIN BARBAR, Algeria (*351 RIM 373*), ore consisting of chalcopyrite, ferruginous blende, galena, quartz, and calcite, crushed through 3-mm. and roasted to increase permeability of chalcopyrite, was separated into six size fractions down to 80-m. Each fraction was treated on a 4-pole Wetherill drawing 35 amp. at 60 v. First pole removed all pyrite and some chalcopyrite, second pole most of chalcopyrite containing some blende, third pole mixed products including some chalcopyrite, fourth pole a mixture containing everything except pyrite and a tailing of blende, galena, and gangue. Middlings were reground, reroasted, and again separated magnetically. Copper concentrate assayed 18% Cu and represented a recovery of 82%; zinc concentrate 40% Zn with an 87% recovery.

At the TROUT mill, ore containing 30 to 35% Mn and 25 to 30% SiO_2 (Philipsburg ore) is roll crushed, and screened into 6~14-m. and <14-m. fractions. Each fraction goes to a separator with three magnets wound respectively with 30,000, 60,000 and 100,000 ampere-turns. Concentrate assays 70% MnO_2, 0.2% P, 6% Fe, and about 10% SiO_2. At EAST POOL AND AGAR, LTD., Cornwall (*2 MQE 341*), gravity concentrates from an ore containing cassiterite, wolframite, arsenopyrite, and chalcopyrite, finely disseminated in a siliceous gangue, were roasted to remove arsenic, increase permeability of iron minerals, and dry the feed for magnetic concentration. The four-pole separators used had 15-in. × 8-ft. feed belts run at 73.7 f.p.m.; cross belts were 2.5 in. wide, magnets were energized by a 4 1/2-kw. motor generator. Four products were made, an iron concentrate containing 5 to 10% Sn, a tinny iron, a tinny wolfram, and a sale-tin concentrate. At the Mill City plants of NEVADA-MASSACHUSETTS Co. (*112 A 833*), ore containing scheelite disseminated in a gangue of garnet, quartz, epidote, calcite, and pyrite is concentrated by gravity methods, followed by flotation to give a concentrate containing 50% scheelite, with pyrite, garnet, and tramp iron. The dried concentrate is passed through a six-pole separator; the magnets are wound for 30,000, 60,000, and 100,000 ampere-turns and draw 1.4, 11.4, and 21.4 amp. at 120 v. Tramp iron is removed at the first pole, altered pyrite at the second and third poles, and the bulk of the garnet at the remaining poles. The nonmagnetic concentrate is given a magnetizing roast and is passed through a second six-pole separator, similarly wound but drawing 3.5, 11.4, and 21.4 amp. at 120 v. Pyrrhotite is removed at the first pole, the remaining poles remove a middling of iron minerals, garnet, and scheelite for retreatment. The nonmagnetic concentrate is again roasted and passed through a Dings M-2 separator, resulting in a product assaying 73.6% WO_3, 20.6% CaO, 2.3% SiO_2, 1.3% Fe, 1.2% Al_2O_3, 0.3% MnO, 0.3% Mo, 0.4% S, and P and As <0.02%. At MOONLIGHT, pyrolusite and psilomelane are separated from dolomite, limestone, and quartz by 3 @ 6-pole separators, two of which are fed 10~20-m. material and the other 20~48-m. Speed of

feed belt, 75 f.p.m.; take-off belt, 300 f.p.m. Feed contains 1.5% moisture and assays 47% MnO_2; tailing, middling, and concentrate assay 15, 60, and 71% MnO_2, respectively.

At Sakiet-Sidi-Youssef, Algeria (*97 J 899*), a modification of the Wetherill machine (Fig. 36) was used to treat roasted blende-pyrite concentrate, assaying about 30% Zn before roasting. Belt *a* (14-in.) traveling at 175 f.p.m. carried the feed stream between two sets of powerful primary electromagnets *b* and *c*, with wedge-shaped pole-pieces, the upper pole of *b* and both poles of *c* being enclosed in metallic drums. The first magnet drew 7 to 9 amp. at 40 v. and the second 10 to 12 amp. at the same voltage. Magnetic material drawn up against the first drum was thrown onto cross belt *d* and thence discharged. At the second magnet, magnetic material clung to the upper drum until it reached a weaker part of the field, where it left under the combined action of gravity and momentum. Adjustable knife edges divided discharge into three products. Two sizes were treated on separate machines, *viz.:* 3~1-mm. and <1-mm. Each separator made four products: (*1*) highly magnetic iron product assaying 17 to 18% Zn, (*2*) a less highly magnetic iron product carrying 19 to 20% Zn, (*3*) a zinc-iron middling assaying 27 to 28% Zn, and (*4*) blende concentrate, 42% Zn. The last two products were mixed to yield a salable product assaying about 40% Zn and represented about 90% of the zinc in the original feed. Roasting was done in a 5-hearth McDougall-type furnace, and cooling in a multitube rotary cooler, each tube individually water-jacketed; tubes were about 2.75 in. diam.; slope, 7%; 8 r.p.m.

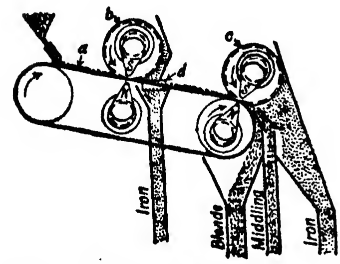

Fig. 36. Wetherill-Mechernich separator.

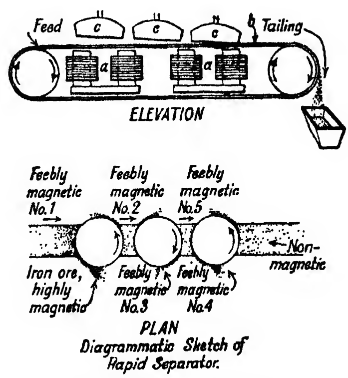

Fig. 37. Rapid separator.

Rapid separator (Fig. 37) is another high-intensity machine in which powerful fields are induced in sharp-edged secondary poles overhanging the flat-pole primary magnets *a* placed below the upper run of an endless-belt conveyor *b*. The secondary magnets are saucer-shaped rotating disks *c*, with diameter several inches greater than the width of the belt. Any given point on a disk, when over the belt, is also over the pole-piece of a magnet and therefore becomes magnetized and lifts magnetic material from the belt. As the disk revolves, this point travels to one side, induced magnetism is lessened, finally passes through zero in reversing polarity, and its load of magnetic material is discharged under the combined influence of gravity and centrifugal force. By tilting the axes of the disk shafts as shown, the effective strength of the secondary magnetic fields may be varied with the result that successively less-magnetic products are discharged as indicated in the figure.

This machine is supplied with 2, 3, or 4 poles and respectively with 1 or 2, 2 or 3, and 3 separating disks. Where the number of disks equals the number of poles, the first disk, acting as a rougher, operates over only one pole. Belt widths range from 10- to 15-in., speeds from 50 to 200 f.p.m. Power required for magnet excitation ranges from 726 to 1,320 watts, for mechanical driving from 1/2 to 3 1/2 hp. Capacity may be estimated from belt speed and size of feed.

Performance. At Storey's Creek, Australia (*18 MM 266*), a wolfram-tin separation was made. The feed contained 50 to 66% WO_3, magnetic concentrate assayed 70 to 74% WO_3, and nonmagnetic product 65 to 68% Sn. Capacity of separator was 1.5 t.p.h. Another wolfram-tin separation at a mill in Tasmania (manufacturer's catalogue) was made on a feed containing 73% wolfram, 20% cassiterite, and 7% silica and iron pyrites. The wolfram product assayed 73% tungstic acid and 0.7% Sn; the tin product 66.5% Sn and 0.6% tungstic acid. These assays are averages taken over an 8-mo. period. A sphalerite-siderite separation is also reported; a feed of 38.9% Zn giving a zinc concentrate of 48.8% Zn and a siderite product containing 1.4% Zn.

In another machine of this type, the keeper with flat poles is placed below the upper run of the belt and the electromagnet above the belt. The collecting surface is a rotating ring whose cross-section shows a broad, flat surface adjacent to the primary poles, while the sides form a parabolic curve ending in a highly peaked vertex. In a third machine the collecting disk is milled with three sharp edges instead of one.

Rapidity separator (Fig. 38) is a recent modification wherein the rotating bridge disk *a* operates over two feed belts *b* moving in opposite directions. Discharge of magnetic material takes place in the space between the belts. Disks are operated at peripheral speeds slightly higher than the belt speed, and since the collecting edge does not travel across the belt, as in the Rapid separator, higher disk speeds and consequently higher belt speeds may be used. The time spent by a magnetic particle in the magnetic field, for constant belt speeds, is longer in the Rapidity model. The magnetic area is shaded in Fig. 38.

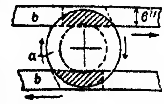

FIG. 38. Diagram of Rapidity separator.

Machine is available with two poles, one disk, two 6-in. belts, requiring 850 watts. Belt speeds ranging from 80 to 150 f.p.m. for monazite sands, 150 to 378 f.p.m. for ilmenite from black sands, and 100 to 200 f.p.m. for garnet are reported. At COCKS ELDORADO dredge, Victoria (*29 CEMR 186*) (see also Sec. 2, Fig. 149), the gravity concentrate of an ore containing gold and tin is treated in an amalgamating barrel to remove gold; the residue is concentrated by tabling and the dried concentrate assaying 0.5% Sn is passed through a Rapidity separator energized by a 3 kw. 110-v. motor-generator set. A magnetic residue containing 0.35% Sn and a tin concentrate of 71% Sn are made with a ratio of concentration of about 4 : 1. A capacity of 2 1/2 to 3 tons per 8-hr. shift is reported.

Tray-type separator (Fig. 39) is a low-intensity machine for treating highly magnetic materials. The essential parts are the two fixed primary electromagnets *a* with pole-pieces *b* suspended above the feed tray or belt and shaped as circular arcs with chords equal to the tray width. Cast-aluminum, brass, or bronze circular plates *c* about 26-in. diam., carried on gear-driven inclined shafts *d*, carry on their periphery Y-shaped laminated-steel segments *e* 1 to 2 in. long and spaced a similar distance edge to edge. The upper part of these segments closely engages the arc-shaped poles of the primary magnets while the lower ends barely clear the bed of feed in the shaking tray *f*. A steel bed-plate *g* underlies the tray. The magnetic circuit is substantially that indicated by the dotted lines *h* passing through core *a*, pole-pieces *b*, segments *e*, air gaps between *b* and *e* and between *e* and *g*, and completed through bed-plate *g*. The segments at any given time above the tray are, therefore, magnets, and lift magnetic material from the mass on the tray. As plate *c* revolves, any given segment passes out of the field of a given pole as it approaches the edge of the tray or belt and as it does so it loses its induced magnetism more and more until it reaches the diameter perpendicular to the tray axis when its magnetic flux becomes zero. Further revolution causes it to approach the opposite pole of the primary magnet where induced magnetism of opposite polarity is effected. As a segment carrying magnetic material leaves a primary pole, the least-magnetic material is dropped out, owing to the decreasing strength of field, and at the neutral point the most highly magnetic material is dropped. Since the diameter of the segment circle is 8 in. greater than the width of the tray, the magnetic concentrate drops clear of the tray into chutes *i* provided to receive it. The second magnet usually has more ampere-turns than the first, thus allowing it to pick up the magnetic material that the first passed, and the air gap of the second is adjusted to a smaller distance than the first. This adjustment is effected by changing the length of the tray-suspension rods *j*, by means of hand wheels *k*. Thus concentrate is delivered into hopper i_1, middling into hopper i_2, and tailing from the lower end of the tray.

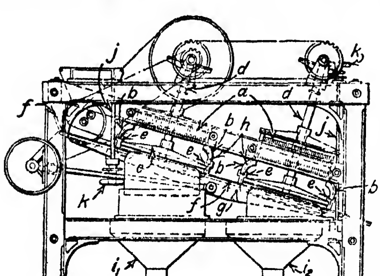

FIG. 39. Tray separator.

In another form of the same machine, the shaking tray is replaced by a rubber conveyor belt. The tray type is superior where hot roasted ores are being handled or where agitation of the feed is necessary to prevent entrainment of low-grade material in the concentrate; the belt is quieter and gives less trouble mechanically.

The standard width of belt or tray is 18 in. The tray is vibrated 450 to 500 s.p.m. and slopes about 4 i.p.f.; the belt is horizontal and runs between 50 and 100 f.p.m. CURRENT drawn is about 2 amp. on the first magnet and 3 on the second. CAPACITY on roasted zinc-iron concentrate passing 3/16-in. screen is about 1 to 2.5 t.p.h.

Performance. Roasted zinc-iron concentrate was treated in Wisconsin (*107 J 1110*) by passing it over two machines in series, the first a 2-disk shaking-tray rougher, and the second a 1-disk belt-type finisher. Shaking tray was made of maple with 1/4-in. pressed-asbestos liner, sloped 4 i.p.f. and vibrated 450 s.p.m. Magnets over first rougher disk drew 2 amp. at 225 v. when heated to 100° F.;

over second disk, 3 amp. at the same temperature. Tips of secondary poles were spaced 3/8 to 1/2 in. above the top of the tray liner. Finisher had two 12-in. feed belts running at 70 f.p.m. and discharging at the center of the machine under an armature of solid steel 24 in. diam. and 6 in. thick, revolving on a vertical shaft. Primary-magnet poles were 3/4 to 7/8 in. below the lower face of the revolving armature. These magnets had 6-in. cores and carried a current ranging from 9 amp. minimum cold and 7.5 amp. hot to 19 and 15 amp. maximum respectively. Capacity of the two machines was 40 to 45 t.p.d. Cost of roasting and separating (1919) was $1.28 per ton, excluding overhead.

Gröndal drum-type wet magnetic separator (Fig. 40) consists essentially of the ordinary drum-type separator *a*, 16- to 24-in. diam. and 17- to 67-in. face, with alternating-pole magnets, mounted above a spitzkasten *b* in such a way that the lower face of the drum just touches or just fails to touch the water surface. Magnets are made adjustable in angular position and the drum as a whole is adjustable vertically and horizontally. Feed is kept in suspension by rising water currents, and all solid matter is forced to flow through the effective part of the magnetic field by means of properly disposed baffles *c*. Sand tailing sinks to the bottom of the spitzkasten and is drawn off through appropriate ports; slime overflows with excess water as shown; concentrate adheres to the drum surface until it has been lifted sufficiently to be discharged over the side of the spitzkasten. At this point the bank of magnets ends and concentrate is washed off by a spray into a concentrate launder. When two drums are run in series, a strong current is carried in the first to lift all magnetic material as a rough concentrate for retreatment on the second machine which, in turn, produces finished concentrate and a middling for regrinding, retreatment, or discard as tailing, according to the exigencies of the problem.

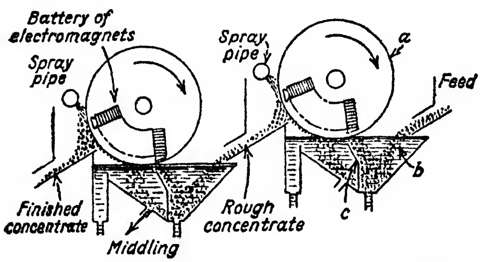

Fig. 40. Gröndal drum-type wet magnetic separator.

In another form of this separator used in Europe, the drum surface is composed of alternating radial strips of nonmagnetic material and iron. The primary magnet has a pointed pole-piece directed vertically downward and mounted directly above the baffle in the spitzkasten. Hence the induced magnetism in the iron strips is greatest when the strips are submerged and decreases as they emerge, becoming sufficiently small by the time they reach the horizontal diameter of the drum to permit concentrate to be washed off.

Usual drum SPEED is from 30 to 35 r.p.m. Suitable FEED SIZES range from 8-m. to 100-m. CAPACITY on magnetite ores is from 2 to 4 tons per ft. of width of drum face per hr. CURRENT requirement is from 6 to 24 amp. at 110 v., and from 1/2 to 1 1/2 hp. is required to drive the drums. Water consumption is about 10 g.p.m. per ft. of drum width.

Use. Primarily for concentrating <14-m. magnetite ore. DISADVANTAGE is that magnetic particles must be pulled through the air-water interface.

Performance. At BENSON MINES, N. Y., two machines were run in series, the second taking rough concentrate from the first; tailing from both was sent to waste. Two such pairs handled 700 to 750 t.p.d. of 20-m. feed assaying 30% Fe and about 0.35% P, but the machines were somewhat overloaded and a third pair was installed. Titanium in the feed ran 3.5% and in the concentrate, 1%. Table 10 gives sizing-assay test of concentrate. Tailing assayed about 8.5% Fe, not all magnetic. HANOVER BESSEMER IRON AND COPPER CO., Fierro, N. M., treated 400 t.p.d. of 30-m. feed assaying 48% Fe, 0.6% Cu, and 0.02% P on three sets of two Gröndal machines in series. Concentrate assayed 60% Fe, 0.2% Cu, and 0.007% P. At BETHLEHEM STEEL CO., Lebanon, Pa., the ore consists of magnetite, pyrite, and chalcopyrite in talc and ferromagnesian silicates; assay, 43% Fe, 1.8% S, and 0.4% Cu. 3,000 t.p.d. crushed to 30-m. went to 20 Gröndal machines in sets of two in series. Concentrate assayed 60% Fe, 0.9% S, and 0.2% Cu. Sintering reduced S to less than 0.1%. At SHOWA STEEL WORKS, South Manchuria (*Bul 425 USBM 275*) the ore, consisting of magnetic and nonmagnetic oxides of iron finely disseminated throughout a silicate rock, is first roasted to increase permeability, then after crushing to <150-m., is concentrated on Gröndal machines. A concentrate assaying 58 to 60% Fe and a tailing of 10 to 14% Fe are made from the furnace product, which assays 38.5% Fe and 15% FeO.

Table 10. Sizing-assay test of concentrate of Gröndal separators, Benson Mines Co., N. Y.

−0.074	11.5	62.88	0.042

Steffensen separator (Fig. 41) is similar to the Gröndal separator but differs in that the drum is submerged; hence magnetic material is not pulled through the air-water interface. Feed is introduced into the bottom of the feed box through conduit *A;* water entering through pipe *B* under sufficient head suspends and carries solids upward toward the rotating drum *C.* Magnetic material attracted to the drum surface and carried upward by rotation is cleaned by the winnowing action caused by the alternate polarity of the pole pieces and by the countercurrent washing of water admitted through openings *D.* When out of the magnetic field, concentrate is discharged with the aid of spray *E.* Tailing discharges over weir *F.*

The drum is 30 in. diameter, 40 in. long, and has an active magnet width of 36 in. A smaller machine having drums of the same diameter but only 22 in. wide is also made. Power required for driving ranges *from* $1/2$ *to* 1 hp. per drum; *for magnet activation, maximum* power required is 2,000 watts.

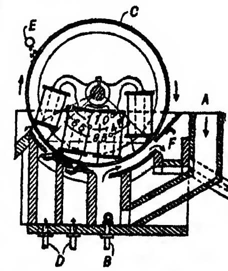

FIG. 41. Steffensen separator.

Performance. At the Lebanon plant of BETHLEHEM STEEL Co. each separator unit consists of three drums in series. The first drum makes finished tailing and a concentrate which is retreated in series by the second and third drums. Finished concentrate discharges at 60 to 75% solids. The second and third drums operate at reduced field strength. Density of feed to the unit is not critical and may range from 20 to 60% solids. Treating Cornwall ore, from which pyrite and chalcopyrite as well as iron are recovered, each 3-drum unit has a capacity of about 350 to 400 t.p.d. Finished concentrate, at 48 *mog,* assays between 60 and 62% Fe; final plant tailing, 0.25% Fe; feed, 43% Fe, of which 38 to 40% is magnetic iron. At 200 *mog,* P. L. Steffensen (*PC*) reports finished concentrates assaying 66% Fe. Sintering difficulties necessitate the coarser grind. In all cases separator capacities are materially reduced by slimes.

Ullrich separator (Fig. 42). The essential parts are one or more concentric rings of wedge-shaped pieces of soft iron *e* carried depending from a revolving table *d;* powerful fixed magnets *a,* radially disposed, with windings *b* and flat pole-pieces *c* for energizing the suspended wedge pieces by induction; feed devices *k* that lead the feed in a thin uniform stream between the primary and secondary poles; suitably disposed receiving spouts *l* and *m,* alternating with the fixed primary-magnet poles, for magnetic material, and a common central hopper *n* for tailing. As the wedges come over a pole and feed chute in the course of their revolution a strong magnetic field converging on the wedge is formed and magnetic material is drawn from the feed sole to the induced pole. On passing to the next radially disposed pole, which is of opposite polarity, the induced magnetism reverses sign and magnetic material is dropped or removed by a scraper. By varying the air gap between successive rings of secondary poles and the poles of the primary magnet from a maximum at the outer ring to a minimum at the inner, fields of increasing intensity are traversed by the radial feed streams, thus permitting the production of several classes of product in a very small space. The separator is made for either dry or wet service. In dry service the feed channels are shaking trays or traveling belts about 6 to 8 in. wide; in wet, they are shallow launders. In wet work the revolving table *d* is filled with water and discharges through pipes to form water sheaths around the wedges. These sheaths are continuous with the liquid in the feed launder (by reason of the small pole distance and the high surface tension of water) so that the movement of magnetic material to the poles is made under water.

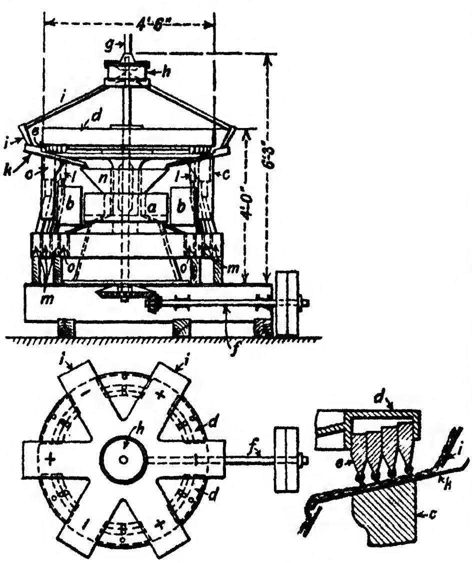

FIG. 42. Ullrich separator.

Performance. Kranafeldt, writing as the distributors' representative (*34 CMJ 708*), stated that the capacity on strongly magnetic material at 2-in. size is 7 t.p.h. while with fine material of the same character 4 t.p.h. can be treated. Capacity on feebly magnetic material passing a $3/8$-in. screen is said

to be 0.5 to 3 t.p.h. The data on performance in Table 11 are from the same source.

Wet machines, treating blende-siderite ore in SARDINIA (*100 J 911*), were fed 7~4-, 4~2-, and <2-mm. material, each size on a separate machine. Feed pulp contained about 20% solids. Combined capacity of the three separators was 2.5 to 3 t.p.h. Power, 1.5 hp. for driving and 10 amp. at 125 v. for excitation of each machine. Assays: Feed, 34% Zn and 38% Fe; concentrate, 53% Zn and 5% Fe; tailing, 2.5% Zn and 48% Fe. Recovery 96% Zn; 90% of siderite eliminated.

Crockett submerged-belt separator (Fig. 43) consists essentially of a battery of flat magnets, arranged side by side so that their pole-pieces lie in an arc *A*, dipping into pulp in a multihoppered tank. A belt *B* is so supported as to intervene between the pole-pieces and the pulp; it is driven at an average speed of 200 f.p.m. in the direction shown. Clear water drawn into the space between the belt and the pole-pieces at *M* by a frictional pumping action discharges along the sides of the belt throughout its submerged run, thus excluding grit. The magnet battery, consisting of 20 electromagnets spaced about 4 1/2 in. c. to c. and having succeeding poles of opposite polarity, is enclosed, except for the pole-pieces, in a nonmagnetic stainless steel or copper housing, made waterproof by welding. Magnets are energized by direct current; the sections over the feed chute *C*, tailing hopper *D*, and middling hopper *E* are designed to give progressively weaker fields, rheostat control being provided for the last-named section. The catenary shape of the magnet bank insures close contact of the endless take-off belt therewith. Feed tray *C*, inclined 10 or 15° from the horizontal, may be adjusted to increase or decrease distance from magnet according to the size of the feed. Tailing and middling hoppers are equipped with baffles *F* to prevent water from flowing with the belt. A series of underwater sprays *G* is directed toward the belt. Ore pulp, introduced through feed box *H*, flows down the feed tray where it comes within the relatively strong field of the first magnet section. The magnetic portion is lifted and held against belt *B*, which carries it forward. The winnowing action due to the alternating polarity, the weaker magnetic field over the tailing hopper, and the underwater sprays act jointly to free entrained gangue particles in the tailing section; these factors act similarly to drop middling when the material on the belt is over the middling section. Thereafter magnetic material is carried over a shallow tray *I* which is partly filled at normal operating pulp levels; two unsubmerged sprays located here are operated at sufficient pressure to wash material held against the belt; the major portion of the dislodged material, running down toward the middling hopper *E*, is picked up again before entrance thereto. Finally magnetic material is carried forward

over a dewatering tank J and then out of the magnetic field and is discharged into concentrate hopper K. Rheostat control of magnets over the middling section is used to control grade of concentrate. Water level, adjusted by means of overflow weirs L, is always kept above the active zones of the separator; it is highest at the concentrate end of the separator. Slimes overflow weirs L.

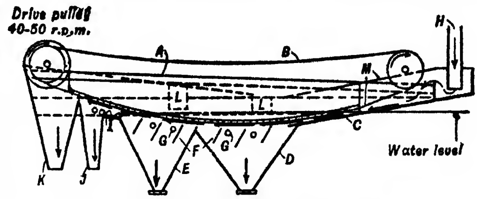

Fig. 43. Crockett submerged-belt separator.

Table 12 gives manufacturer's data on various mill sizes. Capacity figures vary greatly with size of feed and concentration ratio. Belt speeds average 200 f.p.m. Water content of feed may range through wide limits; average figures are 66% water for fairly coarse ore and 80% for extremely fine feeds, *e.g.*, 100-m. A variant of the machine described has been designed to clean ferrosilicon medium used in sink-float processes; it differs in that the middling hopper is eliminated and the magnet battery slopes upward more toward the concentrate end, to promote cleaning and dewatering. The ferrosilicon machine is made with magnet widths of 12, 24, and 36 in., requiring 600, 1,200, and 1,800 watts, and has capacities of 6, 14, and 22 t.p.h. respectively.

Table 12. Manufacturer's data on Crockett separator

Magnet width, in.	Belt width, in.	Capacity, tons ore per hr.	Watts, d-c.	Hp.	Water, g.p.m.
6	8	1/2	500	1	5
12	18	4 to 18	1,200	2 & 3	15 to 45
24	30	9 to 38	2,400	3	30 to 75
36	42	14 to 55	3,600	5	45 to 110
48	54	20 to 80	4,800	5 & 7 1/2	60 to 150

Use is primarily in low-intensity wet separation of unsized permeable ore at maximum size of about 4-m. The machine can be used to make two finished products and a middling for retreatment. Its most important applications to date are in the concentration of magnetite ores and in the cleaning of ferrosilicon medium.

Performance. At Scrub Oaks, Crockett machines are used to separate magnetite from a siliceous gangue. Magnets are 36 in. wide, take 2 1/2 hp. for excitation and 1 hp. for driving. Belt speed is 200 f.p.m. Distance of feed tray from battery magnet, 3/4 in. Attendance required is 12 machines per man. Table 13 gives performance data.

Table 13. Performance of Crockett submerged-belt separators at Scrub Oaks

Separator number	1	2	3	4
Capacity, tons solid per 24 hr.	1,200	600	500	600

Tailing	0.40	0.25	0.39	0.34
Middling	19.5	0.4	5.0	1.2
Concentrate	67.5	68.4	65.4	71.5
Ultimate recovery	99.6	99.4	98.1	99.4

At the Tahawus plant of National Lead Co. 8 @ 48-in. Crockett separators are used as roughers and 4 @ 48-in. as cleaners, with no intermediate regrinding. Results are shown in Table 13*a*. R. E. Crockett (*PC*) estimates a magnetic iron content of 0.75% for the combined tailings and middlings, which, if correct, indicates a recovery of over 99%.

Linney belt separator (Fig. 44) is a pick-up type wet-belt machine, generally similar to the Crockett, but with curved magnet battery A on a relatively steep slope, and with different feed and washing arrangements. Feed enters box B, is distributed across the underside of belt C by box D, aided by pressure water, and overflows into shallow tray E, down which it flows in a thin stream in close proximity to but not in contact with the belt. The overlying magnet section F has a relatively strong magnetic field. Magnetic material is drawn up to the belt through the air-water interface, and is carried up-slope, past the entry point of the feed, to a middling section G, of somewhat lower field strength. Here it is sprayed with water from pipes H, located opposite the pole-pieces, and drops out middling and entrained gangue, which discharges into a separate tray I; that which escapes recapture in flowing

down the tray discharges through opening *J*. Concentrate is similarly reworked under field *K*; middling is dropped through slot *L*, and final concentrate is dropped at *M*. Magnets are wired in groups to give four sections of controllable field intensity.

At Republic Steel Corp., Port Henry, N. Y., belts are 54 in. wide with 20 @ 48-in. magnets. They are inclined about 35° to reduce carriage of dirty water from the lower to the higher sections. Belt speed is 225 f.p.m. Spray pipes use about 75 g.p.m. Capacity depends on size and magnetic content of feed; R. J. Linney (*PC*) quotes average figures at 75 t.p.h. for an iron ore containing 50% magnetic Fe, and 100 t.p.h. for 35% magnetic Fe content. Power for driving is 5 hp. Concentrate averages 69.5% magnetic Fe and tailing 2%.

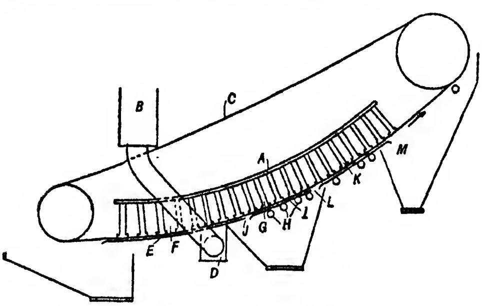

Fig. 44. Linney belt separator.

Dry *vs.* wet magnetic separation. The size at which separation is contemplated and the permeability of the material are the principal factors in determining whether dry or wet separation shall be used. Existing wet separators are limited to a maximum feed size of about 1/4- or 1/8-in., hence if magnetic separation at a coarser size is desirable, as is usually the case when finished tailing or finished concentrate can be made at such sizes, dry separators are used. For this purpose the so-called cobbers or rock-pickers are best, with strong fields and special gap distances chosen according to the size of ore treated. For separations at sizes less than 1/4- or 1/8-in. the determining factor is permeability; for weakly magnetic materials a high-intensity machine is required and, since no high-intensity wet separator is available, dry separation is practiced; for strongly magnetic materials current practice favors wet separation, although dry separation is practiced in some older mills.

The principal advantages of wet separators over dry in treatment of fine materials are: (1) Feed to wet separators need not be sized, whereas close sizing is required for dry separation. (2) Feed to dry separators must be thoroughly dry to permit freedom of movement between the particles on the feed sole; if excessive dusting results or if fine gangue particles adhere to the surfaces of magnetic particles, *e.g.*, apatite on magnetite, thorough washing is also required to avoid production of a low-grade concentrate. (3) State health laws regarding silicosis may necessitate air conditioning if dry separation is used.

Wet separators, in addition to the difference implied by their classification as of the holding or pick-up type, differ according to whether the tailing or concentrate or both pass through the gas-liquid interface. Passage therethrough requires that a force of approximately $0.226D$ grams (D = diameter of particle) be exerted to overcome the interfacial tension; for a 10~14-m. particle this force amounts to 0.032 gm., and for 150~200-m., 0.0020 gm. The ratio of this force to the gravitational force is $0.006/D^2\rho$, where ρ = density, hence the crossing of the gas-liquid interface becomes a matter of increasing importance as the size of the material decreases, and may actually become of the same order of magnitude as the separating force, when pick-up may be prevented.

6. ROASTING TO MAGNETIZE

Roasting is practiced in the case of many iron-bearing products in order to convert the iron-bearing mineral into a magnetic state. Fe_3O_4, *gamma* Fe_2O_3, and Fe_7S_8 are highly magnetic compounds of iron, whereas Fe_2O_3 (hematite), $2Fe_2O_3 \cdot 3H_2O$ (limonite), $FeCO_3$ (siderite), and FeS_2 (pyrite) are feebly magnetic or nonmagnetic. These latter may, however, be converted to the magnetic state by proper roasting. Chalcopyrite, bornite, and other complex sulphides containing iron are similarly rendered magnetic.

Hematite is changed to Fe_3O_4 by abstraction of oxygen at temperatures ranging between 370° and 600° C., the lower limit being set by the time allowed for reduction, the upper limit by the necessity for preventing incipient fusion. Change can be effected by strong heating in air, less heat in a reducing atmosphere, and a still lower heat when there is intimate admixture of a reducing substance such as hydrogen or carbon. Reducing roasting has had some commercial application in Europe, and much experimentation therewith has been done. Theoretically only about 1% by weight of carbon or equivalent fuel would be necessary to effect the conversion of pure Fe_2O_3, if there were no heat losses, but the Minnesota School of Mines Experiment Station has determined that on a typical low-grade hematite ore from 5 to 10% by weight is necessary. Their conclusions as to operating conditions follow: (1) For efficient and rapid roasting the temperature should exceed 400° C. (2) Comparatively small increases in temperature effect considerable increases in efficiency. (3) Efficiency generally increases with increase in duration of roast. (4) Efficiency increases with decrease in size of particles, but this factor is less important than temperature and duration. (5) Simple heating in air produces little change in magnetic character. (6) The reducing agent should contain as little methane as possible, as this gas has low efficiency.

Siderite is converted to the magnetic oxide by calcining with restricted access of air at 700 to 800° C. Over-roasting produces the feebly magnetic ferric oxide, Fe_2O_3.

Pyrite may be converted by roasting either to Fe_7S_8 or to Fe_3O_4, both of which are highly magnetic, according to the character of the roast. When heated in the presence of air, pyrite (and marcasite) decrepitate at 60° C., and as the temperature is raised lose sulphur more and more rapidly until at about 400° C. the magnetic sulphide, Fe_7S_8, is formed, the sulphur igniting and passing off as SO_2 gas. If the period of subjection to heat is short (FLASH ROASTING), only the surface of the pyrite is altered, and Fe_7S_8 is formed, but this surface shell of magnetic material is sufficient to cause the particles to be lifted by the magnet in a field of high intensity. Further roasting at 500 to 600° C. with limited air and an atmosphere of CO, H, and SO_2 results in conversion to the highly magnetic Fe_3O_4, more or less complete according to the duration of the roast and the size of the particles. Roasting to form the magnetic sulphide is hard to control; some of the more strongly magnetic oxide is sure to form, especially from the smaller particles, while the larger particles contain mixtures of the original material and the various possible products. The product is, therefore, difficult to separate on account of the varying permeability of the constituents, and for this reason it is frequently better to carry the roast to magnetic oxide. Over-roasting, especially if accompanied by access of air, causes conversion of Fe_3O_4 to the feebly magnetic Fe_2O_3. Where conversion must be closely regulated the ore must be closely sized before roasting and, if complete conversion to oxide is desired, it should be ground to $<$2-mm. On the other hand, if the feed is too fine, it is difficult to obtain proper exposure to the furnace gases, with the result that roasting is again uneven.

Furnaces. Several types of furnaces have been used in magnetic roasting; they are of the rotary-tube, multiple-hearth, shaft, and turbulence types. Capacity of a 6- or 7-hearth, 22-ft. furnace in this service is 100 to 125 t.p.d. on $<^3/_8$-in. material; of a shaft type with a 4-ft. heating zone 6 ft. in diameter, about 200 t.p.d. on $<^3/_4$-in. material.

Reducing agents. A gas mixture essentially CO, H_2, and N_2 obtained from natural gases by passage together with air and water vapor over a Ni catalyst, water gas obtained by passing steam through incandescent coke, producer gas, and coke-oven gas have all been used.

Cooling. Roasted material must be cooled before it is passed through the separators, on account of the destructive effect on the machines and difficulty in handling. Cooling must be done out of the presence of air in order to prevent reoxidation. Temperature of material leaving the cooler should be less than 100° C. Revolving cylinders, usually with water sprays on the outside of the shell, are frequently used.

At TRAIL (*120 P 864*) it was found that the effect of a roast to increase the magnetic quality of pyrrhotite without complete conversion to Fe_3O_4 was lost if immediate quenching or slow cooling was practiced, but retained with rapid cooling in a rotary cooler.

Performance. PYRITE-BLENDE CONCENTRATE, Wisconsin (*107 J 1107*): Self-roasting furnaces of the Wedge and Skinner types were used with rotary coolers. Characteristic roaster feeds range from 21.6 to 45.9% Zn, 12.8 to 27.4% Fe, 0.22 to 0.82% Pb, 1.50 to 2.15% CaO, and 35.7 to 41.6% S. One plant used an 8-hearth Wedge furnace, 22 ft. 6 in. diam. by 24 ft. high. Ore was heated gradually by the heat of its own combustion to a maximum temperature of 900 to 1,000° F. on the lowest hearth, at which temperature marcasite is strongly oxidized but blende is unaffected. Gases contained 4 to 5% SO_2. Decrepitation and abrasion increased the percentage of $<$40-m. material from 9% in the entering feed to 30% in the discharge. Four rotary coolers were used, 2×26-ft., 6 r.p.m., with outside spray (30 g.p.m. each). Magnetic quality of the roasted ore was greater when slightly warm than when cold. Dings tray-type separators made rough concentrate assaying 56 to 58% Zn; this was raised to 61.5% Zn by a high-intensity cleaner; tailing contained 4 to 5% Zn and 25% S, which

is suitable for sulphuric acid manufacture. At another plant in the same district (*99 J 977*) the zinc-iron gravity concentrate was given a slight, positively controlled roast in an oil-fired revolving kiln, was cooled in a revolving cooler, and separated on a Campbell separator (tray-type with cross belts for concentrate removal). The raw concentrate assayed 21 to 34% Zn and finished concentrate 49 to 61%, with recoveries of 92 to 95% reported. Shrinkage in weight during roasting ran from 50 to 70%. The iron product was suitable for acid manufacture if not over-roasted. Cassiterite-pyrite separation, Llallagua (*100 J 513*): The furnaces were of McDougall type, 5-hearth; ore was self-roasting (no carbonaceous fuel added); feed was all <1-mm. and assayed about 25% sulphur as pyrite and 15% Sn; furnace feed contained about 5% moisture. Best results were obtained on Stern-type wet separators. (A star-shaped pole-piece revolving 10 to 20 r.p.m. around a horizontal axis in a tank of pulp picks up magnetic material and carries it above the surface of the pulp, where it is washed off the pole arms and over the sides of the tank by a strong jet of water. Current draft is about 6 amp. at 110 v. Capacity: 18 tons per 24 hr. was handled when the roasted product contained 10 to 12% S. Under these conditions the magnetic product contained 50% Fe and 22% S and the nonmagnetic 2.5% Fe and 1.5 to 2% S.) Properly roasted product was black with metallic luster; over-roasting was indicated by a reddish product on which the separators did poor work and discharged a tin product high in iron. Capacity of roasting furnace was about 0.04 ton per sq. ft. of hearth area per 24 hr. Amount of flue dust was less than 5% of the furnace feed and tin content of dust was about 5% on a 20% feed, due in part to the fact that cassiterite does not decrepitate. There was never more than 2% loss of tin in dust. Copper-iron, Calumet and Arizona Smelter, Douglas, Ariz. (*Bul 9 MSM 38*): Davis states that magnetic roasting was incidentally performed at this plant in connection with drying and desulphurization prior to smelting. The ore, crushed to pass a 1-in. screen, was roasted in a 6-hearth McDougall-type oil-fired furnace 21 ft. 6 in. diam. at the rate of 80 to 100 tons per 24 hr. with conversion of about 80% of the iron to magnetic oxide at a total operating cost in 1919–20 of \$0.31 per ton.

Hematite from tailing pile, Cooley, Minn. (*A TP 731; 22 MCJ 20*): Ore was crushed to pass 3/4-in. screen, then screened at 4-m. and the products binned. Screened products were fed to a shaft-type furnace, coarse ore in an outside annular position, fine ore centrally, in a ratio of 5 : 1. Furnace was heated by oil; heating zone was 4 ft. high, 6 ft. diam.; reducing zone (located immediately below heating zone) was 14 3/4 ft. high and 3 1/2 ft. diam. Fine and coarse ore were mixed at the head of the reducing zone by suitably disposed baffles. After passage through the reducing zone, ore was cooled over a distance of 7 ft. and finally quenched. An operating time of 692 hr. in one month, with a loss of 3.9% of possible time, during which 5,802 tons of ore was reduced, is reported. Oil consumption was 9.5 g.p.t.; electric energy 3.3 kw-hr. per ton; 1.3 men per shift were required. Cost was 67.7¢ per ton, of which 55.5¢ was for oil, 5¢ for power, and 7.2¢ for labor. Calcined ore was concentrated by wet cobbers, which make a concentrate of 62.3% Fe and tailing of 21.4% Fe from a feed of 46.8% Fe, with a recovery of 64.3%. Taconite-like ore, Anzan, South Manchuria (*Bul 40 # 42 UM 13*): This is the largest magnetic-roasting plant in the world. Ore is crushed, sized to 4~0.4-in., and given a magnetic roast in a shaft-type furnace at 600 to 700° C. Calcine is ground to 150-m., and concentrated on Gröndal separators. Concentrate is dried and sintered. Furnace capacity is 300 to 400 t.p.d.; fuel consumption per ton of ore is 54 to 68 lb. of powdered coal and about 35,000 cu. ft. of coke-oven gas; electrical energy, about 2.2 kw-hr. Ore assays 38.4% Fe and 6% FeO, concentrate 57% Fe. Recovery is 80 to 90%. Production of sinter is 260,000 tons per year. Spathic iron ore, Eupel mine, Germany (*Bul 425 USBM 279*): Ore is crushed to <120-mm., roasted, and the calcine screened to 120~70-, 70~35-, and <35-mm. The two coarse sizes go to picking belts where tailing, intermediate products, and half-roasted material are picked out. Intermediate products are crushed through 35-mm. and join the <35-mm. calcine; this mixture is screened to 35~18-, 18~12-, 12~6-, and <6-mm. These products, concentrated on drums, yield concentrate, middling, and finished tailing. Middling is combined, reground to <4-mm., and separated on a drum into concentrate and tailing. Crude ore assays 39 to 40% Fe, 7.4 to 7.5% Mn; concentrate, 49 to 49.3% Fe and 9% Mn. Recovery is 95%.

7. GUARD MAGNETS

Lifting magnets are used primarily in crushing plants to remove tramp iron and steel from the feed before it goes to a crusher incapable of handling it. It is stated (*112 J 728*) that at Melones Mining Co. a magnetic pulley placed ahead of a primary crusher saved \$1,400 per month in delay and repairs. The magnet is usually placed either at the head pulley of a conveyor belt or over the belt itself. In the former position it should be hung at an angle and offset to prevent magnetization of the pulley (Fig. 45*a*). When placed over the conveyor (Fig. 45*b*) a sufficiently long suspension is used so that the magnet can be swung aside for discharging. Magnets are usually of the type used for lifting scrap iron in handling plants, and are sufficiently powerful to lift pieces of steel from the rapidly moving masses of coarse ore and, as the load builds down, to hold it against the blows of the material moving

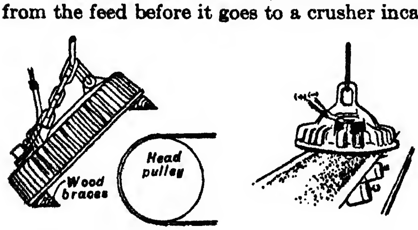

Fig. 45. Locations of mushroom-type guard magnets.

with the belt. Auxiliary signaling devices are available to warn operators when magnets are overloaded. High-intensity rectangular magnets, as wide as the belt, are lighter than a circular magnet for the same purpose.

Performance. Table 14 summarizes results of a study (*Bul 425 USBM 293*) of guard magnets at four washeries. At St. Joseph Lead Co., Hughesville (*IC 6447*), a 39-in. magnet drawing 17 amp. at 125 v., suspended over head pulley, guards a cone crusher; at Mt. Isa (*IC 7073*) cone crushers are protected by 2 @ 2-pole high-intensity magnets; at Balmat (*IC 6574*) a #39 magnet placed between jaw and gyratory crushers protects the latter; at Cananea (*IC 6261*) a suspended magnet and magnetic pulley were used to protect cones; at Pioneer (*112 A 679*) a 29-in. magnet suspended over a

24-in. belt is powered by 5 kw.; at Fresnillo (*112 A 736*) a 42-in. magnet is suspended over a 30-in. belt, and with a magnetic head pulley guards a cone crusher. At McIntyre-Porcupine, Ontario (*Bul 425 USBM 296*) a 55-in. magnet is suspended above the head sprocket of a 48-in. pan conveyor. It is inclined 23° from the vertical and offset 4 in. above the center line of the head shaft. The conveyor, moving 5 f.p.m., carries <7-in. ore from the primary crusher. Depth of bed is 20 in.; about 140 lb. of tramp iron is removed daily at a cost of 0.05¢ per ton of ore. Power, 5.25 kw. Since this magnet misses some metal, a second magnet, 45 in. diam., drawing 20 amp. at 216 v., is located over the discharge belt from the following cone crusher. The belt is troughed, 36 in. wide, travels at 275 f.p.m. and carries <1.5-in. material. The second magnet is reported to miss no metal, and collects 60 lb. per day at a cost of 0.035¢ per ton of ore.

Magnetic pulleys are frequently used as guard magnets. Pulleys have the advantage that tramp iron, which frequently stratifies next to the belt, need not be pulled through the bed; they do not accumulate iron above the belt, with consequent danger of redischarge into the stream by jostling or power failure; and they require less inspection.

Performance. At Sunshine (*Bul 425 USBM 206*) a 24-in. magnetic pulley at 11 1/2 r.p.m. removes 40 to 50 lb. of tramp iron per 24 hr. 60 t.p.h. from <8-in. material. Pulley draws 15 amp. at 120 v. Another pulley at 12 3/4 r.p.m. is fed 100 t.p.h. of <12-in. material on a 30-in. belt.

Guard magnets cannot be used in plants treating magnetite ore, on account of the magnetic character of the ore itself. Also, guard magnets will not lift manganese steel, because of its low permeability. At the Replogle Steel Co. plant, vertical disk crushers set to 1/4-in. were guarded by a screen with 3/4-in. aperture sending oversize in closed circuit to a set of rolls. These were rugged enough to break up the steel fine enough to pass the disk machines without injury to them. At the Utah Copper Co., where manganese-steel dipper teeth are used on the steam shovels, close watch is kept on the shovels and when a tooth is missing a telephone message is immediately sent to the mill (18 miles distant) and particularly close watch is kept as the ore is unloaded to the primary crusher, until the tooth is found and removed.

Magnetic chute. Fig. 46 shows a method of applying a guard magnet to a chute. Magnets *a* are so arranged as to produce a strong field in the chute and catch and hold tramp iron until it is removed

by an attendant. Just below the magnetic zone a tilting section b is placed in the chute bottom. This is held in closed position by the magnets c so long as there is current flowing through the guard magnet but if current is cut off, accidentally or otherwise, the tilting section is released and spills the released iron together with the feed stream onto the floor until such time as the feed is cut off or the tilting section is closed with current again flowing.

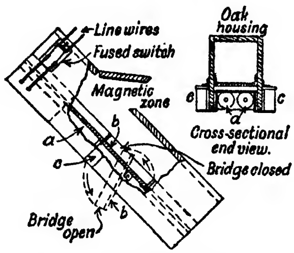

Fig. 46. Magnetic chute.

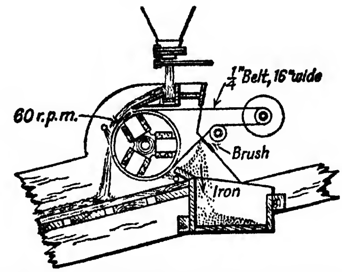

Fig. 47. Pulley-type separator in tube-mill circuit at Simmer and Jack mill.

Magnets in grinding-mill circuits are used in cyanide plants to remove iron introduced by abrasion from the crushing and grinding machines.

Unless removed, this iron, being difficult to grind, builds up to such an extent that it may amount to as much as 15% of the total circulating load (Alaska-Treadwell Gold Mining Co., *96 J 452*).

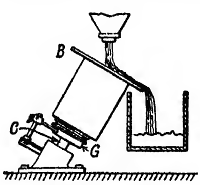

Fig. 48. Brown electromagnet for tube-mill circuit.

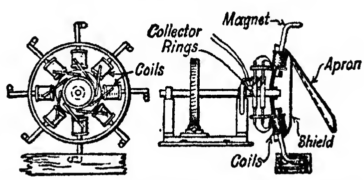

Fig. 49. Magnet for tube-mill circuit at Alaska Treadwell.

Schmidt (*RMP*) states that as much as 900 lb. of metallic iron per day has been removed from a Rand tube-mill circuit and that prior to the introduction of a magnet at the Simmer and Jack mill it was necessary to open the tube-mill circuit for 15 min. each day, and pass the whole pulp to the cyanide plant without regrinding, in order to clear out the accumulation of iron. Fig. 47 shows an application of a pulley-type separator (Art. 4) at this mill. Fig. 48 shows another type of separator in similar service (*90 J 445*). A flat disk-shaped cast-iron pole-piece B of an electromagnet with cast-iron core is mounted to revolve on shaft C, which is inclined 35° from the vertical. Current enters through slip-ring G; the other end of the coil is grounded. Winding is encased water-tight by a zinc sheath soldered to the iron bobbin of the winding. The magnet is driven at 6 r.p.m. by a 0.5-hp. motor; exciting current is 2.5 amp. at 100 v. Iron is caught on the rim of the plate and is scraped off by a piece of canvas belting.

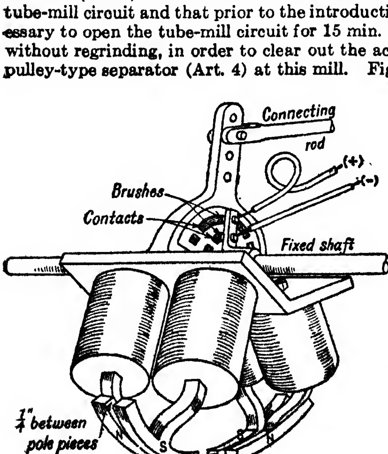

Fig. 50. Pulp magnet at Liberty Bell.

A magnet used at Alaska-Treadwell is shown in Fig. 49. The magnet poles dip into the tube-mill discharge launder leading to a Dorr classifier. Current on a given pole is broken by a commutator when the pole-piece reaches a position above the apron. Fig. 50 shows a pair of oscillating magnets with curved pole-pieces that were swung in a semicylindrical section of a main pulp launder at the Liberty Bell G. M. Co. Water jets washed the poles as they emerged from the pulp and current was cut off when the magnet reached the highest point of the swing at which time it overhung the edge of the launder. Each pole had 800 turns of wire and drew 2.0 to 4.0 amp. at 110 v. The machine made 4 to 5 oscillations per min. and required about 0.1 hp. for driving. Feed rate was 100 tons of <16-m. material per 24 hr. in a pulp carrying about 10% solids. Removal of metallic iron was reported practically complete.

Manufacturers. The typical machines described are built by different manufacturers as follows; for a particular type the products of the different manufacturers differ primarily in mechanical or electrical details, but not in basic principles.

American: Bauer Bros. Co.; Cutler-Hammer, Inc.; Dings Magnetic Separator Co.; Electric Controller & Manufacturing Co.; Exolon Co.; A. E. Jacobson Co.; Jeffrey Manufacturing Co.; Ohio Electric Manufacturing Co.; Stearns Magnetic Manufacturing Co. *British:* Rapid Magnetting Machine Co.; Bepco Canada, Ltd. *Swedish:* Aktiebolaget Industrimetoder; Patentaktiebolaget Gröndal-Ramén; Aktiebolaget Arboga Mekaniska Verkstad.

8. MAGNETIC FLOCCULATION

Magnetic flocculation is based upon the fact that magnetized particles of a magnetically hard material, when free to move, will bunch together with unlike poles in contact so far as possible, the net effect being to reduce the external field to a minimum.

Gröndal slime separator consists of a primary magnet with wedge-shaped pole-piece mounted above a spitzkasten through which the slime feed is run. Mineral particles of relatively high coercive force become magnetized under the influence of the magnetic field, are drawn together just below the water surface, and there form flocs that sink and are drawn off from the bottom of the tank. In another form a strong horizontal surface current skims the enriched surface layer of slime from the tank before sufficient agglomeration has occurred to cause the magnetic material to sink; in this case the mineral may be magnetically soft.

Demagnetizer. For materials of low coercive force, the demagnetizer consists of a conical coil comprising a large number of turns carrying alternating current, surrounding an iron pipe carrying magnetized pulp. For materials of high coercive force a demagnetizer made of a water-cooled solenoid 3 in. in diam., 3 1/2 in. in height, with 6 turns per inch, connected to a 3 kv-a. mercury-arc converter drawing 5 amp. at 220-v., 60-cycle alternating current, is effective; the frequency is estimated at 50,000. Also effective with high coercive material is a solenoid comprising 5,000 turns of No. 22 double cotton-covered-magnet wire wound over a 3-in. length of 1 3/8-in. nonmetallic tubing; electrical connections are made as shown in Fig. 51. The oscillatory discharge of the condenser is effective in demagnetization.

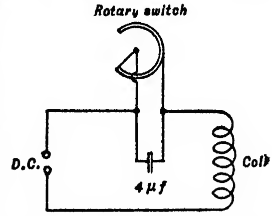

FIG. 51. Circuit for a demagnetizer.

Use. When an ore that has been over a magnetic separator is finely ground, there may be sufficient residual magnetism in the magnetic particles to cause them to agglomerate and, in classification, to go with the unground sands rather than overflow with the slimes. Effective closed-circuit grinding is thus prevented. Passage through a demagnetizer remedies this difficulty. At MESABI IRON CO. a conical demagnetizer was used on the ball-mill discharge feeding bowl classifiers. Demagnetizers are also used on the ferrosilicon medium of the sink-float process after magnetic cleaning.

9. DESIGN OF MAGNETIC SEPARATORS

The fundamental elements of every successful magnetic separator are (*a*) a magnetic field of sufficient intensity and inhomogeneity to cause a marked difference in the magnetic forces acting on the magnetic and nonmagnetic particles in the mass to be separated; (*b*) a means for bringing the material to be separated to the magnetic field in such a way that the particles have sufficient freedom of movement under the influence of the magnetic forces to permit the magnetic particles to move away from the nonmagnetic or *vice versa;* (*c*) a force or forces such as gravity, centrifugal force, or the friction of a solid or fluid, acting against the magnetic force, and serving to intensify the difference in direction of movement of the magnetic and nonmagnetic particles; (*d*) a means for removing both magnetic and nonmagnetic particles from the magnetic field after separation.

Design of magnetic systems to give fields of sufficient intensity and inhomogeneity for efficient magnetic separation involves (*1*) proper choice of pole shapes and a disposition thereof to produce most efficient inhomogeneity of field (not necessarily maximum inhomogeneity), (*2*) selection of proper materials for cores and poles, and (*3*) specification of winding of the required number of ampere-turns.

Shapes of pole-pieces are determined empirically on the basis of designs already in use. The usual method of producing nonuniform fields is to use wedge-shaped pole-pieces on the collecting poles (see p. 23) or to build collecting armatures of alternating disks of magnetic and nonmagnetic materials. Arrangement of pole-pieces yields to solution by mathematical means in simple cases; the more complex cases are solved by graphical mapping of the field followed by a determination therefrom of the degree of inhomo-

geneity (A. D. Moore, *Fundamentals of Electrical Design*). The extent and character of the inhomogeneity desirable in a field to be used in separating ores should be determined by the conditions of operation and the character of the ore. The rules are yet to be enunciated; in most designs the subject is not even investigated.

Selection of magnetic materials for cores and pole-pieces is made according to the particular characteristic required. Thus for an electromagnet, a material having a relatively large permeability and large saturation flux density is usually desired in order to reduce the magnetomotive force and the weight of material. On the other hand, if the electromagnet is to be used to produce an alternating magnetic field, the energy dissipated in the core must be kept at a minimum, hence material possessing a hysteresis loop of small area is desired. If the electromagnet is to be used in a particular range of flux density, the material should have its maximum permeability in this range and the μ-H curve (see Fig. 5) should not be too peaked. If the magnet is to be subjected to large variations in temperature the μ-temperature curve (see Fig. 7) should be as nearly parallel to the temperature axis as it is possible to obtain. Materials used in magnets for ore separators are of high permeability with large saturation flux density (see Table 15).

Permanent magnets are used in the Frantz Ferro-filter (p. 21). Increasing use of magnetically hard materials is forecast by the advent of newer magnetic alloys and by the ever increasing use made of such materials in the field of instrumentation. With permanent magnets the characteristics sought are a high coercive force and a large value of the energy product BH since the latter is a measure of the energy stored in the gap (see Table 16).

Windings of coils may be calculated to give the desired field intensity in the gap in any number of ways, *e.g.*, the total reluctance of the magnetic circuit may be calculated from Eq. 12, since the gap range and mean path in core (set by dimensions and design of separator magnet) as well as the permeabilities are known, the ampere-turns required are then computed by means of Eq. 11. The problem

is thus resolved into a proper choice of coil such that for a given voltage across its terminals the desired ampere-turns are produced without overheating. Standard procedures are here followed (*Standard Handbook for Electrical Engineers*, Sec. 5, McGraw-Hill Book Co.), making allowance for any special limitations imposed by the problem.

ELECTROSTATIC SEPARATION

Electrostatic separation utilizes the force of an electric field, coacting with some other force, to produce differential movement of mineral grains. The basis for such separation is found in the differences in interfacial resistance offered by different minerals to the passage of electrons therethrough, modifying factors being specific gravity, size, shape, surface condition, and purity of the mineral particles, as well as the mechanical and electrical attributes of the separator.

10. PRINCIPLES

Charges are fundamental entities which possess the property of attraction or repulsion for one another. Two types are recognized, a positive charge (PROTON) and a negative charge (ELECTRON). The force exerted by one charged body upon another is given by e_1e_2/r^2 where e_1 and e_2 are the charges of the two bodies and r is the distance between them; a negative value of this force denotes attraction, a positive repulsion.

Electric field of a charged body is the surrounding space through which its influence extends. As with the magnetic field, the electric field may be mapped by lines of force, at every point of which the tangent has the direction of the force that would be exerted on a positive charge located at that point. The magnitude of this force is known as the ELECTRIC FIELD INTENSITY and the work required to bring a unit positive pole from infinity up to this point as the ELECTRIC POTENTIAL.

Matter is conceived of as a collection of positive and negative charges together with certain other fundamental particles, the ensemble constituting a complex dynamical system in equilibrium. Thus a hydrogen atom is said to consist of a central positively charged nucleus about which there revolves an electron. In general, the atom is composed of a large number of positive and negative charges, the former being concentrated in the nucleus about which the latter revolve, in much the same fashion as the planets revolve about the sun.

Polarization. Influence of an electric field upon an atom is approximately the resultant of the influences upon the constituent charges. In an atom between two dissimilarly charged plates, the electrons are attracted by the positively charged plate and repelled by the negatively charged, while the nucleus is attracted by the latter and repelled by the former. The result is that the centers of position of the positive and negative charges no longer coincide but are shifted apart through a distance which depends upon the intensity of the field. This phenomenon is known as polarization. If a large number of atoms are strung together to form a particle of matter, the effect of the electric field is to shift the electrons toward that end of the particle which is closest to the positively charged plate. The nuclei, on the other hand, being tremendously heavier than electrons, and held together by the cohesive forces of matter, are not appreciably shifted; in any event, a displacement of the centers of position of the positive and negative charges has taken place.

Current. Movement of electrons through matter, noted above, constitutes a CURRENT. The ease with which this flow takes place depends upon the nature of the material; in all cases it is resisted by a force, analogous to fluid resistance. RESISTANCE depends upon the chemical and physical properties of matter. Substances which offer small resistance to the passage of electrons are known as CONDUCTORS, those offering large resistance as nonconductors (INSULATORS or DIELECTRICS). It should be noted that conduction takes place through all materials providing the driving force exerted on the electrons is sufficiently great. The principal flow of electrons with solid conductors is along the surface.

Charging by induction. If a polarized particle, maintained free of any contact with a conductor while in the electric field, is removed from the field, the polarization is found to have disappeared and the particle is uncharged. However, if a polarized particle is placed in temporary contact with a grounded conductor (conductor connected to the earth) when in the electric field, it is found to be charged upon removal from the field. It can be shown that the conductor provided a path along which electrons could be removed from or brought to the polarized body under the driving force of the electric field, the earth serving as an electron reservoir.

Charging by conduction. When two spherical particles charged with different amounts of electrons are brought into contact, flow takes place from the more highly charged to the other, and ceases when the charge on the two is the same. This may be considered as a kinetic exchange of electrons between the two; when so viewed it appears that the work done in moving an electron from the more highly charged sphere against the forces of repulsion due to the electrons on the other is less than the work done in moving an electron in the reverse direction. Flow continues from the body at higher potential to that at lower potential until the potential difference between the two bodies vanishes. If the potential difference between two bodies placed in air is sufficiently great, the bodies need

not be brought into contact for electrons to flow from the body at higher potential to the other, since now the resistance of air to passage of electrons may be overcome.

Pyroelectric charging. A limited group of natural and artificial crystals exhibit polarization upon change in temperature. Thus when a tourmaline crystal is heated, a positive charge appears at the pointed end of the Z-axis (termed the ANALOGOUS POLE) and a negative charge at the opposite end (ANTILOGOUS POLE); cooling of a tourmaline crystal develops charges in the opposite sense. The poles are readily located by dusting the polarized crystal with a mixture of positively charged litharge and negatively charged sulphur (*20 Wied. Ann. 592*). The lines of force are similar to those of a bar magnet (Fig. 1); they are rendered visible by placing the polarized crystal in a container filled with smoke produced by burning magnesium ribbon (*24 Proc. Camb. Phil. Soc. 491*), when filaments of magnesium oxide develop along the lines of force. Crystals exhibiting pyroelectric effects are characterized by absence of a center of symmetry and of twinning, *e.g.*, calamine, tourmaline, and boracite. Some twinned crystals such as topaz, axinite, and dioptase exhibit pyroelectricity in a somewhat modified form, the electrical axes being replaced by ill-defined regions (*9 Z. techn. Phys. 430*). Many crystals show a pseudo pyroelectric effect when subject to changes in temperature; actually the effect noted is due to piezoelectricity developed by internal stresses arising from the temperature gradients established by the heat treatment. Thus quartz when heated and maintained at a uniform temperature shows no polarization, but if the crystal is then cooled three axes of polarization appear (*45 Ann. Phys. 737; 46 ibid. 221*).

Piezoelectric charging. Excepting crystals belonging to the class 432-0 (Bragg and Bragg, *The Crystalline State*, Bell, 1933, p. 86), natural or artificial crystals, lacking a center of symmetry, develop electric charges on their surfaces when subjected to mechanical stresses. In general, three polar axes corresponding to six surface areas of charge are found. Charges are also developed on the surfaces of uncharged, stressed crystals when the stresses are removed. Development of internal strains by temperature gradients, magnetostriction, etc., is invariably accompanied by piezoelectric charging.

Interfacial resistance. The ease with which electrons enter or leave a polarized body depends upon the resistance offered by the interface between the body and the conductor. The interfacial resistance depends upon the potentials of the body and conductor at the point or surface of contact, upon the nature of the contact, *e.g.*, point against a flat surface, and, in general, upon the chemical and physical properties of the contacting materials. Thus the interfacial resistance of a TiO_2 crystal in contact with gold is fourteen times greater than when it is in contact with magnesium (*27 Compt. rend. acad. sci. URSS 547*). Also the interfacial resistance with crystalline materials differs along the different crystallographic axes. With materials that are good conductors, the number of electrons per unit of time that can be transported across the area of contact depends primarily upon the area of contact and the number of electrons in the vicinity of the contact area. The latter depends upon the shape of the particle, *i.e.*, in a spherical charged body the electrons are uniformly distributed over the surface, whereas in an irregular body the electrons tend to concentrate at the peaked parts of the surface. With poor conductors the rate of transfer of electrons depends additionally upon physical structure and orientation. Column 4 of Table 17 (after Johnson, *A TP 877*) gives a relative empirical measure of interfacial resistance based on an assumed resistance of unity for graphite.

Electrostatic forces. The laws of attraction and repulsion of charged particles are strictly analogous to the laws describing the interaction of permanent magnets. Coulomb's law describes the force existing between two charged bodies, if the fields of the bodies produce no alteration in distribution of charge. The electrostatic equation analogous to Eq. 21 is

$$F_x = -\rho_e \frac{\partial V}{\partial x} - \frac{E^2}{8\pi}\frac{\partial \epsilon}{\partial x} + \frac{\partial}{\partial x}\left(\frac{E^2}{8\pi}\rho \frac{\partial \epsilon}{\partial \rho}\right) \tag{35}$$

where ρ_e = the charge density and ϵ = dielectric constant, and V and E are analogues respectively of A and H in Eq. 21. The first right-hand term of Eq. 35 is the Coulomb term; the second accounts for variable inductive capacity of the body; the last for the energy stored within the body as a consequence of configuration changes. As with magnetic bodies, in the absence of a permanent charge, *i.e.*, $\rho_e \frac{\partial V}{\partial x} = 0$, the force is determined primarily by the inhomogeneity and magnitude of the field intensity, and by the inductive capacity of the body. One important difference should be noted: unlike magnetic poles, charges may move slowly over the surface of the body.

If a negatively charged insulated sphere is brought near an uncharged particle suspended by an insulated string, polarization is induced in the particle and it is attracted

toward the sphere, since the latter possesses a convergent field of force. When the attracted particle touches the surface of the charged sphere it becomes negatively charged by conduction and is immediately repelled by the Coulomb force. If either sphere or particle is a poor conductor, high interfacial resistance may cause a time lag of several seconds before the particle becomes charged by conduction and is repelled. If the suspended particle is initially charged negatively to a lower potential than that of the sphere, the particle is first repelled, then attracted. The repulsion is Coulomb repulsion between the negative charges on sphere and particle. On closer approach polarization induced in the particle by the electric field of the sphere surpasses the initial negative charge on the particle, and electric-dipole attraction becomes stronger than the Coulomb repulsion so that the resultant is an attractive force. If the negatively charged sphere is located at such distance from a negatively charged particle that a force of repulsion is exerted, and the particle is touched for a short though finite length of time to a grounded conductor, the force changes to attraction if the particle is a sufficiently good conductor and the interfacial resistance is low enough to permit draining off the initial negative charge in the time available; induced polarization then determines the force exerted by the sphere. Conversely, the force remains repulsion. Further contact time may cause the particle to become positively charged through the loss of electrons. On long contact with a grounded conductor, even a poorly conducting particle becomes positively charged. Relative conductivities of minerals are given in Table 17.

Reversibility. An originally uncharged particle momentarily grounded when in the field of a charged electrode develops a charge of polarity opposite to that of the electrode. The time required for the induced charge to build up depends upon the electrical properties of the particle. If the uncharged particle is introduced onto the surface of a grounded roll A (Fig. 52) and brought into the electric field of the charged electrode B (which can be charged either positively or negatively as desired), the situation is strictly analogous to that described above. The time permitted for inductive charging of the particle depends upon the speed of A and the arc length covered by the electric field. In the absence of any field, conducting and nonconducting particles leave the roll under the action of the gravitational and centrifugal forces and follow thereafter a normal parabolic trajectory, the heavier particles reporting farther from the roll. In the presence of an electric field, the particles conducting in that field are first polarized, then lose or gain electrons to or from the grounded roll, according as the electrode B is negatively or positively charged, and thus become correspondingly positively or negatively charged. Owing to the charge developed, an electric force acts and the trajectory is spread beyond the gravitational trajectory. The particles nonconducting in the field follow their normal trajectories since their interfacial resistance to passage of electrons is too high to permit charging in the time the particle is in the field. Johnson (*A TP 877*), using the experimental setup shown in Fig. 52, determined the potential of electrode B required to shift the particle trajectory from D by an arbitrary amount DC. The values obtained are given in Column 5 of Table 17.

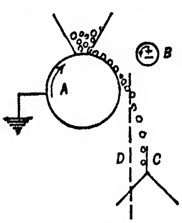

FIG. 52. Experimental setup for reversibility testing.

Johnson also reports that some minerals differ in their behavior according to the polarity of the charged electrode. He has called such minerals reversible. Thus calcite acts as a conductor at a potential of 10,920 v. only when electrode B is negatively charged; when B is positively charged, calcite acts as a nonconductor. Assuming the validity of the classical explanation of inductive charging, it follows that the interfacial resistance offered to passage of electrons from calcite to metal roll is less than the resistance to passage from metal to calcite. If this is true, then calcite will again act as a conductor when B is positively charged to some potential greater than 10,920 v. Minerals that apparently develop only a positive inductive charge Johnson terms REVERSIBLE POSITIVE; conversely, reversible negative minerals are also found. Such reversibility is generally exhibited by the poorer conductors, principally by silicates, carbonates, and some oxides; silicates and oxides are usually reversible negative and carbonates reversible positive. As with tables of magnetic permeabilities, Table 17 is probably subject to errors due to impurities in the natural minerals. It is also reported (H. B. Johnson, *PC*) that the polarity of the reversibility, in the case of some minerals, changes with size and possibly with shape.

11. MACHINES

Electrostatic concentrators are of two principal types, classification being based on intensity of the electrical field. In HIGH-INTENSITY MACHINES a relatively wide divergence

[a] Non = not reversible, RP = reversible positive, RN = reversible negative.

in path between conducting and nonconducting particles is attained by pinning the nonconducting particles to a movable charged roll, the conducting particles being repelled therefrom. In LOW-INTENSITY MACHINES pinning is at a minimum or is entirely absent, divergence due to repulsion is small, and separation is effected rather by close regulation of splitters coupled with repetitive treatment. In both machines time-factor is an essential element.

Sutton separator (Fig. 53) has a convergent electric field of high intensity developed between a grounded material-conveying electrode *A*, a charging electrode *B*, and the neon-tube electrode *C*. Electrode *A* is a brass cylinder, 6 in. diameter by 4 ft. long, fed by a Syntron-vibrated plate *D* from hopper *E*. Electrode *B* is a comblike structure parallel to *A*, comprising a rod provided with needlelike discharge points *F;* it is maintained at a high negative potential by connection to the secondary of a step-up transformer. The position of electrode *B* and the orientation of the discharge points are adjustable; the points are usually set a little above the line of centers of electrode *A* and rod *B*. A tube-type rectifier permits use of ordinary a-c. circuits. Power equipment is well insulated and enclosed; access thereto is through a door which automatically throws main power switch when opened. When tube electrode *C* is not energized the electric field between electrodes *A* and *B* is similar to the magnetic field shown in Fig. 14*b*. A similar though less convergent field exists between electrodes *A* and *C* when *B* is off. With both *B* and *C* energized, the lines of force terminating at electrode *A* are pushed together by mutual repulsion of the two fields.

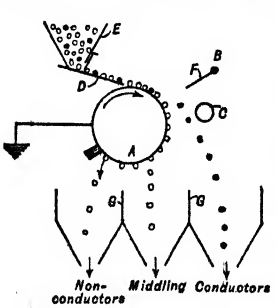

Fig. 53. Sutton separator.

Electrode A, rotating as indicated, carries a feed layer one particle deep into the electric field, where it receives an electron spray from B. The conducting particles lose electrons through grounded electrode A and are then attracted by B because of an induced polarization, and, possibly, through positive charging brought about by an oscillatory discharge caused by surface irregularity. Their trajectories are the resultants of the electrical and gravitational forces and their initial momenta. Nonconducting particles lose electrons very slowly to the grounded electrode, hence they remain or become negatively charged; a positive charge is induced in the region of the grounded electrode close to the particle, and as a result the nonconducting particle is pinned to this electrode. Thus held to the surface, the particle is carried by rotation of the electrode to a point beyond the action of the field, where it may fall by gravity, or to a point further on where it is mechanically brushed off the roll surface. After leaving the electrode A, conducting particles are still subject to electron bombardment and may again acquire a net negative charge, some of which tends to leak off through the air to the grounded electrode. If this reacquired negative charge becomes sufficiently great, the particles tend to be repelled by B and C. If the position of the particle with respect to C is such that the upward vertical component of the repulsive force exceeds the horizontal component toward A, the effect will be to lengthen the trajectory of the particle by decreasing the net downward pull thereon. It seems probable that this is the primary function of electrode C; this electrode undoubtedly also serves to attract conducting particles that for one reason or another escape the effect of electrode B. Adjustable knife edges G are set to divide the falling particles into conductors, nonconductors, and a middling.

Operation. Roll speeds range from 50 to 400 r.p.m., the higher speeds being used for the finer feeds and for feeds having a wide spread in electrical properties. Upper limiting speed is set by the effect of centrifugal force in loosening pinned particles. Speed is kept at the maximum allowable in order to prevent bouncing of feed particles. The following roll speeds are most commonly used (G. W. Jarman, Jr., *PC*): 20∼28-m., 110 to 130 r.p.m.; 28∼48-m., 150 to 190 r.p.m.; 48∼65-m., 200 to 240 r.p.m., and 65∼150-m., 250 to 400 r.p.m. Voltage of the charging electrode ranges from 15,000 to 20,000 v. depending upon the resistance to charging of the conducting particle. Current drawn across the air gap to the grounded electrode ranges from 0.0001 to 0.0003 amp. Power required for mechanical operations ranges from 1 to 1.5 hp. Capacity ranges from 1.5 to 2 t.p.h. per roll, being higher for the larger particles, for those of higher specific gravity, and for mixtures with the larger differences in conductivity. Series-operated rolls may be arranged to suit the individual requirements of the problem; the Y-type separator consists of four rolls; the first two operated in parallel make finished concentrate and a middling which is combined and scavenged by two rolls in series, the first of these making finished concentrate, the second a middling and a finished tailing. Feed must be within the range 8∼150-m. and closely sized; closer sizing is required at the coarse end. Feed must be so prepared that surface condition of particles is proper for electrostatic separation. In all cases the surface must be dry; in some cases feed must be washed and even given a surface grind (scuff). Temperature of feed at conveying roll should be 150 to 180° F., but material is usually preheated to 220 to 250° F. and then allowed to cool to the lower temperature, in order to take advantage of any pyro- or piezoelectric charging. With feeds that are difficult to maintain at proper dryness, a gas- or oil-fired heating element is located within the hopper. Operating variables are roll speed, electrical potential, the position and orientation of the charging electrode, and the positions of the dividers.

Performance. The NORTON ABRASIVES Co. (G. W. Jarman, Jr., *PC*) uses two electrostatic separators in series to separate fused alumina from silicon carbide. Scrap abrasive wheels, etc., are crushed, washed to remove clay, and kiln-treated to remove resins and other bonding materials. Feed goes to the first roll, which makes finished alumina concentrate, finished silicon carbide concentrate, and a middling product which is treated by the second roll, which also makes three products. Middling from the second separation, about 3% of original feed, is returned to the first roll. Assays: feed 40% SiC, 60% Al_2O_3; carbide concentrate, 99.5% SiC; alumina concentrate, 98% Al_2O_3. Capacity is 3,500 to 4,000 lb. per hr. Other separations currently being made are rutile from zircon; scheelite from wolframite, ferberite, and hübnerite, but principally from pyrite; and stainless steel grindings from abrasive grain (*ibid.*).

Johnson separator, manufactured by the Ritter Products Corp. (Fig. 54), consists of an electrode A (CLASSIFYING ELECTRODE) which separates feed into two products of distinctly unequal sizes, each of which goes to a series of separating electrodes B. The grounded classifying and separating electrodes are cylinders of 3-in. diameter and 8-ft. length made of copper, brass, or stainless steel, the choice assertedly depending upon differences in the nature of the charge developed by friction between the feed and electrode surface. The similarly charged electrodes C are rods of about 1/4-in. diameter. The charged electrodes D are brass cylinders about 1 in. in diameter and are rotated at 75 r.p.m. in the directions shown. Material fed onto the top of A is carried by its rotation into the electric field, where polarization of the particles is induced. The conducting particles with the higher induced moment are subject to an attractive force owing to the convergence of the field, or to an induced polarity of opposite sign. Under the combined actions of the electrical and gravitational forces and the momentum, the conducting

particles follow a trajectory which carries them beyond the normal gravitational trajectory. Since the attractive force depends upon the volume of the particle (see Eq. 35), the trajectory of the smaller of two particles of identical electrical properties deviates less from the normal trajectory. The nonconducting particles have normal gravitational trajectories, which are steeper for the smaller particles. By proper adjustment of dividing edge E, two roughly sized fractions may be made, the coarser particles in the fine fraction being nonconductors and the finer particles in the coarse fraction being conductors. These sized fractions proceed by gravity to electrodes B, where separation is effected. Metal-wool composition pads F serve to discharge any conducting particles which come to rest on the surfaces of electrodes D. Any electrical arrangement of electrode combinations B-D may be made to suit the separation. In the arrangement shown, the first four B-D combinations each side act as roughers to make a clean tailing; the last three as cleaners to make finished concentrate and a middling for retreatment. For small separators a tube-rectifying electrical set is used; for large installations using a single polarity on all charged electrodes a mechanical-rectifying set consisting of a motor, exciter, generator, and mechanical rectifiers mounted on a common shaft is used. The generator output is 110-v. single-phase current, which is stepped up by a transformer and then mechanically rectified. In a heavy-duty separator utilizing reversibility a double-polarity mechanical-rectifying set is used. Energizing power required by heavy-duty sets is 2 hp. starting and 1 1/4 hp. operating; these sets can service units handling 150 t.p.h.

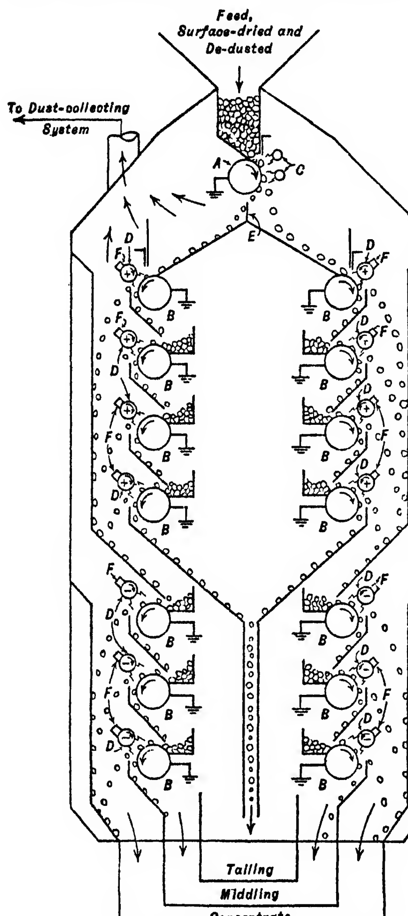

Fig. 54. Johnson separator.

Operation. Electrodes B are operated at 35 to 60 r.p.m.; the higher speeds are used for the finer feeds and for mixtures having a wide spread in conductivities. Potential of charged electrodes of roll A ranges from 3,000 to 6,000 v., of electrodes D from 5,000 to 18,000 v. Current flowing from electrodes D to rolls B averages 0.00005 amp. Power required for mechanical driving of each pair of electrodes is about 1/10 hp. Separating capacity ranges from 9 to 12 t.p.h. each side with 8-ft. rolls; classifying capacity from 25 to 30 t.p.h. Feed must be within the 10~150-m. range and closely sized. As in the Sutton machine, feed must be prepared by washing and desliming, if necessary, followed by surface drying; feed temperatures range from 150 to 270° F. Thickness of feed bed on rolls B ranges from 3/16 to 1/4 in., depending on particle size.

The polarity of electrodes D of the roughers may be the same as or different from that of the cleaner D electrodes, depending upon the reversibility characteristics of the mineral grains. Separation of a mixture of nonreversible minerals or a mixture of reversible minerals of opposite polarity is possible at any potential relative to which one mineral acts as a conductor and the other as a nonconductor, regardless of the polarity of electrodes D. For a mixture of two similarly reversible minerals separation is possible when electrodes D have polarity opposite to that of the minerals and a potential at which one mineral is conducting and the other is not. A mixture of a nonreversible and a reversible mineral is possible regardless of polarity of electrodes D when the nonreversible mineral is the better conductor. When the reversible mineral is the better conductor, electrodes D must have polarity opposite to the reversibility for separation. In all instances the polarity assigned to electrodes D is one for which the spread in conductivities is a maximum, *e.g.*, a mixture of a nonreversible mineral X, conducting at 5,000 v., and a reversible positive mineral Y, conducting at 5,500 v., shows a difference in conducting potentials of 500 v. when electrodes D are negatively charged, and 5,000 v. when elec-

trodes D are positively charged; hence the latter polarity would be used. In the series arrangement of the D electrodes a polarity consistent with the above restrictions and best suited to the separation is used; thus if the separating electrodes are used as roughers, such polarity is imposed as will make the valuable minerals behave as conductors; in cleaning, the polarity is chosen, if possible, so that gangue and middling act as conductors.

The only operating variables at the disposal of the operator are the polarity and potential of the charged electrodes; the other variables, *i.e.*, conveying electrode speed, position of charged electrodes, and position of dividers, are set by the manufacturer at the time of the installation and locked to prevent change in the settings.

Performance. At the Pierce, Florida, plant of the American Agricultural Chemical Co. two double 9-electrode separators are used to upgrade phosphate-flotation concentrate. The first six electrodes, acting as roughers, are positively charged to a potential of 15,000 v.; the last three, acting as cleaners (middlings are recirculated), are also positively charged, but to a potential of 17,000 v. All rolls B run at 35 r.p.m. Each duplex separator has an operating capacity of 16.8 t.p.h. (average of a 6-month period) and produces 16.1 t.p.h. of concentrate. Feed size is <35-m.; temperature 165° F. Operation is continuous. Time loss chargeable to the separator is well under 1%. No labor is required unless the separator is to be shut down or started up. Assays as per cent. B.P.L.: feed, 71.74; concentrate, 76.89; tailing, 14.86. Insoluble in feed is 11.97%; in concentrate, 5.44%. Recovery of B.P.L. is 98.3%, ratio of concentration 1.1 : 1. Two double 9-electrode separators are also used to concentrate washed matrix. Electrodes are arranged as for concentrate but are negatively charged to 15,000 and 17,000 v. All other conditions are the same as for the concentrate separators. Capacity per duplex unit is 26.1 t.p.h. making 18.5 t.p.h. of concentrate. Assays as per cent. B.P.L.: feed, 56.6; concentrate, 71.9; tailing, 19.7. Assays as per cent. insoluble: feed, 29.7; concentrate, 11.2. Recovery, 89.9. Ratio of concentration, 1.4 : 1.

At the Libby, Montana, plant of the Universal Zonolite Insulating Co. (H. B. Johnson, *PC*) two double 12-electrode separators are used to separate vermiculite from a gangue consisting principally of kyanite and pyroxenite. The first nine electrodes are used as roughers, the last three as cleaners; middlings are recirculated. Conveying electrodes are run at 35 r.p.m. Feed to the separators is sized into 6~28-m. and <28-m. fractions, each fraction going to a separate unit; temperature of feed is 250° F. Capacity of each unit is about 12 t.p.h. The kyanite and pyroxenite are both reversible negative, hence charging electrodes may be charged positively or negatively, a positive charge giving somewhat better results. When the electrodes are negatively charged, the coarse-ore separator is operated at 18,000 v. and the fine at 15,000 v.; when electrodes are positively charged, coarse-ore separator is operated at 16,000 v. and the fine at 12,000 v. Concentrates contain 3 to 6% moisture. Assays as per cent. vermiculite: feed, 32%; concentrate, 96%; tailing, 2.5%. Recovery is 96% and ratio of concentration is 3 : 1.

Other electrostatic separations currently practiced (*ibid.*) are: grindings from abrasives, silicon carbide from aluminous abrasives, rutile from zircon, separation of chemical salts, and the cleaning of various food products.

SECTION 14

MISCELLANEOUS METHODS OF CONCENTRATION

The methods of concentration grouped in this section are unrelated on any logical ground except, perhaps, that they are limited in utility, either on the score of limited applicability or limited efficiency or both, and hence constitute a part only—and that usually minor—in any given treatment scheme. They utilize a considerable variety of mineral properties. Thus hand sorting is dependent on one or more of the characteristics, color, luster, shape, grain size, and specific gravity of the materials comprising the crude; amalgamation depends upon the differences in solubility of the ore minerals in mercury; differential grinding depends upon differences in hardness and toughness and is closely allied in principle to scrubbing and washing (Sec. 10); separation by means of decrepitation is closely related to the foregoing method, in that it also depends upon differences in response to a disintegrative force, in this case heat; liquation and retorting likewise depend on differential responses to heat, the first in respect to melting point and the second to boiling point.

HAND SORTING

1. INTRODUCTION

Hand sorting or HAND PICKING is manual removal of selected grades of material from a mass of broken ore. A concentrate of high-grade or SHIPPING ORE is one of the grades commonly selected. Such material may be worth more per ton, on account of its size, than mill concentrate, and, if taken thus early, is not subject to the loss attendant on further treatment. Tailing or WASTE for rejection is likewise frequently made. The advantages of this practice are: (*a*) saving the cost of milling waste, (*b*) increased capacity from a given mill equipment, (*c*) increase in the possible mining rate, and (*d*) reduction in wear on mill equipment. Even if increased capacity is not utilized, there may be marked increase in efficiency because of the reduction in load on the mill. Sometimes both shipping ore and waste are picked at the same operation and a third class, *viz.*, MILLING ORE, requiring mechanical treatment, is the residue. High-grade complex ores may be picked into several classes; as many as 16 have been made at one time at CLAUSTHAL (*4 SMQ 196*). Such close work requires breaking with hammers in addition to the actual sorting (see Sec. 4, Art. 11).

Sledging, spalling, and cobbing are rarely practiced in the United States except around prospects and one-man mines, but they are established practice in many countries where labor is cheaper. At certain CORNWALL mines picking and cobbing produced (*a*) rich copper pyrite, (*b*) coarse rich galena, and (*c*) coarse rich blende, all of which were sent directly to the smelters; (*d*) fine tin oxide, (*e*) pyritiferous milling ore, (*f*) waste. At CLAUSTHAL (1880–1884) six products were made from the original ore, *viz.*: (*a*) copper pyrite, nearly pure, (*b*) mixed copper-iron pyrite with copper predominating, (*c*) the same with iron predominating, (*d*) iron pyrite, nearly pure, (*e*) pyritiferous milling rock, (*f*) pyrite-chalcopyrite-galena-blende-gangue middling. The first four were sold to smelters, the fifth milled, and the sixth further cobbed by expert workmen, producing: (*g*) galena, (*h*) mixed copper and iron pyrite (distributed between (*b*) and (*c*)), (*i*) intergrown pyrite and galena, (*j*) galena milling rock, (*k*) pyritiferous milling rock, (*l*) mixed pyrite and blende. Lots (*i*), (*j*), and (*k*) were accumulated

and milled separately; (l) was further cobbed. These are extreme cases, but they resulted in salable or treatable products from an ore from which such products could then be made only with extreme difficulty, if at all.

When the ore-treatment process is chemical, sorting may be resorted to to remove deleterious substances, such as those that consume chemicals, hinder settling and filtration, absorb and carry valuable solutes into tailing, etc.

Apart from the necessity for removing refuse such as rope, wood, steel, dynamite, etc., from any mill feed, and dangerously deleterious substances from feed to chemical ore-treatment processes, the decision as to the advisability and extent of sorting is purely economic. The cheaper the labor and the more inefficient and expensive the mechanical treatment, the further sorting can be carried and *vice versa*. Undoubtedly sorting could be introduced with advantage in many plants, but just as undoubtedly it is being practiced in some places where economy demands its discard or curtailment. For formulas applying to the economics of sorting, see Sec. 19, Art. 24.

Sorting of some kind is a part of every mining and ore-treatment operation. In narrow ore bodies with distinct walls, much of the country rock that is unavoidably broken in mining is sorted out underground and left at some convenient place, or used for filling. In certain mines in which the ore contains segregated masses of pure valuable mineral, as in some of the Lake Superior native-copper deposits, at DOME, etc., coarse valuable mineral is picked out underground and sent to the surface separately. In general, however, underground sorting is uneconomical on account of restricted working places, poor lighting, poor presentation of material, and the obscuring effect of the fine dirt present. Some sorting to remove wood, rope ends, powder, and tramp steel is done ahead of the primary crusher in practically all mills. This work is, however, incidental to crusher operation and is hardly to be considered as a part of the general problem, although many tons may be sorted daily, *e.g.*, at MIAMI, and the sorted material may carry recoverable value, as at INTERNATIONAL NICKEL.

Picking is much more common with nonmetallic crudes than with metalliferous ores. Whenever valuable mineral occurs as coarse aggregates, or when considerable waste is mined and the mineral and gangue or milling ore and waste are readily distinguishable by eye, the economics of sorting should be investigated. If there is an appreciable difference in specific gravities between valuable and waste minerals, it may be cheaper to sort by heavy suspensoids (Sec. 11, Art. 28).

2. SORTING SURFACES

Sorting is performed on floors, stationary tables, and grizzlies, and on various sorts of moving surfaces such as revolving tables, conveyors of the pan or belt variety (see Sec. 18), and shaking surfaces such as shaking feeders or shaking screens or grizzlies. In modern practice in United States and on the Rand the material fed to sorting surfaces is prepared mechanically and there is little or no breaking during sorting, but in European and some Latin American mills considerable breaking (spalling and cobbing) of the ore is done during sorting (*ante*).

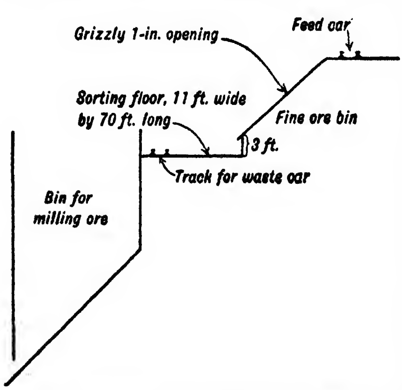

FIG. 1. Arrangement of sorting floor at a South African cyanide plant.

Floors are used for sorting where labor is cheap or where spalling and cobbing are practiced. In its crudest form a sorting floor is any level space with a surface that can be swept up thoroughly, on which the ore to be sorted is dumped and picked over. The usual practice in such sorting yards is to let the work on contract, assigning to each contractor a certain space on the floor, delivery of feed and collection of products being made by the company. With coarsely aggregated complex sulphide ores, such as the German and Austrian lead-zinc-iron ores, Cornish tin ores, and certain Bolivian tin ores, it is possible by such methods to get out high-grade salable concentrates that could not be separated, or could be separated only at great expense, after grinding. The costs of such work are so variable and so dependent on the ore, the products required, and on local custom as to be entirely unreliable for quotation. Sorting floors

were carried to their highest development at some of the Rand gold mines, but have long been superseded by mechanical means for presentation to the sorters and for removal of nonselected material.

Fig. 1 shows one arrangement. The floor was covered with 1/2-in. steel plate. About 550 tons per 24 hr. was fed over the grizzlies by two men per shift. Nine men per shift on the floor dragged the oversize out with heavy 2-pronged rakes, washed it, did some sledging, sorted out about 70 tons of waste per shift, and threw this into cars on the floor, while coarse milling ore was shoveled over into the coarse ore bin at a cost (1896) of about 35¢ per ton sorted. Waste was quartzite and some slate, the ore a cemented conglomerate.

Similar arrangements are relatively common at mines at which ores of residual types are mined, *e.g.*, barite, rock phosphate, and manganese; and either high-grade, milling ore, or waste may be present in separate lumps of considerable size. See Sec. 2, Fig. 135.

The DISADVANTAGES of floors are that all material must be moved manually and that the sorters must work in a stooping position, which is tiring. The ADVANTAGE is thorough inspection, since every piece of material must be turned over and the pickers are not unduly hurried.

Table for sorting is shown in Fig. 2. Feed is delivered by cars or wheel barrows running on the floor at the left and is dumped onto a perforated plate submerged 1 or 2 in. in water in tank *A*. Shovelers standing on this plate work fines through the screen and wash the coarse oversize, then shovel it onto the inclined table *B*. Pickers sitting on plank *C* remove whichever separable component of the feed is present in smallest bulk and drop it below them into proper receptacles, finally scraping the residue through the opening into the tank below *B*.

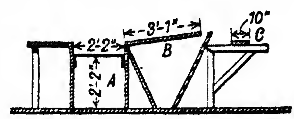

FIG. 2. Hand-sorting table (*after Richards*).

For sorting on a small scale a punched-plate screen set horizontally on horses or the like is recommended as superior to a floor or table (*106 J 412*). It saves stooping, screens out, during the sorting operation, material too small to pick, and the reject is readily hoed off at one end.

Fixed chutes and grizzlies for sorting are of the usual types with the limitations, however, that their slope shall be near the sliding angle of the material (see Sec. 18, Art. 15, and Sec. 7, Table 20) and that the width shall not exceed that readily inspected and worked, *viz.:* about 24 to 30 in. when worked from one side and 48 in. when worked from both sides. If the slope is less than the sliding angle, material is worked along with rake or hoe; if more, the flow is stopped as desired by a board, hoe or shovel inserted into the stream. Such sorting surfaces are not used when a large percentage of the total material is to be removed or when close sorting is desired. They serve principally when rope, wood, powder and steel are being taken out of the primary-crusher feed in order to obviate trouble in the mill. A grizzly makes selection easier than a chute because of removal of fines, but if the particles are tabular or wedge-shaped, the grizzly clogs badly at the low speeds at which material passes and it is, consequently, difficult to control the movement of material.

A sorting grizzly of adjustable slope used at the PORT HENRY IRON ORE Co. at Mineville, N. Y., is shown in Fig. 19, Sec. 7.

Moving surfaces for sorting include belt and pan conveyors, revolving tables, and shaking chutes and screens. Such surfaces have the advantage that manual handling of rejected material is eliminated, but this rejected material is not turned over by or for the picker and material is therefore passed through oversight that should be removed. Further, all material passes at a given uniform rate, irrespective of the content of material that should be removed, with the result that pickers are, at certain times, hurried beyond their capacity and at other times are underworked, if the average speed of travel is right. Notwithstanding these drawbacks, most hand sorting at present is done on movable surfaces because of the advantage of mechanical transport of the reject.

Belt conveyors (see Sec. 18, Art. 6) are the most usual picking surfaces. Belts are commonly 24 to 30 in. wide for a single row of pickers and 36 to 48 in. wide for a double row. Stations for operators are placed 3 to 6 ft. apart along the belt, and chutes are provided at each station for receiving the material removed. These chutes are placed beside the picker or on the opposite side of the belt. It is probable that chutes on the opposite side are best for material up to 3- or 4-in. that can be thrown by a flick of the wrist, but pieces that need two hands are best drawn toward the picker, and it is probably less tiring to draw one-hand pieces larger than 4-in. to the picker's side than to throw them away. Chute mouths should be so large that accurate throwing is not necessary and of such conformation that pieces will not tend to bound out. Speed of belts ranges between 10 and 80 f.p.m.; the average speed is between 30 and 40 f.p.m. The more

difficult the job, *i.e.*, the smaller the pieces and the greater the amount to be removed, the slower the speed and the longer the belt.

Tuttle (*17 SMQ 396*) states that coal-picking belts are usually 4 ft. wide and run at 30 to 60 f.p.m. For picking oversize of a 1 1/2-in. screen at 30 tons feed per hr. he recommends a belt length of 15 ft. plus 10 ft. for each 3% of material removed. On 3/4- to 1 1/2-in. sizes he recommends 30 f.p.m. belt travel and, for a feed rate of 20 t.p.h., 15 ft. of belt for every 1.5% of material removed. For more than 4 to 6% of impurity he recommends washing rather than picking.

The belt should be troughed as little as possible to prevent heaping up in the middle. In many cases a wide flat belt with feed coming on not nearer than 6 in. from the edges is used. A belt conveyor is suitable as a sorting surface for any size of material that can be handled by the pickers, but it will not stand any considerable amount of sledging, and wears excessively with feed coarser than 6- to 8-in. particularly when, as should be the case, the fine material has been screened out. It may be set on a slope not to exceed 20°, and should be sloped somewhat to permit drainage from washed feeds.

For performances see Art. 3.

Pan conveyor (see Sec. 18, Art. 7) is used for coarse material. The arrangement is similar to that described for belts. The speed is usually slower, both for mechanical reasons and because larger lumps are handled. A pan conveyor will stand sledging and is less subject than belts to wear from large lumps. The best form for sorting is one forming the bottom of a shallow trough, which has, therefore, stationary sides. This permits removal of large heavy lumps more readily than when articulated sides form part of the moving mechanism. At Shuler Coal Co. (*21 CA 1077*), a picking pan conveyor 72 in. wide was run at 50 f.p.m.; it spread run-of-mine bituminous coal about 8 in. deep.

Pan conveyors, if beaded or the equivalent, may be set on slopes up to 30°, although material will pile up somewhat against the beads and not be so well presented as on flatter slopes.

The conveyor may be partitioned longitudinally, *e.g.*, into three strips, with loading onto, say, the two outside strips, and a picked product thrown into the unloaded strip for delivery into a separate pocket at the end.

Revolving table. One form is shown in Fig. 3. A metal picking surface (usually inclined toward one edge) is carried on a structural frame with a circular track running on suitably placed wheels on the supporting frame. The platform is revolved by means of gear and pinion. Feed is introduced through chute A, pickers stand or sit at suitably placed stations around the outer and inner peripheries and throw material removed into appropriate chutes or other receptacles. Reject is removed by a scraper B and falls into chute C. Some tables are supported by ribs from a central spindle, which prevents picking stations on the inner periphery. The usual outside diameter ranges from 16 to 25 ft.; speed is usually between 20 and 40 f.p.m. Some tables are double-decked. The upper deck is about half the width of the lower and 6 in. higher; it receives the selected material, thus presenting both reject and selected material to the inspector.

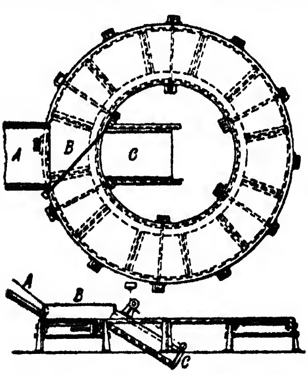

Fig. 3. Revolving picking table.

Revolving tables have been largely used in South Africa and in Europe, but installations in the United States are rare. German tables are 12 to 15 ft. diam., and 12 to 16 pickers work at each table. The cost of sorting on revolving tables on the Rand, where the feed is washed oversize of 1.5- or 2-in. screen, averaging 3-in. size, was 18 to 50¢ per ton, pre-1914. (Truscott, *Witwatersrand gold fields*, p. 413.)

The advantages are compactness with consequent ease of supervision and collection of products; disadvantage, as compared to rectilinear conveyors, is the loss of elevation suffered by the reject.

Shaking surfaces have been used widely in collieries, but, except as primary-crusher feeders have not been used to any extent in metal-treatment plants. They are essentially chutes with perforate or imperforate bottoms, set on an incline of about 10° in the direction of flow and shaken at 100 to 250 @ 2- to 6-in. throws per min. by a simple eccentric. With the Ferraris method of suspension by means of short struts or hangers inclined backward about 15° from the vertical, or with a differential head motion (*e.g.*, Marcus screen) the picking surface may be horizontal. Limitations of width and the arrangement of receptacles are the same as previously discussed.

These are the least satisfactory of the movable picking surfaces for careful picking, but when screen bottoms are used, they serve the triple purpose of screens, conveyors and sorting surfaces and thus justify themselves.

3. OPERATION

Material picked should be that present in least amount in the feed, thus leaving the larger bulk unhandled. Wiard (*112 J 328*) recommends removing ore (one or two classes as the case may be) whenever the tonnages of ore and waste are approximately equal. His argument is that this puts a single and easily defined responsibility on the picker, *viz.:* to remove everything that looks like ore, and makes inspection of the products more simple.

Washing of feed is essential to rapid and accurate sorting. It is usually done in the trommels or vibrating screens removing oversize, but may be done by hose or sprays on chutes, grizzlies, floors, or moving sorting surfaces. Spray water run on to a troughed inclined belt just above the feed point will wash fines down the incline and over the tail pulley where they can be collected in a suitable receptacle. See Secs. 7, 10.

Performances at various mills are given in Table 1.

Handy (*61 A 224*) states that the labor in a typical COEUR D'ALENE sorting plant, in which 800 tons per day, sorted at 1.5- to 4-in. size, yielded 50 tons shipping ore and 150 tons waste, consisted of 20 sorters with 5 bosses and repair men. The normal cost (1917) was 16¢ per ton of run-of-mine rock or 65¢ per ton sorted out. Picking coal on belts in English fields, with the percentage removed ranging from 2.1 to 17.5, the tons picked per worker per hour ranged from 0.03 to 0.35, with the highest tonnage corresponding to the greatest percentage removed; there was general, though not exact, adherence to this rule. (*Louis, p. 98.*) Huntoon (*93 J 53*) gave the cost of sorting 15 to 20% of waste from belts at TONOPAH BELMONT at $0.68 per ton of waste and at TONOPAH MINING CO., $0.80 per ton removed when this comprised 11% of the feed. At INTERNATIONAL NICKEL (*58 CMJ 665*) 7 pickers per shift removed 25 to 30 tons wood per 24 hr. This was burned and high-nickel ash was added to nickel concentrate. Wood chip was blown from belts in roll circuit by fishtail jets to prevent accumulation in circuit and blinding of screens. At HECLA (*IC 6600*), sorting 8~3-in. crude ore on a belt, each sorter removed 12 tons of 50% (Pb) smelting ore, or 25 tons waste per shift at a cost of 20¢ per ton for waste and 35¢ per ton for high-grade ore. At HANNAN'S NORTH, Kalgoorlie (*31 CEMR 333*) 9~1 3/4-in crude was picked on a 3×18-ft. Ferraris table; 22% waste rock was picked off at the rate of 2 t.p.h. per man.

Amount removed by sorting varies according to the ore treated.

With native-copper ores of Lake Superior the amount was as small as 0.001% of the whole at COPPER RANGE. At FEDERAL MINING & SMELTING CO. lead mines and at WITHERBEE SHERMAN magnetite mines 20% total high-grade ore and waste were removed. On the RAND (*20 IMM 307*) material from 8-in. to 1.75-in. constituted 50 to 70% of all rock hoisted. Waste picked out of this varied from 10 to 30% of the total hoisted, averaging about 16%. This constituted about 50% of the total waste hoisted. In IDAHO mills treating coarsely disseminated lead ores, shipping ore picked out varied up to 60% of the total concentrate produced. At SULPHUR BANK (*IC 6429*) 60% of 300 t.p.d. was discarded as waste at 9~1-in. on a 36-in.×40-ft. belt at 40 f.p.m.

Labor is generally that unfit for any heavier work—boys, girls, women, or old or crippled men. Boys and girls are the quicker and, if properly supervised, most satisfactory.

Size of material sorted ranges on the average from 2.5- to 12-in.

Smelting ore as fine as 0.75-in. was picked at the old Morenci plant of PHELPS DODGE and as coarse as 24-in. at the Ogdensburg plant of N. J. ZINC CO., but the number of moves necessary to make tonnage on the small sizes is so great that the capacity of pickers is low, and difficulty in deciding about and handling 24-in. lumps is likely also to slow the operation down below the rate on intermediate sizes. Wiard states (*112 P 327*) that the best size range for sorting is between 1- and 3-in. Richards (*TB 196*) estimates the maximum rate to be on 3- to 4-in. lumps, but Table 1 shows that maximum tonnages per man-hour correspond to feed averaging 6- to 12-in. Comparison between FEDERAL M. & S. CO. and WITHERBEE SHERMAN (Table 1) is particularly instructive since at both mines 20% of the feed was picked as shipping ore and waste and the number of pickers indicates sorting to have been the sole responsibility of the workers. At WITHERBEE SHERMAN 5 tons per man-hour of 4- to 16-in. material was picked against 0.34 ton per man-hour of 1- to 6-in. material at the Federal plant. The high tonnages on coarse material at ALASKA-JUNEAU correspond to easy decision.

Cost of hand picking bituminous coal at different sizes was thoroughly investigated by U. S. COAL & COKE CO. (*Am. I. & S. Inst., 1921*). With labor at $0.55 per hr., the costs per ton, including interest and depreciation on the investment in sizing and picking machinery, for picking at various sizes were as shown in Table 2.

Lighting. An extensive investigation of lighting for picking was made in South Africa, the engineers of the mines and of lamp manufacturers collaborating (*59 MM 234*). Conclusions were that early-morning daylight had a better quality for sorting purposes than afternoon light, and that light from daylight-blue gas-filled lamps made discrimination

easier than light from vacuum-type lamps. It was found that there were appreciable differences in the assays of selected and rejected materials with variations in intensity and character of daylight, and that the changes in selection were gradual and largely unconscious on the part of the sorters. On the basis of this observation, and correlation thereof with the intensities of lighting at which changes in results first began to appear, artificial lighting was arranged for actuation by photoelectric cells so as to cut in artificial light whenever belt illumination fell below 150 ft.-candles and to maintain artificial illumination at a minimum of 160 ft.-candles. Special rectangular reflectors were designed to throw light along the belt but to cut lateral light off below the level of the sorters' eyes. Using 400-watt Osira electric-discharge lamps and reflectors at 4 1/2 ft. above the belts and spaced on 10-ft. centers, the desired light distribution was attained.

Table 2. Cost of hand picking at different sizes (*After O'Toole*)

Size, inches		Cost, dollars per ton of run-of-mine coal
Through	On	
....	4	0.22
4	1 1/2	1.01
1 1/2	1	4.55
1	3/4	7.81
1	1/2	9.88
1/2	3/8	27.63
3/8	3/16	164.38

At Preston East Dome (*62 CMJ 535*) lights are 6 @ 48-in. 40-watt daylight fluorescent mercury-vapor lamps, hooded to about neck level of the operators, and thus 12 to 14 in. above the surface of material on the belt. The mercury-vapor lamps have been widely adopted for coal picking; Mazda Day-blue and Skylight lamps are also used; ordinary incandescent lights have largely disappeared from picking stations.

Table 3. Colors of various minerals under different lights (*After Egeler*) [a]

Ore	Red filter (Mazda)	Sodium	Mazda	Daylight Mazda	Mazda and high-intensity mercury-vapor	High-intensity mercury-vapor
Chalcocite	Red specular	Gray-black; yellow specular	(4) Silver gray	(3) Darker silver gray	(2) Darker silver gray	(1) Purplish hue on deep gray
Covellite	Black	Black	(3) Deep purple	(2) Lighter purple	(2) Deep purple	(1) or (2) Deep purple
Chalcopyrite	Dull red sheen	Green-gold sheen	Yellow brass	Yellow brass; slight hue changes	Greenish gold	(1) Brightest green gold hues, most vivid
Chalcopyrite, bornite, malachite	Pink and gray; malachite gray	Golden gray	Chalcopyrite, yellow brass; bornite, purple; malachite, yellow-green	(2) Same except bornite stands out better	Bornite less purple; malachite brighter green	(1) Malachite bright green. Very contrasty for malachite
Chalcopyrite with bornite	Flat reddish hue	Dull yellow-green with highlights	(2) Purple and dull bronze hues	Purple and yellow brass	Purple and yellow brass	(1) Purple and green contrasting hues with yellow-green highlights
Pyrite	Pink gray with highlights	Yellow with highlights	(3) Deep yellow hue with highlights	(2) Darker yellow with highlights	Yellow, slight green, with highlights	(1) Yellow and deep silver with more vivid highlights
Galena	Black and red specular	Black and yellow specular	(1) Gray-black specular	Gray-black specular	Gray-black specular	(1) Gray-black specular
Sphalerite	Reddish hue, little contrast	Yellowish hue, little contrast	(1) Rich brown and black	Brown	Still lighter brown	(1) Yellow-green
Sphalerite and galena	Black	Greenish black	(1) Gray and brown	(2) Gray and lighter brown	Gray and greenish brown	(2) Gray and greenish brown
Hematite	Gray with black spots	Dull olive with black spots	Brown-black with highlights	Lighter brown-black with highlights	Pale brown, deep choc. with highlights	Pale greenish brown with highlights
Hematite and slate	Black (slate) and pink	Deep olive	(2) Hematite brown-black. Slate gray-black	(1) Hematite lighter brown-black. Slate gray-black	Green-brown, black	(1) Green-brown and gray-black

[a] Numbers in parenthesis indicate order of observers' preferences.

Colored lights affect the appearances of different minerals differently. Hence a light that produces excellent contrast for one ore may not be the best for another. This is brought out by Table 3 (Egeler, *60 CMJ 16*).

Fluorescent light is particularly useful in the case of certain minerals. For a list of fluorescent minerals and their colors see Sec. 19, Art. 9.

Economics of sorting may be analyzed by the methods of Sec. 19, Art. 24. The essential element in such analysis is to compare the monetary yield per unit of production (*e.g.*, ounce of gold, pound of copper) after all charges and allowances. An example of an analysis for the COLD SPRING mine, Nederland, Colo. (W. O. Vanderburg, *IC 6673*), follows:

Example. Run-of-mine ore contains 0.9% WO_3; value at $12 per unit is $10.80 per ton. Sorted ore contains 5.72% WO_3; value per ton, $68.64. Waste rejected in sorting assays 0.025% WO_3, with a tungsten value of 30¢ per ton. Let x = number of tons from which one ton of sorted ore can be produced, and y = number of tons rejected per ton of sorted ore. Then $68.64 + 0.30\,y = 10.80\,x$, and $x - y = 1$. By simultaneous solution, $x = 6.51$ tons r.o.m. per ton of sorted ore milled, and $y = 5.51$ tons waste discarded. Cost of sorting out one ton of milling ore is $1.95. Cost of mining is $2.34 per ton. Transport from mine to mill costs $1 per ton. Milling cost on r.o.m. is $2.85 per ton, and on sorted ore is $3.22 per ton. Recovery on unsorted ore is 80% and on sorted ore 87%. Mill return on r.o.m. is 0.8 × $10.80 = $8.64; costs as above are $2.34 + 1.00 + 2.85 = $6.19. Profit per ton of r.o.m. without sorting is $2.45. Return for one ton of sorted ore is 0.87 × $68.64 = $59.72. Costs are: mining 6.51 tons, $15.23; sorting, $1.95; transportation, $1, if sorting is done at mine, as it should be, of course, under the circumstances; milling, $3.22; total, $21.40. Profit per ton of sorted ore, $38.32; per ton of r.o.m., $5.89. Profit per ton of r.o.m. from sorting is $3.44. The point at which the cost of sorting eats up the profit therefrom is z = $3.44 + 0.30 − 2.45 = $1.29 where $0.30 = 1.95/6.51 = cost of sorting per ton of r.o.m. when profit from sorting was $3.44 per ton of r.o.m. If the waste sorted out yields a profit either from sale or from use as mine support or the like, such profit is to be credited *pro rata* to the sorting operation.

Reef picking is the name given on the Rand to sorting during development work to reclaim and store material of too low grade to rehandle. King and Clemes (*39 JCM 135*) report that in the development of VOGELSTRUISBULT 8,000 tons of >1-in. reef was sorted, containing 8 dwt. per ton (3,200 oz. Au); 6,000 tons 1∼1/8-in. grits was screened out, assaying 3.5 dwt. per ton (1,050 oz. Au), and 100,000 tons of fines, assaying 2 dwt. per ton, was impounded (10,000 oz. Au). This material was substantially all milled in the early months of mill operation at a gross profit estimated at $30,000 per mo.

4. MECHANICAL PICKERS

Several machines have been invented for picking crude anthracite, all built to take advantage of the difference in shape between particles of coal and of slate. The simplest and earliest form, typified by the ZIEGLER picker, consists of a sloping steel chute with a transverse slot in the bottom through which the flat, sliding, slow-traveling slate falls while the rounded, rapidly rolling coal particles "jump" over and pass on to the end. The principal modification of this type is a slate-bottomed chute, which retards slate in the coal more than a steel bottom and causes more rolling of the coal. Another modification of the same device was introduced by shaking the separating chute, which, of course, makes it possible to set the separating surface on a flatter slope and thus save headroom. Another modification is the roller picker, which has a series of transverse spaced rollers across the bottom of the separating chute, the spaces corresponding to the slots in the jump-type pickers. AYERS PICKER consists of a flat apron conveyor traveling up-slope at such an inclination that rounded coal particles roll downhill while flat slate particles are carried up and over the head roller; speed is 150 to 200 f.p.m.

A modification of the Ziegler picker used in separating flat gravel from rounded in a sized product comprised (*34 #10 PQ 42*) an inclined steel chute with just enough water running to keep the bottom wet; flat pieces tended to adhere and slide slowly, whereas the rounded gravel rolled and bounced; an adjustable flap at the bottom made the separation. At another plant (*43 #10 RP 48*) a sized product was fed to boom-type conveyor, 2×6-ft., inclined 30 to 36 in. in 6 ft., with flat idlers running at 160 f.p.m.; round gravel rolled back while flat discharged over the head pulley; 90% efficiency of separation was claimed.

Shaking picker for coal (*44 #7 CA 61*) comprised a surface shaped like a Venetian blind, set at a flat slope with the blinds sloping against the run of the material, blinds adjustable in pitch, the whole shaken and sloped sufficiently to cause material to travel across it. Sized material is fed and the blinds are set to permit slate to slide between but to reject coal.

Spiral picker was the most widely used of the mechanical picking devices. One form is illustrated in Fig. 4. In sliding down the spiral chutes the coal, being rounded, travels

faster than the flat slate, develops a greater component of centrifugal force, and hence works to the outer periphery, and falls off into the larger spirals, which discharge separately from the smaller. Spiral pickers will not work on wet coal, and are of little value for fine coal. They are adjustable for temperature. Each type and size of coal requires a different setting; certain types are not amenable. Feed must be closely sized. Spirals had their greatest success in treating anthracite, because the slaty impurities are tabular while the coal is rounded. They have been supplanted by sink-float separators.

Spiral chutes have also been used for mixing segregated sizes of crushed stone (*43 #11 RP 52*).

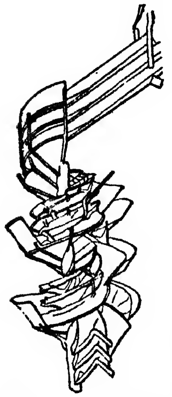

FIG. 4. Anthracite spiral (near side of large spiral cut out to permit view).

AMALGAMATION

5. PRINCIPLES OF AMALGAMATION

Amalgamation is a concentrating process in which metallic gold or silver, or an alloy of the two, is caused to pass preferentially across a water-mercury interface from the water into the mercury, after which the metal-laden mercury (AMALGAM) and the impoverished ore pulp are caused to travel different paths to effect separation. The ore containing the metallic precious metals must be ground fine enough to free them, and should either be in a suspension in the water or at least be moved by it; the mercury body may be fixed in position with the stream of ore flowing past it, or the mercury may be in the form of droplets dispersed through the ore at the time that the selection is made, and be thereafter separated by sedimentation or other means.

Selection. The process depends upon three important properties of the substances involved: (1) that the gold and silver are the only metallic substances in the ore; (2) that they are relatively soluble in mercury and relatively insoluble in water, and are, therefore, wetted preferentially by mercury in the presence of water without formation of a stable three-phase contact angle (Sec. 12, Art. 6); and (3) that the surface tension of the interface water-mercury is high enough (375 dynes per cm.) to cause a metallic particle wetted by the mercury to be engulfed therein while a particle wetted preferentially by the water is similarly engulfed by it. The case is entirely analogous to that of the gangue and conditioned sulphide mineral at an oil-water interface discussed in connection with Fig. 9, Sec. 12, with the difference that the surface tension of the mercury-water interface is so much higher than that of the oil-water interface (which is only 20 to 40 dynes per cm.) that the metal particles are held much more strongly by the mercury, and are even engulfed by it.

Separation is effected by anchoring a film of mercury to a metallic surface, usually plane, over which the pulp flows (plates); or by holding the mercury in a pool by the action of gravity, while the pulp flows across its surface (mercury riffles, traps, etc.); or by utilizing the high specific gravity of mercury and amalgams (13.5; or upward if gold is the amalgamating metal) to effect gravity separation in dilute pulps through which the mercury has been dispersed as droplets by agitation.

The essential operating requirements of the process are maintenance of an interface that is essentially water-mercury, uncontaminated by either liquid or solid films; and presentation to this interface of precious-metal particles with clean metallic surfaces.

Contamination of the mercury-water interface occurs in a variety of ways. The most usual cause of contamination is an oil that is or contains a fatty acid or a fatty-acid salt (GREASE). Most machine and cylinder oils and greases used around mines and mills fall into this category, and a large part of all of such material consumed gets into the ore. The amount is rarely less than 0.1 lb. per ton of ore milled, and at small mines working tight veins in hard rock it may be several times this figure. In the process of grinding, this oil becomes dispersed in small droplets through the pulp, and when such a drop meets a mercury-water interface, the oil spreads thereover instantly. The surface then becomes an excellent collector for sulphides, carbonaceous materials, talc, clays, calcite, lime, etc. (see Sec. 12, Art. 4), and unless the adhering film of such material is scraped away, as by scouring or agitation, access by precious metal particles to the mercury surface is substantially impossible.

Base amalgams ordinarily form by precipitation of metallic ions thrown into solution in the pulp by oxidation of their sulphides. Many of these plate out on iron in acid solution. There is always the probability also, particularly in acid pulps, of galvanic action

in the system, in which metallic mercury and copper or/and iron are in contact with an electrolyte and with each other.

Oxide films. Base amalgams will normally stay bright if not subjected to oxidizing conditions, but they flour (break up into small masses) readily. If they are subjected to oxidizing conditions, most of the base metals oxidize readily, and the oxides, insoluble in mercury, float to the surface thereof and form skins that prevent access of gold to the mercury and encourage flouring. This combination of effects is called SICKENING (see *post*). The base-metal oxides also form insoluble soaps with any fatty materials present, which intensifies sickening.

Sulphide ions are blamed, and probably properly so, for a part at least of the aggravated sickening that occurs with ores containing simple and complex sulphides of arsenic, antimony, and bismuth. The direct evidences against the sulphide ion are: (*a*) that the mercury blackens, and (*b*) that calcining removes much or all of the difficulty (such treatment also removes Sb, As, and Bi, however). Indirect evidences are even more persuasive, *e.g.*, (*c*) pyrrhotite and, to a less extent, pyrite, under oxidizing conditions strong enough to produce acid solutions, and, consequently, some sulphide ion, cause sickening; (*d*) antimony and bismuth sulphides, which are more soluble in strongly basic solutions than arsenic sulphides, are more refractory than arsenic sulphides (see p. 15); (*e*) addition of reagents supplying *e.g.*, Pb^{++} or Cu^{++}, which form highly insoluble sulphides and thus reduce sulphide-ion concentration, is helpful (p. 15); (*f*) addition of strong alkalis, which, with arsenic, antimony, and bismuth, form complex sulphur-oxygen ions with these elements, likewise reduces sickening (see p. 16).

Clean gold. Most lode gold from primary unoxidized ores is bright and clean and, if brought into contact with clean mercury, amalgamates readily and quickly. Gold from oxidized ores, on the other hand, is almost invariably TARNISHED (lightly filmed with a non-gold-bearing film), and frequently COATED (rusty) with a heavy film in which oxides of iron are an important part. Tarnished gold does not amalgamate readily; coated gold will not amalgamate at all. Preparation, in such cases, must be such as will remove the tarnish and coating; mechanical means (grinding) is almost invariably the method employed.

Rose states that when gold is hammered the surface gets hard and is then very difficult to amalgamate, but that annealing restores the ready response to mercury. Head (*134 A 256*) has reported that some rusty gold contains particles of rock driven into the surface. These are possible explanations of the difficulty in amalgamating even the coarser gold in some overground pulps.

Coating with chemical collectors. The fact that at the ST. JOSEPH LEAD Co. mill, Atlanta, Idaho (*IC 6836*), amalgamation of rod-mill discharge was improved by addition thereto of flotation reagents comprising 0.6 lb. copper sulphate, 2 lb. soda ash, and 0.01 lb. ethyl xanthate per ton has been cited as evidence that coating with a flotation collector does not inhibit the amalgamation of gold. The facts are not even persuasive to the conclusion stated. The preponderance of copper ion in the pulp over xanthate ion is so great that the concentration of xanthate ion available for coating precious-metal particles is negligible, so that it must be assumed that there were no collector-coated metallic particles in the pulp presented to the mercury either with or without the xanthate addition. The effect of the soda ash in emulsifying lubricating oil, the stabilizing of the emulsion by sulphides and clay or similar gangues, and the removal of sulphide ion by further excess of copper ion are much more likely explanations of the improvement noted.

Amalgams are defined as alloys of mercury and other metals. Considerable evidence is cited (*Rose*) for the existence of a series of compounds of gold and mercury ranging from $AuHg_2$ to Au_8Hg. Mercury filtered from amalgams contains about 0.14% Au at normal temperatures (*9 Phil. Mag. 468*) and 0.65% at 100° C. (*30 Bul. Soc. chim. 20*); these figures are taken to indicate solubility. The usual mill amalgam made with medium to coarse gold is not completely converted to alloy or compound, but contains particles of gold with alloyed surfaces and unaltered gold cores. The solid amalgam is not readily soluble in mercury. Pressing (*post*) of mill amalgams expresses mercury of a low gold content and leaves a brick containing 20 to 40% Au, according to the force employed, the coarseness of the gold, and the age of the mass.

Apparatus employed for bringing the precious metals into contact with mercury surfaces are (*a*) PLATES, *i.e.*, metallic sheets, almost invariably copper, on which a film of amalgam is held relatively stationary while the gold-bearing pulp is flowed over or splashed against it; (*b*) POCKET AMALGAMATORS, *i.e.*, traps, riffles (Sec. 11, Art. 26) and the like, in which a body of substantially liquid mercury is maintained below and in contact with a stream of pulp; (*c*) PRESSURE AMALGAMATORS, in which it is attempted to bring the gold particles against a body of mercury with a force in excess of the force of gravity; (*d*) MIXING AMALGAMATORS, in which the mercury is caused to disperse through the pulp in relatively small droplets, thus increasing the extent of mercury-water interface and correspondingly the probability of contact therewith by gold particles. In forms *a*, *b*, and *c*, the mercury is relatively stationary; in form *d*, both mercury and pulp are in motion relative to the apparatus.

6. PLATE AMALGAMATION

Plates may be either stationary, or oscillating with a small amplitude; the great majority are stationary.

Apron plates are plane, inclined, of 10 or 12 to 100 or more sq. ft. expanse. When they follow stamps, they are as wide as the mortar or slightly wider, and usually 8 or 10 to 20 ft. long; when they follow a tumbling mill they are ordinarily narrower, *i.e.*, 3 or 4 ft. wide, because of the difficulty in obtaining uniform distribution of the pulp over a greater width.

Construction. The frame (Fig. 5) is a shallow trough with bottom usually of 2×4-in. planed soft lumber (redwood, fir, soft pine) on edge, spiked and through-bolted, with sides of the same lumber, also through-bolted, projecting 3 or 4 in. above the bottom and sufficiently below for bolting to supports as shown. It is essential that the trough be tight against leakage of mercury; it must, therefore, be framed carefully, with ample tightening bolts; litharge in glycerine may be used at joints, but it is probably safer to depend on swelling; both lead in oil and asphalt are likely to introduce contamination whenever the plates are steamed, and the oil would certainly cause contamination in early operations, probably, in fact, as long as it was effective as a seal.

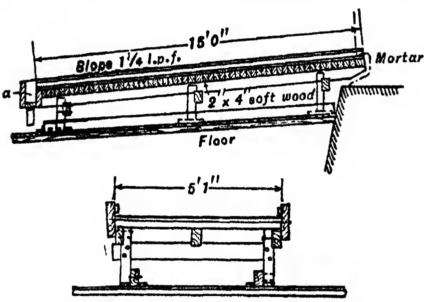

Fig. 5. Frame for amalgamating plate.

Supporting frame should be heavy and rigid and should be completely independent of the battery frame, since vibratory effects on pulp flow are unpredictable and hard to counteract, if harmful.

Slope ranges from 1 to 3 1/2 i.p.f., being low for narrow plates, fine grinding, dilute pulps, and siliceous ores, and relatively steep for the reverse conditions. Adjustment may be provided for in the frame, but it is usually effected, if necessary, by wedging under the feet. The desideratum is to have the pulp flow in a succession of waves or ripples, without deposition of banks; slope and dilution are adjusted to particle size and ore character until the desired state is attained.

Drops of 1/2 in. to 2 or 3 (occasionally 4) in. are frequently provided between succeeding sections of apron plates. These aid in bringing ore particles into contact with plate surfaces, and are claimed to aid in ripple formation. Their primary and obvious effect is contact at the drop, which is testified either by accumulation of amalgam at the drop or by scour at the same point; if scour occurs, the drop is, of course, too great.

Plate is usually of copper (occasionally Muntz metal), not less than 1/16-in. thick, usually 1/8-in., occasionally 1/4- or 3/8-in.; it is screwed to the trough bottom, or held down by side strips wedged under cleats on the side walls. The copper should be of high purity and annealed; it may have an electroplating of silver (2 or 3 oz. per sq. ft.), in which case it is easier to effect the initial setting (*post*).

Area of plate required depends upon the size of the gold, being greater the finer this is; and upon whether amalgamation is the principal means of concentration, or is used only to rough out the coarse, clean gold. Area ranges from about 1 to 6 or more sq. ft. per daily ton, with the average probably between 4 and 5 sq. ft. when amalgamation is the principal process.

Battery plates are plates placed in a stamp mortar. They are usually placed on the chuck block, and may be curved at the top substantially quarter-round, in an attempt to catch gold in the drop-back from the screen in a position that is somewhat protected from the direct splash from the screen.

At Argonaut (*IC 6476*) a vertical-faced chuck-block plate was ribbed horizontally with half-round iron strip, spaced 2 in., which helped protect amalgam. Inside plates are infrequently used nowadays, but at Guysborough 95% of the plant recovery is made in the mortar.

Splash plates are plates set on a relatively steep angle in front of a battery screen, at such a distance that the splash through the screen falls on them with as little impact as is consistent with a reasonable supply of pulp.

At Argonaut (*ibid.*) two such plates were used, 5 in. and 8 in. wide, sloping 3 i.p.f. and 4 i.p.f., respectively, toward the screen, with a 2-in. drop between them, the lower with a 5-in. drop to the mortar lip.

Sluice plates are plates placed in launders, usually between grinding mills and their classifiers, or between grinding-mill classifiers and following apron plates.

At Homestake such a plate in the launder to the classifier was 12-in.×7-ft.; it loaded up in 4 hr. and was replaced by a freshly dressed strip at this interval (*IC 6408*).

Swinging plates are suspended substantially vertically in a flowing stream of pulp either in such a way that the flow of the stream causes an irregular swing, or better, they are mechanical sweeps with sufficient stirring action to raise the layer of settled sand from the launder floor. They are used infrequently, usually with the idea that fine gold will impinge against them with launder velocities.

Shaking plates, usually with a side-shake mechanism similar to that of a side-shake vanner (Sec. 11, Art. 24), are sometimes used when the available headroom is insufficient for apron plates, or when sand packs badly on such plates. They are set on slopes of 1/4 to 1/2 i.p.f. and run at 180 to 200 @ 1-in. s.p.m. Width is usually as great as is structurally possible (5 or 6 ft.) in order to give a thin bed. They give more agitation than is obtainable on a fixed plate and can be operated with thicker pulp. They may be riffled near the head, and should be followed by a trap (*Bul 363 USBM*).

Gibson amalgamator is a shallow rubber-lined riffled box shaken by a shaking-table head motion and having transverse amalgamating plates against which material impinges.

Covered plates. Amalgam is an overpowering temptation to many laborers, and with the conditions that have prevailed since the early 30's, it is cheaper to put mechanical deterrents in the path of the amalgam thief than to depend on the law, despite that locked coverings over plates and stacking them to gain capacity within small enclosures results in decreased efficiency, owing to difficulty in inspection and dressing. A number of forms of boxed-in amalgamators are on the market. All consist of some variant on a tier of small plates in series, rarely totaling in area per ton that of an apron plate, all narrow and hence carrying deep streams, and all depending on multiple drops from plate to plate, with splash plates at the turns, or in some cases, upon impingement effected by motion of the plates, to compensate for the deep stream. None of them affords inspection, of course, without unlocking, and all must be run on a time-schedule so far as dressing (*post*) is concerned.

Preparation of plates (SETTING) is aimed at the production on the upper surface thereof of a sheet of amalgam of such consistency that it deforms readily under pressure of the finger or of a stiff-bristle brush or whisk broom, yet will not weep mercury. To do this involves amalgamating the plate; this requires a clean plate and clean mercury.

Usual procedure is to scrub the plate thoroughly, first with fine sand and later with fine emery cloth until it is free of all stain and tarnish, taking care not to scratch. Some operators use fine sand impregnated with mercury and moistened with dilute cyanide solution or a stronger ammonium-chloride solution for scouring, thus insuring that the mercury is brought to a clean plate. Cyanide was found to be a necessity when nonsilvered plates were coated at PORCUPINE UNITED (*IC 6433*). Silvered plates may then be amalgamated directly with mercury by sprinkling the mercury on and rubbing with a grease-free brush or rag. Copper plate is more usual, however, and silver amalgam is employed for the first application because the catch is easier. Once a catch is effected, the coating is brought to the desired consistency by thinning with mercury or thickening with silver (or plant) amalgam. *Rose* states that about 0.21 oz. Hg and 0.08 oz. Ag amalgam per sq. ft. is required for setting new plates, and that it is desirable in the case of copper plates to set them several weeks before putting them into service. Chapman recommends 0.5 oz. Hg and 0.25 oz. Ag per sq. ft. (*Bul 138, Ariz. Bur. Mines*).

Muntz metal (60 Cu, 40 Zn) plates are said to be better than copper plates for heavy-sulphide and arsenical ores, because of greater resistance to sickening, and for custom mills because of easy, rapid, and more complete clean-up, owing to smaller penetration by the mercury. They do not require aging after the first setting. Stains can be removed with sulphuric acid. Amalgamation is effected by first cleaning by scouring with dilute sulphuric acid, then making a first catch by hard rubbing at one spot with mercury and a flannel cloth and then working more mercury in across the caught spots. Muntz-metal plates are not as satisfactory as copper for highly acid ores (*Rose*).

Purification of mercury is effected by distillation followed by acid treatment of the distillate. Gross impurities are first removed by straining through tight canvas, chamois, or the like. Lime, to take up fatty acids, and iron filings, to take up sulphur, are placed in the still. Some base metals volatilize with the mercury; in part these condense as solids prior to condensation of the mercury (b.p. = 675° F.). Zn, Cu, Fe, and Sn may be leached out of the distillate by shaking with dilute HCl, or by placing a layer of dilute (1 : 3) HNO_3 over the mercury and stirring occasionally. Other methods are to drip the mercury repeatedly through a long column of $HgNO_3$ or dilute HNO_3, or to shake with aqueous solutions of strong oxidizing agents ($FeCl_3$, H_2SO_4, $K_2Cr_2O_7$), or to blow air through a layer of the metal covered with a dilute solution of HNO_3 or H_2SO_4 (*Rose*). Dilute cyanide solution may also be used.

Pure mercury forms no tail when flowed over a clean surface; when floured it coalesces in water plus metallic sodium, or with an electric current (*Rose*).

Purified mercury should be kept in iron, earthenware, or glass flasks, and should be handled as little as possible, with special attention to exclusion of organic matter of all kinds.

Silver amalgam is made by grinding precipitated washed metallic silver with mercury in a porcelain mortar, adding sufficient silver to produce a mass of buttery consistency (about 1 Ag to 3 Hg). The silver may be made by reducing precipitated AgCl with HCl and metallic iron (*e.g.*, iron nails), or by precipitating silver on copper strip from a dilute solution of silver nitrate (12 to 24 hr. required for complete precipitation). The precipitated silver is loosened from the copper by heating the solution almost to boiling. It should be thoroughly washed and dried before amalgamating.

Sodium amalgam is sometimes used for refractory ores, particularly for those containing arsenic. The sodium content is minute (1 part Na to 2,000 Hg on GUYSBOROUGH ore). It is made by adding

small grains (*e.g.*, 1-mm.) of clean metallic sodium to mercury; it is of proper strength when it will just stick to a clean nail (indicating 0.5 to 2 parts Na to 1,000 Hg). It may also be made by electrolysis (Chapman, *loc. cit.*) using a 10 or 15% solution of sodium chloride over the mercury and an automobile storage battery for current, making mercury the negative pole (insert lead through glass tube immersed in Hg before pouring on the salt solution). Use nail test; 10 or 15 min. electrolysis is usually sufficient.

Chapman (*loc. cit.*) states that sodium amalgam promotes formation of base-metal amalgams.

Operation of Plates

Operation of plates comprises (*a*) DRESSING, *i.e.*, bringing the amalgam coating to a state that is best for catching gold and at the same time resisting scouring and loss, and (*b*) cleaning, which consists in removal of amalgam.

Dressing of plates has several facets. From the mechanical standpoint, it seeks to correct the conformation and consistency of the surface resulting from differences in abrasion and from uneven rates of formation of amalgam; from the chemical angle dressing is directed toward removal and correction of stained and sickened areas. The desirable rippled flow is promoted if the surface is finely ridged transversely to the direction of flow, and such ridging tends also to prevent uneven banking of sand with resultant channeling and staining. Hence the consistency of the covering is made stiff enough to hold ridging, and the finished texture is applied with a whisk broom or stiff-bristled brush which is stroked across the plate. Stiff amalgams also hold mercury well, thus preventing leakage or weeping. On the other hand, the activity of an amalgam surface in catching and holding gold is greater the softer the surface. Hence the consistency sought is the best compromise between these two demands, and in general is as described under ***Preparation of plates*** (*ante*).

Procedure in dressing is to cut off flow of pulp to the plate, wash down fine sand with a hose, at the same time brushing black sand and/or sulphides toward the top of the plate for subsequent clean-up, to soften hard spots by adding mercury and mixing it in by rotary or reciprocating brushing, and then to resurface by transverse brushing, working from the bottom up and from center to sides, finally removing any excess of amalgam or mercury that collects along the edges.

Staining and sickening are evidences of unwanted chemical reactions at the amalgam-water interface between substances derived from the pulp and/or the atmosphere and/or the metals comprising the plate and its amalgam coating. The only element in the system that is not under suspicion in such a case is the gold. Both staining and sickening prevent amalgamation of the precious metals, and cause the mercury to flour and fail thereafter to coalesce.

The general nature of the reactions that cause sickening has been discussed in Art. 5. Remedies have developed by trial-and-error over the years, but can be much more intelligently applied by consideration of the chemistry involved.

Any one pulp comprises a mixture of solids, having more or less chemically active surfaces, with an aqueous solution more or less saturated with salts dissolved from the ore or derived therefrom by oxidation reactions, and containing also solutes and suspended materials picked up by or intentionally added to both ore and water in their travels to the point under consideration. Additionally, in amalgamation practice, there are frequently two or more metals in contact with the electrolyte, and a metallic circuit closure exists, so that electrolytic effects are also present. This is the system with which the amalgamator must deal.

Organic materials containing fatty acids and soaps are much more harmful with ores containing talc and graphite than they are in clean siliceous ores, because they are the means through which these and like ingredients of such ores are held at the mercury-water interface (Art. 5). A small amount of such oils, such as is introduced in mining, is readily tolerated by clean ores, but the amount should be kept as low as possible by use of drip pans in the mill, and by exclusion of surface wash, particularly such as is oil- or grease-contaminated, from the pulp stream. If pulp spill in the mill is likewise minimized to the extent that it can be washed directly to the tailing launder in mill cleanups, one source of difficulty will be removed. Furthermore, pure hydrocarbon lubricants, without vegetable-oil dopes, are satisfactory for most oil lubrication in mine and mill. Such oils are relatively harmless, if fatty acids and soaps from other sources are kept out of the pulp. Greases are thickened with soaps. These are usually lime soaps in the cup greases, and the lime soaps are relatively insoluble in water, or in oil in the presence of water, and have very little surface activity or collecting ability; hence they are not particularly harmful. Soda soap is usually the thickener in stiff greases; it has high surface activity, *i.e.*, it spreads readily at air-water and mercury-water interfaces; it is readily soluble in water, and is an excellent collector, particularly in conjunction with its accompanying oil, for calcium and magnesium minerals, and for heavy-metal sulphides; it must, therefore, be rigidly excluded.

When fatty-acid-bearing oils cannot be excluded from the pulp, their effect can be minimized by addition of lime; this reacts with the fatty-acid ion to form the insoluble calcium soaps, which then tend to adhere more or less indiscriminately to any solid surfaces in the pulp, and thus to minimize

the chance that gold will be smeared. The addition should be made as far ahead of the amalgamating plates as possible in order to give maximum opportunity for reaction and nullification.

Talcose, clayey, and graphite ores low in sulphides can be substantially denuded of these nonmetallic constituents and of organic materials at the same time by running the ground pulp through a flotation machine with a small amount of frother (Sec. 12, Art. 13) as the only reagent added, and operating to make a light fragile froth; this will carry little or no precious metals unless these are in sulphides. If iron sulphides tend to float they can usually be kept down by lime (Sec. 12, Art. 47).

Talc, clay, and graphite will cause no trouble in the absence of fatty-acid-bearing oils.

Heavy sulphide ores are not suitable for plate amalgamation, primarily because of their tendency to form banks on the plate and shield the surface from access of gold. They are usually amalgamated in barrels (*post*). There, if the pulp is kept alkaline, they cause little difficulty unless they contain sulphides of arsenic, antimony, or bismuth, or complex sulphides of the heavy metals of the arsenide or antimonide type. The general prescription for their treatment in the barrel is to do most of the grinding before adding mercury, during this time to maintain the pulp alkaline, and preferably of oxidizing character, and to make the actual time of amalgamation as short as possible. If, during the grinding, ions are present which precipitate or complex the heavy-metal ions brought into solution by oxidation of the sulphides, it is probable that the behavior during subsequent amalgamation will be improved, but the danger of forming scaly base-metal amalgams by electrolytic discharge of their ions is not so great as in plate amalgamation, because of the relatively larger amount of mercury present in the barrel.

Arsenic, antimony and bismuth sulphides are the worst offenders in ores, so far as sickening is concerned. Leaver and Royer (*RI 3275*) report results of laboratory tests as in Table 4. The experiments were made by grinding together 10 parts of the listed minerals, 90 parts sea sand (primarily

Table 4. Mercury losses due to grinding in artificial mixtures of sea sand and the listed minerals (*After Leaver and Royer*)

a Erroneously reported as 66.0.

quartz), water in unrecorded quantity but apparently 40 to 50% of the mixture, and mercury in an amount equivalent to 400 lb. Hg per ton of other solids. Grinding times were 35 min. (which gave a 65-m. grind) and 240 min. (which yielded a very fine pulp). The ground material was subsequently panned, residue amalgamated on a plate, and plate residue floated with amyl xanthate and pine oil. Net mercury losses after the successive treatments are the tabular values. Blanks on sea sand showed no loss after panning. *Rose* states that bismuthinite acts the same as stibnite, but less rapidly. Jackson and Knaebel (*Bul 363 USBM 106*) report that when mercury is sickened by Sb- and As-bearing ores, it becomes black, which indicates the presence of sulphide ion in the pulp. Flynn (*42 CIMM 150*) reports that addition of lead ion to an arsenic-bearing pulp prevents sickening, and a similar report comes from Seal Harbor (*Tref, 10/38*), where litharge is effective to lower the gold content of barrel tailing and decrease sickening. The effect of the lead ion would, of course, be to decrease the con-

centration of sulphide ion in the pulp; it would also tend to precipitate at any solid surface where sulphide ion was available and thus close the surface against further emission of sulphide ions.

Flynn also reports that the addition of 0.7% NaOH, 0.85% As_2O_3, and 1.5% lead acetate or white lead, based on the solid charge to the barrel, made it possible to grind an arsenopyrite ore 9 hr. in the presence of mercury with no mercury loss and a high (80%) recovery of gold, when without the reagents, there was marked sickness, heavy mercury loss (18%), and low recovery. The time-factor effect of the reagents is shown in Fig. 6. The pH of such a pulp, if it contained the usual high percentage of solids employed in barrel grinding, would be high enough to throw much of the lead into plumbite form, in which it is available to sulphide ion (Sec. 12, Art. 10), but not otherwise available in the system, and to dissolve the As_2O_3 as arsenite ion. Excess of arsenite ion in solution tends to hold back decomposition of arsenopyrite, and thus decrease the supply of sulphide ion further.

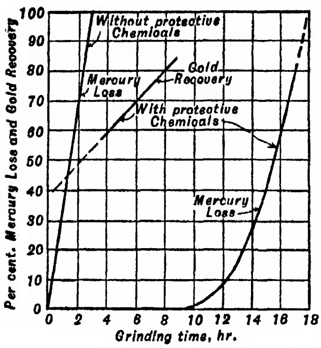

FIG. 6. Effects of time and protective reagents on mercury loss (*after Flynn*).

Sodium amalgam is commonly reported as having some effect against sickening in some cases, notably with arsenical ores, but to be harmful with antimony and bismuth sulphides. The sodium is oxidized by water at the amalgam surface to form sodium hydroxide and hydrogen, as a result of which any metallic oxides at the mercury surface, including mercury oxides, are reduced. The action with arsenic is probably the same as that of strong sodium hydroxide, which tends to complex the arsenic, as discussed *ante;* the continuous formation of hydroxyl ion directly at the mercury surface by decomposition of water by metallic sodium results in high concentration of hydroxyl ion at the interface, although the concentration reckoned on the bulk of the pulp solution is low. Both antimony and arsenic sulphides are soluble in strong sodium hydroxide solutions, with resulting low concentration of sulphide ion. But since the sulphides of mercury and arsenic have much the same solubilities in aqueous solutions, the precipitation of mercury sulphide is low. Antimony sulphide is, however, much more soluble than mercury sulphide, so that when sulphide ion from this source is made available in the presence of mercury, the mercury sulphide precipitates. Bismuth is similar in this respect to antimony.

The sulphides of arsenic, antimony, and bismuth have the further peculiarity that they are collectible by neutral hydrocarbon oils alone (Sec. 12, Art. 6). Since there is always enough fatty acid in any such oils present in an ore to cause them to spread at a mercury-water interface, it is probable that much of the ill effect of these sulphides is due to co-action with lubricating oil, in which case the presence of lime during grinding, or better, conditioning with lime prior to grinding, would go far toward eliminating a part of the difficulty.

Staining is usually a sign of acid pulp. A green stain (VERDEGRIS) is due to copper, and occurs principally at places where the amalgam layer is thin and/or where sands bank. It is probably caused by solution of copper oxides at the mercury surface and precipitation of the dissolved copper as carbonate, in regions of high concentration of copper and/or maximum exposure to air and protection against scour. The stain is removed readily by complexing with cyanide or ammonia (sal ammoniac) or by solution with dilute strong acids (HCl or H_2SO_4).

Brown stains are ordinarily due to iron salts. The usual remedy is to flocculate the hydroxide by making the pulp alkaline; otherwise the stain must be removed by dressing.

Reagents used in dressing plates are ammonium chloride (sal ammoniac), sodium or potassium cyanide, weak solutions of hydrochloric and sulphuric acids, and sodium hydroxide or lye.

Ammonium chloride removes oxide stains and probably complexes copper and iron. It is used both as a solid and, more frequently, as a dilute solution.

Cyanide ion complexes copper and iron readily, rendering them soluble in the absence of excess of the metallic ions; removal of the cyanide ion raises the alkalinity of the remaining solution and thus makes it effective in removing grease. Gold, silver, and mercury are also complexed, however, so that cyanide dressing solutions must be dilute, or concentrated solutions must be used locally and in small quantities, *e.g.*, as by holding a lump of cyanide in tongs just above a wetted stain for a short time.

Acids dissolve base-metal and mercury oxides. Dilute HCl and H_2SO_4 dissolve substantially no metallic mercury.

Alkaline bases are used primarily for saponification of fatty acids, thereby rendering them soluble and causing them to emulsify hydrocarbon oils with which they may be associated. They also tend to disperse clays and talcose materials and thus detach them from a mercury-water interface.

Dressing interval depends upon the rate at which amalgam forms and upon the tendency of the plates to stain and sicken.

At ARGONAUT (*loc. cit.*) chuck plates are inspected hourly and accretions removed and/or mercury added as conditions indicate, while outside plates are dressed at 24-hr. intervals; the ore is clean and

the bulk of the recovery is made in the battery. At St. Joseph Lead Co., Atlanta mill (*IC 6836*), outside plates are dressed every 2 hr.; at Porcupine United (*IC 6470*), every 3 hr. These citations represent usual extremes; average lies between 4 and 6 hr. At Atlanta 0.17 oz. of mercury and 0.86 oz. per sq. ft. of softened amalgam from previous clean-ups are added in dressing. At Argonaut 3 1/2 hr. is required to dress 1,032 sq. ft. of apron plates. At Homestake, where feed for plates is ground in rod mills, mercury for maintaining proper consistency on the plates is largely added through the rod mills in predetermined amounts at 30-min. intervals.

Clean-up of plates consists in removing a more or less large percentage of the accumulated amalgam. The interval ranges from daily to monthly or even quarterly, and the extent of cleaning varies almost as widely. A simple clean-up is typified by practice at Atlanta, where a daily clean-up is made. The battery is shut down, the plate hosed off, the upper half of the plate is scraped hard with a piece of rubber belting, and the loosened amalgam is taken off with a putty knife. The plate is then washed off with caustic solution, hosed, and redressed. Such treatment requires 10 to 15 min. per battery.

Steaming. After several weeks or months of light clean-ups, plates tend to become coated with a hard scaly amalgam which ties up considerable gold and also decreases effectiveness as a gold catcher. Usual practice is to steam such plates and then scrape with a metal scraper. On the Rand (*RMP*), at 3- or 4-mo. intervals, a wooden hood was placed over the plate and steam was turned in for 10 or 15 min. The plate was immediately scraped with a putty knife or similar metallic scraper, taking care not to scratch, and thereafter redressed with mercury while still warm.

When battery amalgamation is practiced, clean-up procedure is much more elaborate. Screens and dies are removed and washed in a tub, the mortar is cleaned out thoroughly, the removed material is panned, and the residue is returned to an uncleaned mortar or ground in a barrel or pan (*post*). Such cleaning, with thorough plate cleaning, and clean-up of all mill traps, may take several days, and constitutes, say, a monthly program at small mills treating high-grade ores.

Since the catch is better on a surface that has a good coating of plastic amalgam than on one that is newly and thinly amalgamated, it follows that thorough clean-ups should be made as infrequently as is permissible from operating and financial viewpoints.

Size of feed. Feed should be fine enough to free the gold and not so coarse that scour is excessive. Feeds as coarse as 8-m. are frequently treated; <1/4-in. feeds have been handled, but scour is so great that unless very coarse gold is thus removed from a coarse stamp-battery discharge, the practice is not justified. Feeds <35-m. and not so fine or slimy that fine gold is suspended are ideal.

Pulp density should be low in order to aid settling of gold; 10 to 25% is the best range (*Bul 363 USBM*).

Heat increases the catch and aids in coalescence of mercury (*Rose*) but also increases the solubility of the ore salts in water and of the base metals in mercury. It also softens amalgam and may increase scouring loss. *Smart* recommends 80° F. maximum. If water is too cold, amalgam becomes hard and crumbly.

At Atlanta water temperature is held to 45° min. in winter by heat exchange on Diesel cooling water. Temperature of 150° in barrel amalgamation at Wendigo is noted in Art. 4.

Old plates develop uneven surfaces and holes and must be discarded. They contain considerable gold, even after close scraping. Recovery (scaling) consists in first heating gently, as over a log fire, to less than red heat, to expel mercury, then pickling for 8 or 10 hr. with dilute HCl, then heating to a dull red heat and quenching in cold water. A loose scale is thus developed on the working side of the plate. It is collected and boiled in HNO_3 to dissolve out copper and other base metals.

On the Rand (*RMP*) scaling was done without the preliminary removal of mercury by treating 15 min. with a paste of NH_4Cl, 1/2 lb.; KNO_3, 1/2 lb.; HCl, 1/2 lb.; H_2O, 1 lb., applied with a soft brush. The plate was then heated until black, requiring about 1/2 hr., and quenched in water. Scale was melted in a crucible in a charge comprising 1 part each of scale, sulphur, borax, and sand; or 100 scale, 50 borax, 25 sand, and 8 MnO_2.

A copper plate absorbs about 1/4 oz. Au per sq. ft., mostly in the first week. Electrosilvered plates at a Colombia mill are reported to have yielded 3 to 5 oz. gold per sq. ft. after 2 yr. service (*Rose*).

Electrolytic amalgamation, in which a potential difference between the mercury surface and the pulp is set up by immersing an electrode in the pulp and making the mercury the other electrode, has been proposed many times. Shepard (*134 A 265*) reported experiments indicating some enhancement of recovery under laboratory conditions, but no particular promise of practical advantage.

7. POCKET AMALGAMATORS

Pocket amalgamators are devices in which liquid mercury and amalgams are held in pockets while the pulp to be amalgamated is flowed over them. Traps and riffles are the common forms.

Traps are boxes placed in the flow of a stream of pulp in such a way that the level of the outlet is above the bottom of the box. There are many forms. They are best so designed that the velocity of the stream is somewhat slowed in passing through them, that the heavier sand in the stream forms a teeter column in the box, but not a settled bed, and that the outlet is sufficiently removed from the lowest part to minimize scouring out of mercury and amalgam. The commonest form is that made by putting a submerged weir in the cross launder at the end of the apron plate (see *a*, Fig. 5); if this discharges at one end, a low stop will serve; if a central pipe discharge is used, as indicated in Fig. 7, the pipe may be carried up 2 or 3 in. above the floor of the launder, with a hood to divert any direct by-pass from the plate. Such a launder trap will catch and hold all of the coarse and much of the fine amalgam that comes to it, despite that most of the bottom up to the level of the outflow is sanded up and inactive. It also yields a relatively large bulk of material to be cleaned up (*post*).

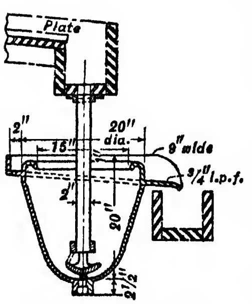

FIG. 7. Mercury trap.

At ST. JOSEPH LEAD CO., Atlanta plant (Sec. 2, Fig. 74), such a cross trap is made 8 in. deep, and is cleaned up once a day; the usual yield is 1/2 to 1 lb. of quicksilver and amalgam, but occasionally, when the plates are working improperly, half of the normal plate yield is made from the trap; a 24-riffle section in the launder following the trap yields about 0.5 lb. of concentrate per week, most of the amalgam and mercury in it being badly fouled, which attests the efficacy of the trap.

Fig. 7 shows a form of trap commonly used to contain a pool of mercury and to amalgamate in addition to its action as a settler for lost amalgam. Fig. 50, Sec. 2, shows a hydraulic trap used at TALACHE (Sec. 2, Fig. 49). These traps are frequently provided with draw-off valves for thin amalgam, which permits longer operation without a clean-up. Traps such as these are highly effective in catching coarse gold, but catch little fine because of rapid rising current.

Riffles (Sec. 11, Art. 26) are frequently used as mercury traps. Procedure is to run the sluice until the inter-riffle spaces have filled with sand and leaks have stopped, then to add mercury slowly to the head of the sluice line, permitting it to find its own pockets, until the desired condition in the riffles is reached. This is when the head-end riffles show clear pools of mercury well up to the top of the riffle cleats, the depth below the top depending upon spacing of riffles and the size and quantity of gravel. Amount of mercury required for charging is given by *Bowie* as 225 lb. for 200 to 300 ft. of 6-ft. sluice, and 80 to 90 lb. for 24 ft. square of undercurrent; Gardner and Johnson (*IC 6787*) report charges on dredge tables (Sec. 2, Art. 21) of 150 to 3,000 lb. for 1,000 to 100,000 sq. ft. of table, common practice ranging from 0.1 to 0.25 lb. per sq. ft. of table area. Usually only the upper 2 or 3 boxes are charged. Subsequent additions are made as required to keep amalgam soft at the head of the line.

Hosking amalgamator, used at FRANCOEUR GOLD MINING CO. (*Bul 342 CIMM 323*) for very fine gold consisted of a battery of parallel 8-in. launders, 5 ft. long, with 8 baffle riffles each, each with 10 cc. of mercury, the assembly receiving a bumping motion from a cam and shaft. On settled sands such motion causes reverse classification.

Gold pan is frequently used to run down small amounts of gold-bearing concentrate with mercury. Charge of concentrate is 5 lb. or less according to the black-sand content. One oz. to 1/4 teaspoonful of mercury is sufficient for a pan load. Copper or copper-bottomed pans are used when it is desired to use the pan as an amalgamator in primary service. It is set, dressed, and cleaned as for plates (*ante*). The sand must be fine; coarse sand and gravel scour the amalgam.

Centrifugal amalgamators are devised on the theory that by multiplying the sedimentation effect on fine gold particles in water (Sec. 8, Art. 13) they can thereby be brought into contact with mercury and be caused to amalgamate. The usual device is a bowl centrifuge with sloping sides, finely riffled circumferentially to hold mercury. They have not been highly successful, because fine sand packs in above the mercury and prevents access of subsequent sand thereto.

8. GRINDING AMALGAMATORS

Grinding amalgamators are used for cleaning of concentrates in which the gold is rusty and difficult to amalgamate, or is very fine, or is locked with other minerals, or is in an

ore which requires high concentrations of protective reagents and agitation to effect amalgamation and/or prevent sickening of mercury. The usual apparatus is the amalgamating barrel; less frequently a grinding pan or a mechanical mortar is used.

Barrel Amalgamation

Amalgamating barrel (Fig. 8) is (usually) a batch-type tumbling mill, trunnion- or gudgeon-mounted, ordinarily with a manhole for charging, and with or without other openings for discharging. SIZES range from 18(diam.)×24-in. to as large as 4×6-ft.; usual sizes are 2×3- and 3×4-ft. TUMBLING CHARGE is usually small and in large units, *e.g.*, 1 or 2 pieces of 4- or 5-in. shafting, or half a dozen 4- or 5-in. balls, but equal or greater weights of, say, 1 1/2-in. balls are used when liberation rather than mere brightening is a major element in the operation. SPEEDS are low in order to minimize agitation, substantially always below cataracting speeds. PULP DENSITY is high (80% solids) or low (20 to 30% solids) according to whether the aim is to impregnate the pulp with mercury droplets or to maintain the mercury in a pool. LINERS are usually omitted, because of the tendency of gold and amalgam to catch and hold in the crevices thereof, but rubber-lined mills may be used (*Bul 342 CIMM 328*). At LEITCH GOLD MINES, Beardmore, Ont., rubber lining in a 2×4-ft. barrel showed little or no wear in a year, with a daily 4-hr. grind of 600 lb. of jig concentrate with lime and lye (*ibid.*). CONTACT TIME with mercury ranges from less than 1 hr. (50 min. at PILGRIM, *IC 6945*) to several hours. When the ore has a tendency to sicken mercury and yet considerable grinding is required, it is usual to do most of the grinding first, then introduce mercury and run for a short period to effect amalgamation.

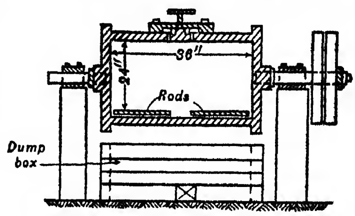

FIG. 8. Amalgamating barrel.

Reagents used depend upon the character of the ore and impurities. Since agitation serves to keep clean mercury surfaces exposed to the pulp, the important end is to prevent such flouring and sickening that subsequent coalescence cannot be effected.

Alkalis in the form of NaOH, KOH, Na_2CO_3, CaO, or $Ca(OH)_2$ are added to combat organic contaminants. Usually lime is used for gravity concentrates (*e.g.*, from stamp mortars, traps, mineral jigs, and tables) and lye or caustic soda for flotation concentrates, where higher alkalinity is necessary to dissolve or decompose collector coatings.

Ammonium chloride is used for the same purposes as in plate amalgamation (Art. 6).

Oxidizing agents. Potassium bichromate or potassium permanganate are sometimes used (WENDIGO; *Tref, Bul M4B12*) with ores tending to yield sulphide ion (Art. 6) in order to oxidize it and thus prevent sickening. The bichromate is also claimed to brighten brown and tarnished gold.

Cyanide is sometimes added in relatively small amounts. *Janin* cites an instance in which use of 1/4 lb. of cyanide per 1,000 lb. of riffle concentrate cut the mercury loss 30 lb. per 100 tons of sand, *i.e.*, from a 20-lb. loss to a 10-lb. gain.

Plumbate-arsenite mixture. See Art. 6.

Operation. CHARGE of pulp plus tumbling bodies should be from 1/3 to 1/2 of mill volume. If grinding is important, PULP DENSITY should be 60 to 80% solids; if amalgamation only is sought, it is usual to operate at 30 to 50% solids. If the pulp is refractory, and addition of mercury is deferred until grinding is substantially complete, pulp is often diluted at this time. HEAT is sometimes employed, particularly when the charge is largely amalgam, as in battery and sluice clean-ups. The amount of mercury added depends upon the richness of the ore; *Rose* recommends 20 lb. minimum for a 700-lb. charge of concentrate; more if the grade is high.

Mill Practice

At ARGONAUT (*loc. cit.*) the residues from battery clean-up were ground 12 hr. with 3 pieces of stamp stem; 350 oz. mercury was then added and grinding continued for 1 to 2 hr. more. The gold extracted was $11.44 ($20 gold) per oz. of mercury fed. The mill discharge was jigged to recover amalgam.

At PILGRIM (*IC 6945*) unit-cell concentrate was charged continuously with 2-lb. NaOH per 24 hr. to an 18×34-in. barrel containing 30 lb. sodium amalgam, and one piece of 5-in. shafting and running at 26 r.p.m. Recovery was 96% with a clean-up every 2 or 3 days. Tailing and cleaner concentrate went to a 20-in.×10-ft. 2-compartment mill with a piece of 5-in. shafting and 30 lb. of sodium amalgam in each compartment. One-half gallon of hot water was charged per min., and contact time was 50 min. Clean-up for this barrel was bimonthly. There was very little flouring or loss with current concentrate, but on old concentrate recovery dropped to 50%.

In NOVA SCOTIA battery and gravity concentrates are arsenical, highly toxic, and contain very fine gold (10- or 20-μ and smaller) (*Flynn, loc. cit.*). Practice is to grind for 1 1/2 to 2 hr. with a few balls

and a little lime, then add 20 to 30 lb. of mercury, run for 1 hr., dilute and dump. Rejects are sent back to the stamps. Longer running after mercury addition results in high losses of mercury and gold.

In the larger RAND mills (*Rose*) concentrate was fed continuously by hand to 4×6-ft. tube mills discharging to shaking plates to settling boxes whence the overflow went to cyanidation, and the settlings, after panning, were returned to the clean-up tube mill.

At RED ARROW (*Tref Bul M7B8*) 50 lb. of mineral-jig concentrate is charged with 60 lb. of 1- and 2-in. balls and 20 lb. of mercury, with enough water to make a pulp of 80% solid, sand ground 2 1/2 hr. Gold is clean and bright. Feed contains 50 to 200 oz. Au per ton; tailing, containing 0.8 oz., is sent back to the jig.

At CENTRAL ZEBALLOS (*Tref Bul M7B8*) 500 lb. concentrate containing 113 oz. Au per ton is charged, with 300 lb. @ 4-in. balls and 200 lb. @ 2-in. balls, 1 1/2 lb. each of NaOH and NH_4Cl, 5 lb. CaO, and enough water to make a pulp of 80% solids, to a 2×4-ft. rubber-lined barrel, and is ground for 17 1/2 hr.; 10 lb. mercury is then added with a further addition of 1 1/2 lb. each of caustic and sal ammoniac, the barrel is filled with water, and rotated at reduced speed for 4 hr. more. Discharge is then started through a 1/4-in. opening and the pulp is run out while rotating into a splash box, discharge time being about 1 hr. Pulp from the splash box runs to a mercury trap and thence over blankets. Blanket concentrate is returned to the barrel with the next charge; blanket tailing (0.5% >100-m.; 23 oz. Au per ton) goes to the concentrate thickener Cost of amalgamation and refining is 24¢ per ton milled.

At WENDIGO (*Tref Bul M4B12; Bul 342 CIMM 414*) charge for a 3×4-ft. barrel is 800 lb. concentrate (pyrrhotite, pyrite, chalcopyrite) at 40 to 50% solids, 35 lb. $Ca(OH)_2$, and 4 to 6 lb. $K_2Cr_2O_7$. This is heated with steam to 150° F. and is then ground 8 hr. at 24 r.p.m. with a charge of 50 lb. of 1-in. balls; 30 lb. of mercury is then added and grinding is continued 30 to 45 min. Product is run through a Pierce amalgamator and over a plate. Tailing carries 0.5 to 0.75 lb. Au. Use of sodium amalgam instead of dichromate caused bad sickening, a mercury loss 4 1/2 times normal, and a tailing assaying 2.1 oz.

At GOLDEN ANCHOR (*IC 7024*) gravity concentrate from the grinding circuit is ground 6 hr. with mercury, lye, and about 1 doz. 4-in. balls. Recovery is 76% on plant feed. Tailing, 14 oz. Au per ton, is shipped.

At GOLDEN CHARIOT (*15 MMt 443*) blanket and riffle concentrates from a quartz ore are ground 2 or 3 hr. with a small number of 4-in. balls, 2 lb. soda ash, and about 1 oz. NaOH.

At ALASKA-JUNEAU (*IC 6236*) a gravity concentrate assaying $20,000 to $30,000 per ton is charged to a 2×4-ft. barrel with 600 oz. of mercury (cleaned in HNO_3) and 3 lb. slaked lime, and is ground 5 to 6 hr. at 30 r.p.m. with one piece of 6-in. shafting. The mill is discharged, while running, through a 1/2-in. hole into a 4-ft. mechanical batea which overflows a galena product assaying $75 per ton in gold. The amalgam, cleaned further by hand, contains 60 to 65% Au. Mercury loss is 1%.

At PORCUPINE UNITED (*IC 6470*) grinding time in a 16×36-in. mill was 10 hr. with 250 oz. mercury and 3 lb. slaked lime, using worn balls.

At GLOBE & PHOENIX mine, Southern Rhodesia (*51 IMM 253*), corduroy and trap concentrates containing pyrite and stibnite with some pyrrhotite, tetrahedrite, and chalcopyrite, are ground in pans, aerated by blowing in a 5 : 1 pulp for about 12 hr., and, after settling and decantation, are amalgamated in a barrel without further grinding. Introduction of the aerating step reduced mercury consumption 80%. Amalgamation tailing re-enters the concentrating circuit, and is therein subjected to magnetic concentration to remove iron introduced by the pans.

At PRESTON EAST DOME (*62 CMJ 535*) 1,900 lb. per day of mineral-jig concentrate from the grinding circuit is charged to a 3×4-ft. rubber-lined barrel with 12 lb. CaO and 3 lb. NaCN and is ground for 8 hr. The barrel is then opened, filled with water, rotated to mix, the charge is allowed to settle, and the solution is siphoned off. Fresh water and 40 lb. mercury are added and the barrel is revolved at low speed for 30 min. The charge is run to a cone elutriator, overflow to a plate, plate tailing to cyanidation. The high cyanide charge is justifiable since all solution goes to the cyanide plant. The ore contains about 0.02% As and 0.85% S. Mercury consumption averages 1.8 lb. per day; gold recovery is 59% of total plant recovery.

Grinding amalgam. At ATLANTA (*loc. cit.*), clean-up amalgam is ground 3 hr. in a laboratory ball mill with hot water and enough quicksilver to make the amalgam soft. It is then washed with hot water to remove sulphides, cleaned with a magnet to remove metallic iron, and wiped dry with a cloth. A part is set aside for dressing plates (see Art. 6) and the balance is squeezed to about 60% Hg.

Concrete mixer as amalgamator is recommended in *IC 6787* for cleaning up pan residues from sluice-line clean-ups. A charge of 2 or 3 pails in a 1- or 2-ft. hand- or power-driven mixer, with 1 or 2 lb. of quicksilver and a few 3- or 4-in. cobbles, run for 1 hr., is prescribed, with panning of tailing. Pan tailing might well be sent back to the sluice line.

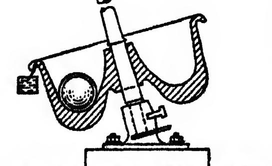

FIG. 9. Berdan pan.

Pan Amalgamation

Pan amalgamators are the Wheeler pan (Sec. 5, Fig. 81), the Berdan pan (Fig. 9), and similar mechanisms. Wheeler pans range from 1 to 6 ft. in diameter.

The Berdan pan is usually from 3 to 5 ft. in diameter, 18 to 24 in. deep, tilted 20 to 30° from the horizontal, and run at 10 to 30 r.p.m. It has 1 to 3 large cast iron balls. It has low capacity as a grinder but is a good amalgamator for <1/4-in. feeds.

An arrastre (Sec. 5, Fig. 79) may also be used, but is slow and more difficult to clean up.

Operation may be either batch or continuous, usually the former. Pulp density during grinding in a Wheeler pan is usually the highest that yet gives sufficient fluidity not to put excessive strain on the machine. Charge recommended by *Rose* for a 5-ft. Wheeler pan with 14-in. walls is 300 lb. and he recommends 12 to 14 r.p.m. for such a pan. In *IC 6787* a speed of 60 r.p.m. (diameter uncertain) is recommended, with a pulp density that will keep mercury suspended. Time of grind is 1 to 4 hr. Rough separation in both types of pan is made by gradual dilution and overflow, with final clean-up in a gold pan.

A pan differs essentially from a barrel for cleaning up sulphidic concentrates in that the pan pulp is thoroughly aerated, whereas the barrel pulp is ground under conditions of restricted oxidation. Hence where oxidation is desirable the pan should ordinarily be employed.

9. RETORTING AND MELTING

Separation of the bulk of the mercury from the precious metals and reclamation of the mercury are effected by filtration and retorting. The last of the mercury (1 1/2 to 2%) is driven off from the gold, and some impurities are slagged off by melting with suitable fluxes. The steps in the operation are (*a*) cleaning the amalgam, (*b*) filtration, (*c*) retorting, (*d*) melting, (*e*) casting the bullion.

Cleaning amalgam consists in thinning it by addition of mercury, if it is not already thin (*e.g.*, sluice amalgam); working it by hand in a gold pan, or with a pestle in a mortar, or by power in a small clean-up pan, usually in hot water, to cause insoluble material to be freed and float, and perhaps to grind particles of locked middling; separating the freed material by overflow, skimming, and with a magnet, with intermediate pouring back and forth in clean porcelain containers to aid in bringing extraneous material to the surface.

Filtration is effected by pressure. In small-scale work the amalgam is squeezed by hand through a strong, tight fabric such as heavy muslin or canvas, the filter being held under water to prevent spirting of the extruded mercury. On a larger scale a plunger press, mechanically or hydraulickally driven, or an air press is used.

At Atlanta an air press consisted of a 3-in. pipe, 13 in. long, capped at both ends. The lower cap was drilled with 1/8-in. holes on 1/4-in. centers; the upper cap had a flexible air connection. In charging, a 60-m. wire screen was placed in the bottom and was covered with 2 thicknesses of tight muslin. The soft amalgam was then charged, the top screwed on, and, after blowing condensate from the air line, air at 100 lb. pressure was admitted.

Brick amalgam after hand pressing contains 60 to 70% Hg; after power pressing it may contain 60 to 70% Au. The expressed mercury contains about 0.15% Au at normal temperature. Hand-pressed brick will usually weep a small amount of mercury, if permitted to drain for a few hours in a funnel; such draining is normally permitted.

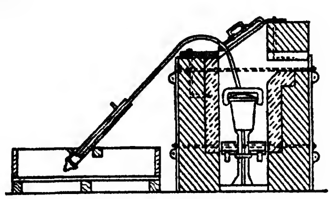

Fig. 10. Pot retort.

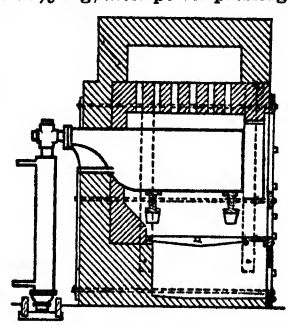

Fig. 11. Horizontal retort.

Retorting is done in pot-type (Fig. 10) or cylindrical (Fig. 11) retorts, according to the quantities handled. The retort is usually coated with chalk, clay, slime, or a mixture of fire clay and graphite, then thoroughly dried and charged with broken amalgam brick to a level such that the level of the molten charge will be well below the outlet (1/3 to 1/2 full) in order to prevent puking. The retort cover is luted on with an asbestos gasket and, usually, a fire-clay paste, and a water-cooled condenser commonly comprising an inclined pipe *a* and an enclosing water jacket *b* (Fig. 12) is attached. The condenser is arranged to discharge under water *c*

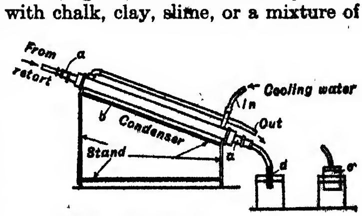

Fig. 12. Mercury condenser.

or into a wet sack *d*, the important factor being to insure that an insufficient volume of water can be forced back, in case the fire fails, to fill the condenser pipe and run into the retort. The retort furnace should be such as to permit application of heat to all sides of the retort and well up to the bend in the outlet riser of a vertical retort, *i.e.*, with a long flame as with oil or wood. In large retorts treating amalgam from base-metal ores, the outlet pipe may choke just beyond the heating zone, owing to condensation of lead and zinc; a poke-hole should be provided for dealing with such a contingency.

Heating is started slowly and the temperature is brought up to the boiling point of mercury (675° F.) in 10 to 15 min. Here the fire is checked and regulated to maintain a steady trickle of condensate over a period of several hours until distillation ceases, when the fire is increased slowly until the retort comes up to a bright red heat, where it is held for a few minutes. The fire is then drawn and the retort allowed to cool until it can be opened.

Caution. Care must be taken during distillation and at the time the retort is opened to guard against inhaling mercury fume.

Retort sponge that has been finished hot contains 1 to 1 1/2% Hg; the vapor contains only a trace of gold.

Retort capacities range from 1 lb. to 200 lb. of amalgam.

Shovel retorting is frequently practiced in small placer operations when the value of the mercury in the small quantities of amalgam handled is less than the cost of reclaiming it. It consists simply in placing the amalgam in a shovel, frying pan, or the like and heating over an open fire until the mercury is driven off. Tinned or galvanized metal should be burned to a red heat and scoured free of coating before use for such service. The heating surface should be clean, and the amalgam should be placed on 2 or 3 thicknesses of paper before heating starts to prevent sticking. Care must be taken, as by working outside, or in a well-ventilated enclosure, to avoid inhaling mercury vapor.

Potato condenser is made by digging out in a half of a large raw potato a central cavity about twice the diameter and height of the piece of amalgam to be shovel retorted. This is then placed over the amalgam during the heating. It condenses some of the mercury, which can be recovered by triturating and panning.

Melting is done to reduce gold to a compact form in which danger of loss in handling is reduced, and to reduce impurities in so far as this can be done as an incident to simple melting and casting. Except where large quantities of gold are to be handled, when special tilting furnaces are used, melting is done in graphite crucibles, which should be sound and be dried by heating for several hours well above the boiling point of water. The charge consists of the retort sponge and, if the sponge is relatively pure, sufficient borax glass to form a cover at least 1/2 in. thick above the molten bullion. If the sponge is dark colored and dirty the flux should contain silica and soda in addition to the borax, and if sulphides are suspected, some niter.

At ATLANTA a charge consisted of 560 oz. sponge, 5 lb. soda ash, 2 lb. borax glass, and 1 lb. powdered silica. Fusion in an oil-fired furnace required 4 hr. At TALACHE a small amount of niter was added additionally.

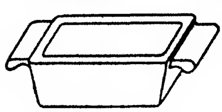

FIG. 13. Bullion mold.

Weight loss in melting ranges from about 0.5 to 7%.

Casting is done in iron molds (Fig. 13) which are brick shaped, with walls converging downwardly. The mold should be heated, and thoroughly smoked, or coated with a heavy oil such as cylinder oil or boiled linseed oil before pouring. Slag should be saved for sale or for plant retreatment. Slag adhering to gold may be loosened by washing with nitric acid.

10. AMALGAMATION PERFORMANCE

For flowsheets and metallurgical results at particular mills see Sec. 2, Arts. 21, 22.

Recovery of gold by plate amalgamation supplemented by grinding amalgamation of battery and trap concentrates ranges from about 60 to 97%, depending largely upon the character of the ore. SILVER RECOVERY is usually 20 or 30% less than gold recovery. With the lower recoveries, amalgamation is supplemented by concentration or cyanidation except in the smallest and crudest plants. With such supplement amalgamation is justified because of its cheapness and speed in producing bullion and cash returns. Thus at TALACHE the COST chargeable to amalgamation was only 6¢ per ton of mill feed out of a total milling cost of 64¢. At HOMESTAKE (Sec. 2, Fig. 51) the cost of scalping out coarse gold by amalgamation is 2.85¢ per ton of mill feed.

Mercury loss depends upon the minerals in the ore, the state of oxidation of the ore, the amount of agitation and/or scour to which the mercury is subjected, the purity of the mercury added and the degree to which it is contaminated before recovery, the means of recovery and of guarding against loss, pulp temperature, and the care and skill of the

operators. Loss in sluices is normally 5 to 10% of the mercury added, and may run up to 25% under adverse conditions such as steep slope, heavy gravel, and leaky sluice lines (*IC 6787*). At Oroville losses ranged from 2 1/2 to 5% on the large dredges and ran up to 5% on the smaller ones (*Bul 127 USBM 143*). Loss is increased by a high clay content in gravels. Loss is ordinarily much lower in lode mills. At PILGRIM, 0.3% loss is reported; at ARGONAUT the loss was 0.17 oz. troy per ton of mill feed, and at TALACHE 0.035 oz.

Cost of mercury during early 1930's was $58 to $68 per flask in 75-lb. flasks; $1 per lb. in 5- and 10-lb. lots at chemical supply houses; and double this at mining camp drugstores and the like (*IC 6787*).

11. DIFFERENTIAL DISINTEGRATION

Differential disintegration includes scrubbing and scuffing (Sec. 10), differential grinding, and decrepitation. The first two methods depend on differences in hardness of the minerals to be separated; the last upon differences in internal stresses set up by heat.

Differential grinding has been employed occasionally, in conjunction with subsequent size separation, to effect a rough concentration of softer from harder materials. Ordinarily a tumbling mill is used for the grinding. The essence of the treatment is to subject a mixture of substances of different hardnesses to a light grind. The method is most effective when the natural grain size of the hard mineral is larger than that of the soft.

At MISSOURI-KANSAS ZINC CORP. (*87 A 94*) tailing in which the blende was present as corners and edges on hard lime rock, and as inclusions in soft, porous, cellular limestone was subjected to a quick ball-mill grind in a thick pulp. A sizing-assay test of the product is given in Table 5; it shows that after grinding, 50% of the material remains on the 14-m. screen, but it contains less than 10% of the values. A 50-t.p.h. mill operated on a feed containing 2.44% blende rejected >3/16-in. (round-hole) tailing assaying 0.54% blende; undersize was sized and concentrated on jigs and tables and by flotation; tailings were, respectively, 0.67, 0.61, and 0.40% blende, and combined concentrates assayed 55 to 60% metallic zinc; milling cost was 20¢ per ton (1929).

Table 5. Sizing-assay test of a differential grind on zinc tailing (*After Banks and Johnson*)

a <14-m.

Differential grinding of the matrix in which Arkansas diamonds occur, together with a diamond, was done in a laboratory mill by A. M. Gaudin at Columbia University, resulting in effective disintegration of the matrix without breakage of the diamond. A light grind to disintegrate cemented diamond-bearing Brazilian gravel prior to separation by sizing and jigging of fines was practiced for a time in a mill designed by A. D. Hughes (*PC*).

Differential grinding of barite with sink-float separation of unground gangue in the mill is practiced at EL PORTAL (see Sec. 3, Fig. 5).

The brittleness of sulphides and their relatively high specific gravities are utilized in grinding for flotation, and in cyanidation in cases in which precious metals are included in sulphides. Procedure involves closing the grinding circuit with a classifier and operating it at relatively high dilution, under which circumstances, sulphides already reduced to the *mog* fail to overflow, but are returned to the mill for further grinding. The brittleness of the precious-metal tellurides was utilized in early days at Cripple Creek (Huntoon, *87 A 102*) to effect partial concentration, by screening crushed ore, either rejecting the coarse when the feed was a low-grade tailing, or taking the fines as an enriched product for special treatment when the feed was of higher grade. Before the advent of flotation the slimes from crushing copper- and lead-sulphide ores for gravity concentration invariably were markedly enriched over the feed, often to the point that they constituted a smeltable product. Recent attempts to concentrate some of the oölitic red hematites of the Alabama region are based on the friability of the hematite and lime as compared to the siliceous impurity.

It has been found (*TP 581 USBM 44*) that there is a relationship between the size of grinding medium and the natural sizes of the grains that it is desired to pulverize differentially. Thus with

the red hematite ore, when a $6\sim100$-m. feed assaying 31.5% Fe was ground with 1.5-in. rods or with 2-in. balls and separated at 100-m., the undersize assayed 39% Fe and 24% insol., but when $1/4 \times 3/32$-in. punchings were used as the grinding medium, the undersize assayed 45.8% Fe and 11.5% insol.

The entire practice of wash-ore treatment on the Mesabi is based on the difference in hardness between the altered matrix of quartz sand and cementing hematite, and the unaltered taconite (Sec. 2, Art. 28).

A Colorado carnotite ore consisting of quartz grains cemented by earthy carnotite and clay containing V, U, and Ra was subjected to differential grinding and separation of <325-m. material; recovery in the fine material was 83% of the V in a concentrate containing 8.3% V_2O_3 (*139 #11 J 43*).

Another form of differential disintegration is utilized in asbestos concentration, where crushing of the crude is done in ways that encourage fluffing up of the asbestos and pulverizing of the associated rock, whereupon sizing and/or air classification is used to effect final separation.

Decrepitation is applicable to a few minerals only, *e.g.*, barite, spodumene (*IC 7084; RI 3336*), and fluorite. The method comprises close sizing, heating to the temperature of decrepitation, and then rescreening, the undersize being concentrate. Despite that considerable concentration can be thus effected, the method was not used commercially, even before the applicability of flotation to the separations was discovered.

12. DIFFERENTIAL PHASE CHANGE

Differences in melting and boiling points of the ingredients of mineral crudes afford a means of separation used infrequently in the case of inorganic minerals, but upon which the entire art of separation of organic crudes is founded.

Liquation consists in heating a mixture of solids of different melting points to a temperature above the melting point of one of them but not of the others, whereupon the melted material drains away from the unmelted. The best known instance in the treatment of mineral crudes is that of sulphur (Sec. 3, Art. 42). The method is also used to further enrich hand-sorted stibnite concentrates. Precious metals are similarly sweated out of tellurides, but the process is not utilizable commercially.

Preferential solution is commonly used to effect differential phase change for the purpose of separation. Thus gold and silver in ores are preferentially dispersed in a liquid aqueous phase by cyanide solutions, and in this phase are readily separated from the residual solid host by draining, decantation, and/or filtration. Copper may be leached similarly with water alone (CHUQUICAMATA) or by dilute sulphuric acid or ferric sulphate (OHIO COPPER; RIO TINTO, etc.). Salt is preferentially leached from underground domes by pumping down water and thereafter pumping up the brine, leaving associated rock in the brine. Nitrates are leached with water in Chile (see Sec. 3, Art. 29).

Preferential crystallization of a part of the ingredients of a solution, with subsequent separation of the solid and liquid phases, is the common method of recovering sodium chloride and a number of the other ingredients of natural brines (see Sec. 3, Arts. 6, 25, 31, 36, 37).

Distillation. Separation by distillation depends upon differences in boiling points of minerals. If a mixture of minerals of different boiling points is heated to a temperature that is above the boiling point of one of them but not of the others, that one vaporizes and, in vapor form, is readily separated from unvaporized material. If the differences in boiling points among the ingredients of the crude are large, as between mercury and the associated gangue minerals, separation is sharp (see Sec. 2, Art. 32). Sulphur also is sharply separated from its ores by distillation (see Sec. 3, Art. 42). If, on the other hand, differences are small, as in the usual crude petroleum, it is impossible to vaporize even the lowest-boiling constituent without at the same time vaporizing a part of the ingredients of higher boiling point, and repetitive distillation and its counterpart, CONDENSATION, performed under closely controlled temperature conditions, are necessary to effect even reasonably clean separations.

Roasting, calcining, and drying are important processes in which beneficiation, or a step therein, usually accompanied by more or less concentration, is effected. Lime burning (Sec. 3, Art. 24), cement burning (Sec. 3A, Arts. 3 to 5), calcination and sintering of manganese concentrates (Sec. 2, Art. 31), drying of clays, chalks, diatomites, meerschaum, pumice, and tripoli (Sec. 3, Arts. 4, 8, 13, 17, 26, 32, 44), dehydration of gypsum (Sec. 3, Art. 21), reducing roasting of oxide iron ores (Sec. 2, Art. 28) and flash roasting of pyrite (Sec. 2, Art. 29) to render them magnetic, and calcination of arsenical gold ores to render them amalgamable (Art. 10) are typical examples.

SECTION 15

DEWATERING

REVISED IN COLLABORATION WITH THE ENGINEERS OF THE DORR COMPANY

1. INTRODUCTION

With the exception of dry crushing and a limited number of operations such as air classification, hand sorting, pneumatic tabling, and electrical concentration, the greater part of ore dressing is carried out in water. The complete or partial elimination of this water from one or more of the products at some stage in the flowsheet is invariably necessary.

DEWATERING is the separation of a mixture of solids and water into two parts, one of which is relatively solid-free and the other relatively liquid-free, with respect to the original mixture. Draining alone is a fairly effective method of eliminating water from coarse sands, but if slimes and fine sands are present, they tend to run off with the water. If the solid matter is so fine that slight movement maintains it in uniform suspension in the water, separation is effected by bringing the water substantially to rest, and allowing the solid particles to settle under the influence of gravity (SEDIMENTATION). This operation, coupled with continuous overflow of water and bottom withdrawal of partially dewatered solid, is called THICKENING. If a solid-free liquid and a solid fraction containing less water than can be obtained by sedimentation are required, filtration is employed (Sec. 16). When thickening is combined with filtration in a single tank, the dewatering action is known as FILTRATION-THICKENING. Substantially complete separation of water and solid is attainable only by evaporating the water (DRYING).

Frequently a combination of methods is employed in dewatering. Coarse sand, for example, may be separated from a slime fraction, and be dewatered by draining, while the slime is thickened prior to filtration. In general, as much water as possible is removed by sedimentation, which is relatively inexpensive, in order to reduce the volume to be handled by the more costly operation of filtration; the latter, incidentally, functions better when given a relatively thick feed. Removal of water by drying is the most expensive operation of all; hence it is usual practice to eliminate as much water as possible by filtration, leaving only the moisture contained in the filter cake for removal by drying.

2. DRAINING

Stationary drainage is a crude form of filtration. The simplest case is a pile of wet material on a floor; the liquid settles to the lowest layers of the heap and, if the supporting surface is inclined slightly, runs away. Some residual liquid is held by adhesion at the surface of the solid particles and by capillarity between adjacent solid surfaces; the volume of water thus retained depends primarily on the size of the solid particles; the finer the grains, the greater the particle area, and the greater the volume of retained water; the lower the specific gravity of the solid the higher the percentage moisture in the drained solid. In some cases a screen forms the draining surface. Bins may replace floors. Rectangular or circular tanks with false bottoms of screen cloth or coarse fabric, coco matting, jute or filter cloth, supported on slats, are frequently used for dewatering fine sandy concentrate.

Another method used with bins and tanks involves more or less watertight construction wherein water is continuously replaced by sand and overflows during filling. When the

bin is full, free water is run off and the bin dug out. In both cases the feed must be diverted to a duplicate unit while the dewatered sand is being removed.

At SANTA BARBARA (*112 J 1056*) lead-carbonate concentrate at the rate of 74 t.p.d. was sent alternately to two concrete tanks 10 ft. wide by 60 ft. long by 4 ft. deep. The moisture content was reduced from 84% to 14%. At LE ROI No. 2 mill (*114 J 1121*) about 30 t.p.d. of flotation concentrate was fed at one end of a series of two tanks each 1 ft. deep, 2 ft. wide, and 22 ft. long, with baffles 6 in. high at intervals along the bottom and double burlap screens at the outflow end. As concentrate accumulated it was tamped down for two or three minutes every hour or so. The material shoveled out when the tank was full contained only 10 to 15% moisture. The froth broke down by flowing across the semi-dry surface of the settled solid. This method is not so cheap as thickener-filter operation but is much cheaper in first cost.

Cone dewaterers are cheap and highly effective for coarse sands. Both diaphragm cones and the automatic types (Sec. 8, Art. 8) are widely used in this service.

Mechanical Drainage

Mechanical drainage devices differ from the stationary apparatus in that they treat small portions of material at a time, in thin layers. These drain rapidly and are as rapidly moved away by the mechanism. Types for coarse materials ($>{}^1/_4$-in.) are screens, perforated-bucket elevators, and scraper dewaterers; finer materials, down to 325-m. if slime-free, can be dewatered quite satisfactorily in mechanical classifiers.

Screens. Any type of screen (Sec. 7) can be used for dewatering, but trommels are most frequently used for lump material and vibrating screens for finer gravels and sands. Screens in this service should be set on as low a slope as will transport the material; vibrators with a pronounced movement are best for accelerating drainage and moving fine sand over the screen. Flat screens are highly effective for $>{}^1/_8$-in. sands; for finer sizes other means are probably better.

Dewatering elevator is a bucket elevator (Sec. 18, Art. 12) with the buckets perforated with holes as large as possible which will yet retain the solid to be dewatered. They are commonly used for dewatering coarse coal, and also for draining heavy-medium from concentrate in the H-H sink-float machine (Sec. 11, Fig. 76). They should be set on a slope sufficient to prevent drainage from one bucket from falling into following buckets, and should be run at relatively low speeds (<100 f.p.m.) in order to afford time for drainage. They are not good for fine sands, both because drainage is slow and because drained sand packs in the buckets and does not discharge at the head. Chain elevators are better than belt because the belt tends to lead drainings into lower buckets.

Scraper dewaterers are used principally for dewatering coarse sand products, and, less frequently, to effect a rough sand-slime separation.

Shovel wheel used at TIGRE MILLING CO. (*97 J 227*) is shown in Fig. 1. Feed entered through a chute, sand settled to the apex of the V-shaped trough, was scraped up-slope by the wheel, revolving counter-clockwise, and discharged through a slot; water or slime overflowed a lip on the opposite side of the box at a level about 4 in. below the sand discharge. The V-box in Fig. 1 was 42 in. long and 52 in. wide, the wheel revolved 8 r.p.m. and treated 125 to 135 lb. solid per min. Performance was affected by the speed and inclination of the shaft and the character of the feed pulp. At the Santa Barbara mill of the AMER. SMELTERS SECURITIES Co. (*112 J 1055*) two 48-in. wheels, revolving in opposite directions so as to raise sand along the transverse centerline of the box, were set in a V-box 9 ft. 6 in. long by 4 ft. wide. Feed was the oversize from a 0.5-in. trommel, fed at the rate of 430 tons per 24 hr.; it contained 42.5% solids; the sand discharge, 70% solids.

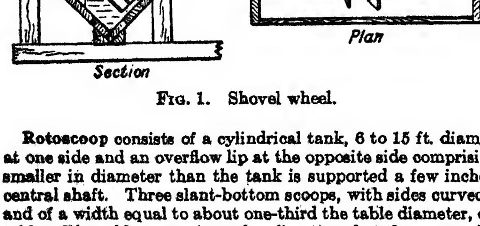

FIG. 1. Shovel wheel.

Rotoscoop consists of a cylindrical tank, 6 to 15 ft. diam. and 12 to 18 in. deep, with a feed launder at one side and an overflow lip at the opposite side comprising 150° of rim arc. A disk or table slightly smaller in diameter than the tank is supported a few inches above water level on a slowly revolving central shaft. Three slant-bottom scoops, with sides curved on radii from the axis of the central shaft, and of a width equal to about one-third the table diameter, depend with equal angular spacing from the table. The table moves in such a direction that the scoops shovel up settled sand from the tank bottom, while further sand pushes that above it upward until it emerges on top of the table. A curved plow, adjacent to the feed launder, scrapes sand off into a sand chute. Water in the elevated sand drains out and is squeezed out in the chutes above the water level. Rated capacity is 20 to 150 t.p.h.

Sand wheel (Fig. 2) consists of a wheel *A* carrying convex, perforated scrapers *S* at the periphery, revolving in a narrow trough *B* supported in a V-box. The wheel in Fig. 2 is 14-ft. diameter to the tips of the scraper blades. A form with hinged angle irons which tilt at the zenith to drop the load onto sloping plates at the sides is described (*34 #10 PQ 42*). The Simplicity wheel (*42 #5 RP 26*), for dewatering <1/8-in. sand, is 14(diam.)× 3-ft. with 24 @ 4-cu. ft. buckets, the bottoms lined with 12-m. cloth over the perforations; it is driven at 2 r.p.m. by a 10-hp. motor.

The most efficient speed for dewatering combined jig and table tailing (<9-mm.) at Doe Run Lead Co. was 2 r.p.m. The 14-ft. machine handled 1,500 tons of such material per 24 hr. The sand discharge carried about 15% moisture. The power requirement was less than 2 hp. A more elaborate

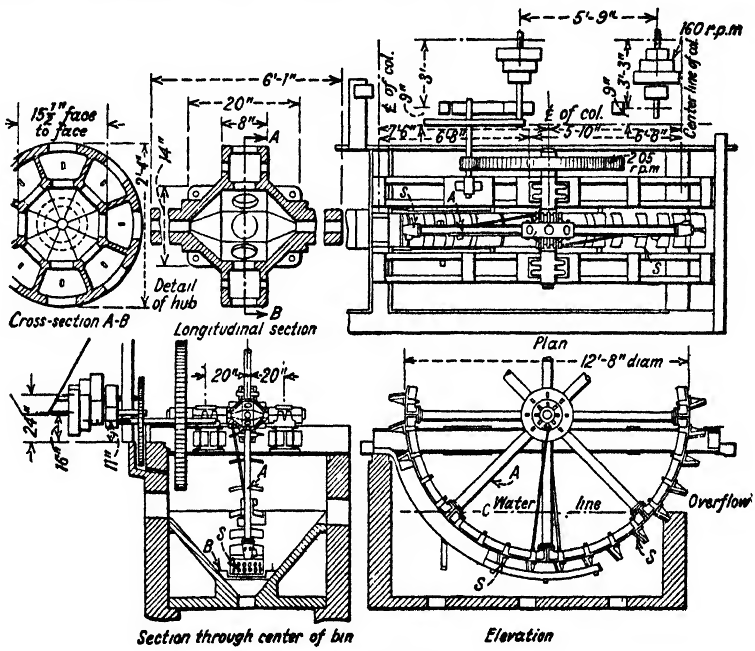

Fig. 2 Sand wheel.

form lifts the sand in buckets carried on a large wheel dipping into the pulp, decants water as the wheel revolves, and finally discharges dewatered sand at the top of the revolution by automatically tilting the buckets. (*111 J 291.*)

Mechanical classifiers with slant-bottom tanks are effective dewaterers for fine sands. Moisture content of sand discharge increases, however, as the sand decreases in limiting size.

Drag classifiers (Sec. 8, Art. 4) are probably most commonly used, on account of cheapness. A small drag with tank bottom about 6 ft. long and set at 45° slope, built as a self-contained unit with floor support and individual motor, is standard equipment for dewatering rougher-jig concentrate prior to cleaning on jig dredges. Drags are also widely used for coal.

At Federal Lead Co. the classifier shown in Fig. 10, Art. 8, dewatered 700 tons per 24 hr. of <12-mm. sand from 77% water to 20%. At Britannia (*113 P 696*) flotation concentrate was sent to a drag elevator and thence to bins. The drag discharge contained 20% moisture and the bin discharge 8% moisture. This method of treatment is applicable only to very quick settling concentrate; normally this limitation would exclude flotation concentrate. Cutting a slot 1 1/2 to 2 in. wide across the bottom, at a distance about one flight space back from the sand lip, is reported (*41 #1 RP 93*) to improve dryness of sand materially; the slot permits a small puddle and some sand to drop through, the sand being sluiced back to the pool. At Compagnie du Boleo (*133 J 153*) a bucket-type drag conveyor placed in a box at the end of a launder carrying granulated slag lifts out the bulk of the solid dry enough to be deposited on a belt conveyor, while water and fine solid overflow the side of the box; the buckets are directed against the flow on the bottom run, and drain on the lift and upper run.

Spiral classifiers (low-discharge type, Sec. 8, Art. 3) are small, relatively cheap, and effective for dewatering finer sands than are the drag machines. They have been used to a considerable extent for gravity concentrate in metalliferous mills. They are also used frequently for commercial sands. They have some advantage over other tank dewaterers in that the drainage slope is greater than the axial slope because the sand progresses along one side of the semi-cylindrical tank bottom.

At Midvale a 30-in. simplex machine, bottom slope 2 1/4 i.p.f., 13 r.p.m., dewatered 45 tons per 24 hr. of <28-m. slime-free sand from 72% water to 19%. The spiral type has been generally adopted for final thickening of ferrosilicon heavy-medium in sink-float operation, magnets along the bottom being used to increase sedimentation forces. An Akins classifier at Crystal Fluorspar Co. (*142 #12 J 65*), dewatering fluxing-grade concentrate, overflows <150-m. sand assaying 20% SiO_2 from a feed containing 4% SiO_2.

Rake classifiers for dewatering are usually fitted with a dewatering lip (see Sec. 8, Art. 6, ***Length of tank***). Typical moisture contents of sands are: Combined jig and table tailings, 15%; copper gravity concentrates, 20% as discharged, 8% after further drainage in bins; <20-m. ilmenite concentrate at National Lead Co., 16%; anthracite fines, 28 to 30% as discharged, draining further to 15% in cars; silica sand, 20% as discharged, 6 to 8% later after draining in stockpiles; salt crystals (NaCl evaporated from brine), 25% as discharged. In general, moisture content of metallic concentrate will range from 15 to 20% at 20-m. limiting size to 25 or 30% at 200-m.; that of material of 2.65 sp. gr. will average 2 or 3% higher throughout the same size range.

At Morenci (old plant), shaking-table concentrate (164 tons per 24 hr. with 383 tons of water) was dewatered in 2 @ 4 1/2×18-ft. Dorr classifiers fitted with a vacuum connection under canvas near the sand-discharge end. The rake product of the first machine contained 12% moisture; overflow went to the second machine, the sand product of which contained 8% moisture. See also Sec. 2, Fig. 159.

Capacity in general dewatering service is easy and may be reckoned at the maxima for sizes corresponding to the finest grains in the feed (see Sec. 8, Table 5).

THICKENING

Thickening is the process of concentrating a relatively dilute slime pulp into a thick pulp, *i.e.*, one containing a low percentage of moisture, by rejecting liquid that is substantially solid-free.

3. PRINCIPLES

Slime is the term used in milling practice to describe a suspension, in water, of the finely divided fraction of pulverized ore; also the solid, whether suspended or after settling and/or drying. The terminology is not precise, *e.g.*, the overflow of a mechanical classifier or cone guarding the discharge of a grinding mill may be called slime as distinguished from the coarser sand, even though the separation be made at upward of 0.5-mm. size; the overflow of a hydraulic classifier is called slime, more or less irrespective of the size of the coarsest grains. Some writers (*41 A 398, 42 A 752*) define slime as crushed rock in water when the rock is of such fineness that it will pass a 150- or 200-m. (0.1- to 0.075-mm.) screen.

The solid particles in mill slimes are rock or mineral fragments formed by crushing operations, and secondary minerals such as steatite, talc, and clayey substances that have been disintegrated and dispersed by wetting. These latter substances are often called true slimes. A slime product separated in the early stages of comminution, which contains, therefore, an exceptionally high percentage of true slime, is called primary slime. Its satisfactory thickening is one of the difficult problems in milling. The product formed by fine-grinding the crystalline part of the ore contains but little true slime; it is often called secondary slime; settlement is normally rapid.

Every slime suspension consists initially of individual solid particles separated from other solid particles by a layer of water. Irrespective of whether the largest particles are 0.5-mm. (20-m.) or 0.07-mm. (200-m.) diameter, they are enormously larger than the smallest particles, large numbers of which are in the size range below 0.001-mm. The difference in settling behavior of these two classes is much greater than that between the coarse and fine particles met in hydraulic classification. The granular particles settle slowly under the influence of gravity, at definite rates approximated by Stokes' equation (Sec. 8, Art. 1). The fine particles may not settle at all, or they settle at a rate so slow as to be of no practical benefit in thickening. The viscosity term in Stokes' equation is relatively very large for these fine particles, and effects such as Brownian movement and the

associated electrical repulsion between particles may counterbalance effectively any residual tendency toward downward motion due to gravity. These particles are in colloidal or semi-colloidal state.

Colloids. The word "colloidal" describes a state of matter. A colloid is not a certain specific kind of matter but any matter in a certain specific state. The COLLOIDAL STATE is characterized by particles of such minute size that they are capable of maintaining their state of uniform dispersion in a given medium, without the necessity for expenditure of mechanical work on the mixture. The dispersed substance, the colloid, may be gaseous, liquid, or solid, and the dispersing medium may, likewise, be in any of these three states, except that gas is never at the same time the disperse and dispersing phase. The mixture is a COLLOIDAL SOLUTION. Such solutions differ from the more familiar types of solution in most solution characteristics except that of maintaining uniformity without requiring mechanical work to be done; their boiling and freezing points do not differ materially from those of the dispersing medium, they do not dialyze in the same way or exhibit osmotic pressure; finally, the dispersed particles are visible, with ultramicroscopic equipment, and separable by means of ultra-filters. SEMI-COLLOIDAL PARTICLES have, in a considerable degree, colloidal properties. The dispersed particles in a colloidal solution are said to be PEPTIZED OR DEFLOCCULATED. The converse condition, resulting from aggregation of the dispersed particles, is called FLOCCULATION, and the aggregates are called FLOCCULES or FLOCS.

Dispersion. The effective mechanism underlying colloidal solution, with accompanying dispersion, is adsorption of ions at the surfaces of the dispersed particles, one kind of ion (+ or −) being anchored to the solid and the other (COUNTER ION) free-swimming in the solution, except as it is held by attraction to the anchored ions. The result is electrical charging of the particle surfaces. Some investigators consider the system a "floating condenser," with inner and outer charged layers of opposite sign (HELMHOLTZ DOUBLE LAYER). The charges cause the particles to repel each other, thus preventing coalescence and settlement. Ion adsorption may be made preferential and specific to the particular colloidal substance by suitable selection of introduced electrolyte with respect to the particular solid (see ***Flocculating agents***). In this way a given solid may be charged negatively in one instance and positively charged in another. Beans and Eastlack (*37 ACS 2667*) showed that only those ions are adsorbed that will, under proper conditions, enter into chemical combinations with the dispersed substance, and that the amount or intensity of adsorption is greatest for those ions that form with the substance chemical compounds of greatest stability.

Flocculation of a dispersed solid may be brought about by several means, all, probably, different facets of the same basic treatment. In natural ore pulp it is rare for all of the mineral species to be dispersed; usually only the silicate minerals are in such state. It has been shown (*87 A 217; 153 A 453*), in a sufficient number of independent cases to eliminate coincidence, that Brownian movement of mineral particles and dispersion thereof are concomitant; also that the dispersed particles are of macroionic character and that flocculation occurs when the macroionic nature is destroyed. Methods of such destruction, postulated on the ordinary concepts of ionic chemistry, are (*a*) suppression of the ionization or (*b*) removal of the anchored ions that impart the macroionic character. Thus Fitt *et al.* (*ibid.*) have shown that zinc sulphide dispersed by sodium arsenate comprises negative macroions from which arsenate ion may be removed by electrodialysis, or by solution in excess of sodium arsenate, and that in both cases flocculation and precipitation occur. Freshly broken galena in ordinary distilled water has lead sulphoxy compounds at the surface (Sec. 12, Art. 3) and is flocculated. It is rendered macroionic and dispersed by sodium carbonate; the macroions are negative, indicating anchorage of carbonate ion, while the low mass solubility of lead carbonate indicates that lead is the counter ion. The dispersion is flocculated by addition of hydrogen ion, which forms the relatively soluble bicarbonate, *i.e.*, dissolves the anchored compound; or by adding xanthate or sulphide ion, both of which replace carbonate ion at the macroion surfaces because of the extremely low solubility in water of the corresponding lead salts; these, for the same reason, are insufficiently ionized to charge the surface enough to effect dispersion. Addition of an excess of sodium carbonate, which may either suppress ionization of lead carbonate by common-ion effect or dissolve it by salt effect (the mechanism is not established, although the fact is) also flocculates carbonate-dispersed galena. Quartz is dispersed in distilled water, indicating reaction with water after the fashion

$$\square SiO_2 + H_2O \rightarrow \square SiO_3^{=} + 2H^+$$

Stability of the dispersion is increased by a low concentration of sodium carbonate, probably by reducing the concentration of hydrogen ion ($2H^+ + CO_3^{=} \rightarrow HCO_3^- + H^+$) and thereby driving the silicate-water reaction to the right and inducing more dense charging

of the silica macroions. Excess of sodium carbonate causes flocculation, the indicated reactions, in order, being hydrogen ion with hydroxyl, with consequent substitution of Na^+ for H^+ as the available counter ion. But Na is not an effective counter ion for $SiO_3^{=}$ because of the relatively high solubility of sodium silicate. The dispersion is also destroyed by adding acid (H^+), the effect of which is to suppress ionization of H_2SiO_3.

Some dispersions, but not all, may be broken by mixing them with others of opposite sign. The old static-charge idea was that the oppositely charged particles attracted each other and came together under the force of the attraction to form aggregates (floccules) of such size that they sank. That did not explain the failures. On the hypothesis herein proposed, the macroions, the counter ions, and any other ions present in the two dispersions are to be considered simply as ionic parts of the colloidal solutions. If, on mixing, conditions in the new system are so changed as to break the anchorage of captive ions, or drive back their counter ions in sufficient numbers, or supply other counter ions which reduce solubility products too greatly, etc., flocculation will occur; otherwise not.

Dispersions are frequently broken and flocculation effected by gelatinous inorganic precipitates and by organic sols of the type that can, under suitable conditions, form gels (*e.g.*, starch, gelatine, glue).

Physical aspects of flocculation are inferable from observation and by analogy with coalescence of bubbles and drops. When destruction of a dilute aqueous dispersion and aggregation of the particles into larger masses are observed under a microscope, the successive steps are: (*a*) cessation of Brownian movement and rapid settling of suspended particles (or rise in the case of oils of low specific gravity); (*b*) horizontal movement of the settled particles along the surface of the slide, when water currents are induced mechanically or by heating; (*c*) collision, followed in most cases by adhesion. (Collision does not occur before cessation of Brownian movement.) When liquid or gaseous emulsions break and the particles thus collide, they usually coalesce. Such action results in decrease of interfacial area of the system and, since the interface is a seat of energy, there is a corresponding decrease in the energy of the system. This is, therefore, action in accord with that form of statement of the second law of thermodynamics which asserts that spontaneous movement in any system which is the seat of energy is in the direction that results in decrease in the total energy of the system. By analogy it may be inferred that in flocculation of a solid system there is a corresponding reduction in the extent of solid-liquid interfacial area and energy. It must be admitted, however, that it is difficult to imagine sufficient reduction in the interfacial area of jagged solid particles to account for the resistance of flocs to redispersion under the influence of agitation (mechanical, work) sufficiently vigorous to break oil droplets. It is possible that in such case there is breakage, but that collision is at the same time accelerated, and that the maintenance of an apparently static flocculated state is actually a highly dynamic phenomenon.

Flocculating agents. Other than the cases discussed under *Flocculation,* little or nothing is known positively of the chemistry of flocculation in ore pulps, and most practical control proceeds on rules-of-thumb, of which the outstanding is: "Use lime."

Lime is widely effective, cheap, and easy to handle. Other common inorganic flocculants are potassium alum, ferric chloride, ferrous sulphate, magnesium sulphate, and sulphuric acid. The basis of the effectiveness of acid on siliceous pulps has been discussed. Lime in pulps containing base metals, alum, and iron salts all tend to form gelatinous precipitates, which entangle and sweep down particles mechanically, entirely apart from any surface reactions. Blood albumen and glue are effective in acid pulps, *e.g.*, those produced in the manufacture of aluminum sulphate from clay or bauxite. Causticized flour and causticized starch (see Sec. 12, Art. 10) have been found to be effective in neutral or alkaline pulps. Use of these reagents to handle the red mud pulps from the Bayer Process in thickening have made it possible to reduce the unit areas required from 50 or 60 sq. ft. per ton of solids per 24 hr., to 10 or 15 sq. ft. Magnesium sulphate is used to flocculate titanium dioxide after the ground pigment has been sized and it is necessary to thicken the finer fraction for dewatering. Highly saline waters (sea water, saline lake water, some mine waters) are usually effective flocculants, due probably in some cases to solubilization by salt effect and in others to suppression of ionization by mass action.

It has been established empirically with respect to electrolyte flocculants that whether the positive or negative ion is the effective one, effectiveness tends to increase with valence. The increase in effect is stated to be of the general order $1 : x : x^2$, and with metallic ions to be $1 : 35 : 1{,}023$ (Wheatham, *Theory of solution, 396*). This is explicable chemically on the scores that the compounds of high-valent ions are, in general, less soluble than the corresponding compounds of low-valent ions, and that, in reacting with ions that are essential parts of the disperse system and precipitating, they tie up more such ions per ion introduced.

Simultaneous flocculation and dispersion is practiced on Hydroseparator feed at Champion No. 1 plant of Pittsburg Coal Co. The feed is a mixture of bituminous coal and clay. Causticised starch flocculates the coal, and sodium metasilicate disperses the clay, thus aiding separation of clay by overflow.

Zones of settlement. A flocculated pulp does not necessarily settle rapidly. Settling rate is dependent upon a number of other factors which must be determined experimentally in every case. Coe and Clevenger (*55 A 356*) have shown that a thickening suspension passes through a succession of stages shown diagrammatically in Fig. 3.

Cylinder E represents the pulp sample after thorough mixing. In F some slight settlement has taken place; zone A, of clear solution, has formed; just below it lies zone B, which is pulp of the consistency of the feed minus any coarse material K that has segregated. Below zone B is a transition zone C, which may be vanishingly thin in some pulps and may fill the entire space between zones A and D, with consequent elimination of zone B, in others; it increases in solid concentration from top to bottom. Zones B and C are commonly designated COLLECTIVE SUBSIDENCE ZONES, as distinguished from zone D, which is the COMPRESSION ZONE. Zone D consists of flocs in rather intimate contact, somewhat like a pile of sponges. Cylinders G and H are similar to F, except for the growth of the compression zone at the expense of the subsidence zones. The CRITICAL POINT is pictured in cylinder I; zones B and/or C have just disappeared, and zones A and D have just made contact. Cylinder J shows the pulp in the final stage of settling, or in what is known as ULTIMATE DENSITY. The pulp is as thick as it will become under the given conditions.

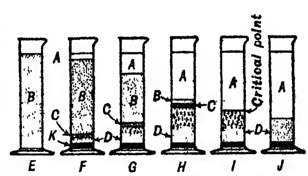

FIG. 3. Phases of sedimentation in intermittent thickening.

This diagrammatic representation assumes a pulp of average feed dilution and a certain degree of flocculation. With the exception of zones A and K, the zones may not be sharply defined, although zone D is usually present and characterized by the presence of vertical channels as indicated, produced by exudation of water.

Settling curves for various types of pulps are shown in Fig. 4. These are obtained by plotting the position of the top of zone B (Fig. 3) against time. Each curve is characterized by substantially constant slope in the early part, a length of rapid inflection, and a slow approach (the more rapid, the sharper the inflection) to an asymptote.

The lower curves of Fig. 4 are characteristic of very dilute suspensions in which clarification is gradual throughout, its rate (slope of the curve) being determined by the free-settling velocity of the slowest-settling flocs. The upper curves are those obtained with pulps in which a sharply defined upper surface of the solid mass appears suddenly shortly after sedimentation starts (LINE SETTLEMENT). The early part of the curves corresponds physically to items E to H of Fig. 3; the period from critical dilution to ultimate density (Fig. 4) corresponds to I, Fig. 3. Thereafter the curves are asymptotic to the time axis, *i.e.*, there is no further compaction. During the time of collective subsidence the settling rate is substantially constant and approximates that of the average falling velocity of the individuals in a suspending medium having a density equivalent to that of the pulp under observation.

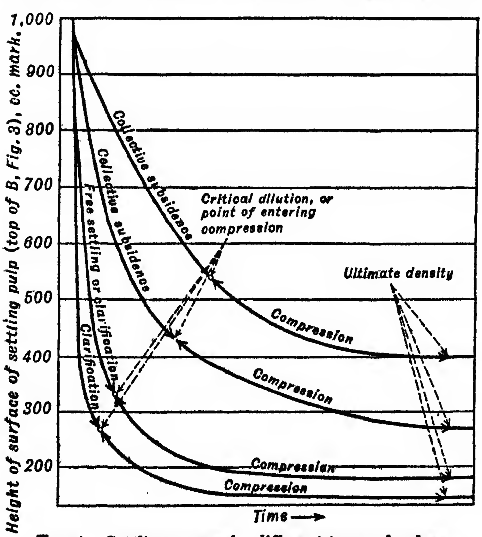

FIG. 4. Settling curves for different types of pulps.

Zones B and C are normally absent or unrecognizable in dilute and slightly flocculated pulps, and demarcation between zones A and D does not become sharply defined until critical dilution is reached. It is possible, however, that the lower curves have short rectilinear portions in the region of critical dilution and that the upper curves have short, much steeper sections, each having an inflection region normally not caught experimentally in the short interval preceding the period of line settlement.

Effect of various substances on settling rate of ore slimes, as determined by Ralston (*101 J 991*), are given in Table 1. Shellshear (*8 Aa 12*), working with 2% suspensions of extreme fineness and of many minerals, found that the powders could be arranged in three groups, *i.e.*, rapid-settling, which comprised blende, calcite, garnet, pyrite, magnetite, stibnite, galena, and fluorite; intermediate-settling, consisting of chalcopyrite, bornite, molybdenite, and quartz; and slow-settling, cassiterite, wolframite, feldspar, steatite, mica schist, rhodonite, and scheelite. Sulphuric acid increased the settling rate of all classes; calcium chloride was particularly effective on siliceous material; lime was not so potent as calcium chloride but, like it, was most effective with siliceous material; sodium hydroxide in small quantities dispersed siliceous material, but accelerated settlement in greater concentrations;

t Deflocculates and sands settle.
u Final pulp, 32% solids.
v All pulps 9.4% solids.
w Speed increasing.

alum and sodium bicarbonate, added together, produced a gelatinous precipitate that swept down the suspension; potassium permanganate accelerated settlement greatly. Bruhl (*107 J 1089*) noted that slaked lime is 30% more soluble than unslaked and produces a more marked settling effect. Sulman (*17 IMM 312*) stated that ammonium chloride and other ammonia salts have marked coagulative effect on ore slimes. Nichols (*17 IMM 322*) found no marked difference in effect between $BaCl_2$ (83 mg. per 200 cc.), H_2SO_4 (17 mg. per 200 cc.), lime (56 mg. per 200 cc.), and NaCl (167 mg. per 200 cc.) in a 2% pulp, but on the basis of weights of electrolyte added, H_2SO_4 was the most potent. At ANACONDA (*49 A 478*), settling a 2.5% slime pulp to 10% in Callow cones, 1 lb. per ton of ferrous sul-

a Undetermined.

phate increased settling rate (capacity) 30%; 2 lb. 40%; and 5 lb. 50%. Sodium chloride, 0.25, 0.5, and 1 lb. per ton, respectively, increased the rate 3% to 4% only. A mixture of glue and ferrous sulphate, 0.25 lb. of each per ton, was remarkably effective; it increased the capacity of a 28×10-ft. thickener from 195,000 to 311,000 gal. of slime pulp per 24 hr., and on round-table concentrate caused the same settlement in 1.25 min. that required 11 min. with untreated pulp. Nicolai (*103 J 1064*) found that $MgCl_2$ in the end liquor from German potash plants, added in the proportion of 1 cc. of solution per liter of slime, increased settling 67 to 95%.

The ionic constitution of the pulp, both as regards particle surfaces and solution, is substantially completely unknown in all of these cases, so that no proper analysis of the data is possible. They must be taken simply as statements of occurrence with particular ores under conditions essentially unknown.

Effect of viscosity in flocculent pulps is complicated by the fact that such pulps behave as plastic solids rather than true liquids (Castleman, *Tech. Note 231 NACA*). While dispersed suspensions do not exhibit yield values (do not become plastic) until the concentration is relatively high, usually between 10 and 50% solids, flocculent pulps may show this characteristic at as low a figure as 3% solids. Plasticity of flocculent pulps results in entrainment, since for any given yield value there must necessarily be particles of such size and density enclosed in some flocs as to impose shearing forces thereon equal to or less than the yield value; these, therefore, remain entrapped. Entrainment often has marked influence on the rate of settling of the flocs, as well as on the entrained particles. Sand or other granular material entrained displaces water and thereby increases the average density of the floc and, consequently, its settling rate. Entrapped air may cause light flocs to float; at least it slows the settling rate materially.

Flocculating agents often precipitate dissolved salts in flocculent state; these tend to entrain fine dispersed solids and thus, in general, increase settling rates.

Density difference between particle and medium is important in determining the rate of fall of particles in the presence of other particles. Fall of a large particle may be retarded considerably by increase in the effective density of the medium owing to the presence of smaller particles of the same substance. Still more drastic change may be caused by the presence of large amounts of fine particles of a higher specific gravity (see Sec. 11, Art. 28).

Consolidation in the compression zone is the final stage of thickening. Water liberated no longer flows evenly around each particle as in the upper zones, but forms channels which are readily observed in settling tests. The flocs rest upon and support each other. Further thickening is due to compression by the weight of overlying particles. After the water between flocs has been displaced, further consolidation occurs by exudation of water from within the flocs through the floc pores, as they become distorted under the superincumbent weight (Deane, *37 AES 659*). The weight required is a function of the yield point of the floc structure. Equilibrium is eventually reached between the imposed force and the increasing yield resistance; at this point thickening ceases. Further dewatering can be accomplished only by mechanical rupture of floc structures, with accompanying adjustment of different sized particles to accommodate themselves to smaller volumes; or by increase in exuding forces. Movement of thickener rakes or of the picket-fence type of mechanism accomplishes mechanical rupture to a marked degree; filtration is an example of increase in exuding force.

Effect of heat on slime settlement is ordinarily to increase the rate. Richards (*2 OD 1147*) called attention to this fact and Dorr (*49 A 224*) stated that heating may prove an economical method of adding 10 to 20% to the capacity of a thickener. Nichols (*97 P 54; 17 IMM 321*) and Ashley (*98 P 831*) showed that the increase in settling rate was, in general, inversely as the fall in viscosity of the water.

A recent thickener-area test (Art. 6) on a cement rock at the Dorr Co. laboratory indicated a required area of 15 sq. ft. per ton at 40° F. and 10 sq. ft. at 70° F. (a 33% increase in settling rate; corresponding coefficients of viscosity of water (C.G.S. units) are 0.0154 and 0.00984 (a decrease of 36%). Serious decrease in capacity of thickeners in winter, particularly as the temperature of the water nears freezing, is a common experience. Nicolai (*103 J 1064*) states that the thickener overflow of a German lead-zinc mill carried from 0.02 to 0.1 gm. solid per liter on warm summer days and 0.2 to 0.4 gm. on cloudy or windy days.

Figs. 5 and 8 summarize experiments by Ralston (*101 J 890*); these confirm the viscosity relationship over a range extending to nearly 40% solids; beyond that another relationship is indicated. It is not improbable that, in the Ralston pulps, sedimentation was substantially by free-settling up to the pulp densities marked by the upper inflection points of the

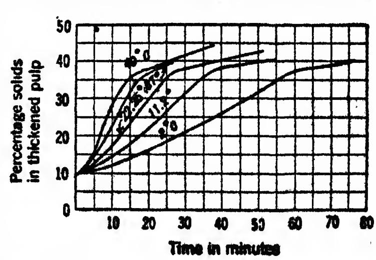

FIG. 5. Effect of heat on slime settlement (*after Ralston*).

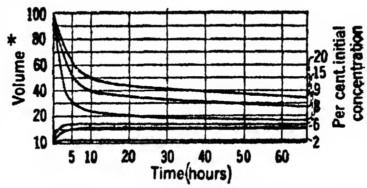
curves in Fig. 5. Under such circumstances obedience of fine particles (uninfluenced by Brownian forces) to Stokes' law (Sec. 8, Art. 1) is well established. At higher densities, particularly in flocculated pulps, consolidation depends upon rise of water through small channels between flocs and upon squeezing of water from the flocs. Such flow should be subject to Poiseuelle's law (Sec. 16, Art. 1), which states that the flow rate, while inversely proportional to the viscosity of the liquid, is also influenced by other resistances. These would, in part, account for the marked decrease in settling rates beyond the inflection points. Rigidity of the flocs themselves causes further resistance.

Table 2. Effect of pulp temperature on settling rate of Anaconda slime (*After Laist and Wiggin*)

Pulp temperature, degrees F.	Time to settle from depth of 17.5 in. to 3.5 in., minutes		
	Average	Maximum	Minimum
35	41.7	57.0	29.5
40	38.0	50.7	27.3
45	35.0	45.2	25.0
50	31.7	40.2	23.0
55	28.5	36.0	20.5
60	26.0	33.0	18.3
65	23.3	29.8	16.0
70	21.2	26.7	13.8
75	19.5	25.0	12.0

Results of tests at ANACONDA (*49 A 479*) are given in Table 2. Laist and Wiggin call attention to the fact, as a matter of practical design, that while the average summer pulp temperature of 50° is greater than that at the average winter temperature of 38°, yet other factors may enter to make the minimum rate at 50° less than the maximum, or even the average rate at 38°, and they conclude that pulp temperature is, therefore, a relatively unimportant factor in thickener-plant design. One such factor is convection currents caused by uneven sun heating or by wind. If intentional heating is to be practiced, the thickener should be insulated, heating should be done outside the thickener, and the surface should be protected from air currents.

Occasionally the benefit from heating is greater than would be expected from viscosity considerations. In certain cases at least this is due to flocculation, which may result either from increased chemical activity resulting in destruction of the macroionic state essential to dispersion or from increased particle movement and collision induced by convection currents in the heated liquid. Conversely Nichols (*17 IMM 293*) reports a case in which high temperature (200° F.) with accompanying violent agitation resulted in deflocculating a pulp and thereby markedly decreasing its settling rate.



* Ordinate is the height of the upper surface of the settling material, divided by the total height of the water surface, expressed as percentage.

FIG. 6. Relation between settling rate and percentage of solids in a colloidal clay suspension (*after Free, 101 J 681*).

Dilution. The effect of the dilution on settling rate is roughly given by the equation $R = K(D - X)$, where R = settling rate, K is a constant, D = dilution, and X is a constant. Graphs for some pulps show considerable curvature, either convex or concave (Fig. 6), and some are slightly S-shaped (Fig. 7) but others are nearly straight (Fig. 8).

Table 3 shows that the same relation holds in the mill and that laboratory settling rates are substantially the same as mill performances. Fig. 9 (*101 J 893*) shows that the difference in settling rates is not merely the one to be expected by reason of the greater freedom of the falling particles in dilute pulps but that at any given pulp density in the consolidating layer the settling rate (velocity of subsidence of the surface of the consolidating layer) is greater the more dilute the feed pulp.

The effect of electrolytes on settling rate is greater, the more dilute the feed pulp.

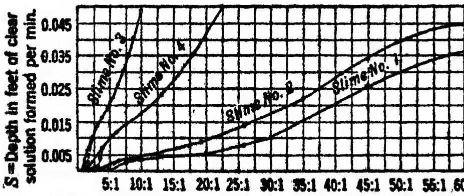


FIG. 7. Effect of dilution on settling rate of ores (*after Mishler, 94 J 646*).

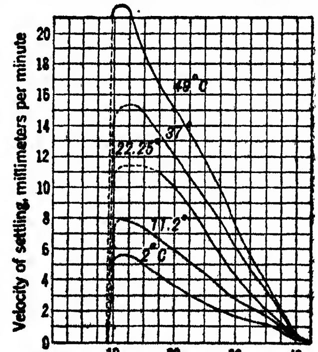

FIG. 8. Effect of dilution on settling rate (*after Ralston*).

Table 4 (*101 J 991*) shows that with 5% solids in the feed, an increase of 35% in settling velocity is effected by addition of 0.025 % lime, while with 20% solids the same lime addition produced only 4%.

Table 3. Effect of feed-pulp dilution on settling rates in laboratory and mill (*After Mishler*)

Mill						Laboratory

F Liquid: solid ratio in feed, by weight. *D* Liquid: solid ratio in discharge, by weight. *T* Tons dry slime per 24 hr. $S = 0.00004912\ T(F-D)$. Mill data are results of daily samples over 49-day period from a 24 ×12-ft. Dorr thickener. Laboratory tests were of 10-min. duration and were made in glass cylinders 0.1 ft. diam. and 2 ft. high.

Table 4. Effect of electrolytes on pulps of different densities (*After Ralston*)

Solids in feed, per cent.		CaO added, per cent.				
		0	0.0031	0.0062	0.0125	0.025
5	Increase in settling velocity, per cent...	0	17	39	39	35
10		0	1	18	7	20
20		0	0	3	3	4
5	Height of surface of settling solids when change from sedimentation to consolidation settling occurred......	23	34	60	70	96
10		67	......	160	190	180
20		197	197	197	198	198

increase in velocity over that with no lime. Addition of lime also caused the change from sedimentation to consolidation settling to take place much earlier in dilute pulps than it occurs without lime, while no such change occurred with thick feed pulps.

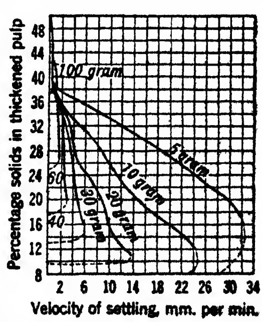

FIG. 9. Effect of dilution on consolidation of slimes.

Capacity of a thickening tank is not determined by the settling rate at feed dilution but by the subsidence rate of a more or less concentrated pulp, since a zone of such higher concentration forms in any continuous thickening apparatus (see Art. 5).

Thickeners

Thickeners are tanks of such capacity that the time required to fill them at the rate of flow of the stream to be thickened is sufficient to permit the upper surface of the solid matter to settle a safe distance below the overflow level and the lower stratum of settled solid to consolidate to the desired consistency. They are provided with an overflow weir and one or more bottom-discharge openings so located as to draw off the settled solids uniformly. They are built either for intermittent or for continuous operation. The latter type may be discharged by gravity or mechanically. Intermittent thickeners have found their greatest use in the Rand gold mills; continuous thickeners, first of the gravity-discharge type but latterly of the mechanical type, are almost universal in the United States.

Centrifugal thickening is accomplished in power-driven machines, which consist of one or more drums capable of being rotated at high speeds within a closed casing. The feed enters at the axis of rotation, and the clear water and solids, which may be continuously or intermittently discharged, are eliminated at opposite ends.

4. INTERMITTENT THICKENERS

Nonmechanical intermittent thickeners are usually rectangular tanks or elongated ponds fed at one end and overflowed at substantially the same level at the other end. Feeding continues until the overflow contains more than an allowable load of solid, when the feed stream is diverted to another tank. After the solids have settled, the supernatant clear liquid is drawn off through pipes variously arranged for adjusting the drawoff level. The thickened solid is finally flowed, sluiced, or pumped out and the tank is ready for another charge. The drawoff level for liquid is varied by means of pipes placed at various heights in the walls, or by means of a jointed standpipe from the top of which short lengths are easily removed, most frequently by means of an inclined pipe, joined by means of a 90° ell with a horizontal pipe in the bottom of the tank (see Fig. 10).

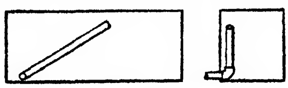

FIG. 10. Adjustable draw-off for intermittent settling tank.

The horizontal cross-section of intermittent settling tanks should be such that the rate of rise of liquid therein is less than the settling rate of the surface of the solids in collective subsidence.

Thomas and Osterloh (*17 JCM 214*) state that two slime ponds with a total circumference of 6,000 to 7,000 yds. are sufficient to handle 30,000 tons of thick Rand slime per month.

Mechanical intermittent thickeners are the intermittent-discharge cone, old-style centrifugals, and the filter-type thickeners.

Cone. Valve for intermittent gravity discharge of thickened pulp from a cone, V-box, or pyramidal box is shown in Fig. 11. Discharge intervals depend upon the amounts of solid fed; the greater the amount the shorter the intervals between openings. Open periods are usually short to prevent rushes. Such intermittent discharge decreases the difficulties in maintaining thick spigot products.

FIG. 11. Ayton intermittent pulp-discharge valve.

Old-style centrifugal thickeners comprised vertical cylindrical bowls, center-fed for a sufficient interval to charge the walls with the thickened pulp, liquid meanwhile overflowing. The bowl was thereupon stopped, when the accumulated solid slumped or was scraped down to a suitable discharge opening.

Filter thickener. See Art. 8.

5. CONTINUOUS THICKENERS

Continuous thickeners are of gravity-discharge type, in which the thickened product flows out through a spigot under a hydrostatic head induced by the body of contained pulp; mechanical-discharge gravity type, in which sedimentation is effected by gravity, but mechanical means are used to aid or effect transport to the discharge port, and other mechanical means are (usually) employed to control flow through the port; and continuous centrifugal thickeners, in which centrifugal force effects sedimentation, and discharge of thickened product must be induced by mechanical scraping devices acting against the centrifugal action.

Thickening cones are typified by the Callow cone (see Sec. 8, Art. 9), provided with goose-neck spigot discharge to decrease head on the underflow.

a Automatic control of underflow density (see Sec. 8, Art. 8).

At the Great Falls plant of ANACONDA COPPER Co. (*49 A 423*) 8-ft. cones treating <200-m. slime were fed with pulp carrying 1.5 to 2% solids at the rate of 25 to 30 g.p.m. or 0.58 to 0.70 g.p.m. per sq. ft. of settling area. Overflow contained 2 to 2.5% of the total solids fed and 90% of the total water. Spigot product ran about 8.75% solids and was discharged through a 3/8-in. goose-neck spigot under 24 in. head. Thirty 8-ft. tanks handled 1,000,000 gal. of slime per 24 hr., carrying 80 tons solid. At the Anaconda plant (*49 A 473*) the capacity of an 8-ft. tank treating <200-m. slime from a different ore was only 12.3 g.p.m. per tank or 0.29 g.p.m. per sq. ft. of settling area. The spigot discharge contained 9 to 14% solids, representing 90 to 95% of the total solids fed (*46 A 253*).

Data on the performances of Allen and N. J. Zinc cones operating on zinc ores at the Franklin and Ogdensburg plants of the New Jersey Zinc Co. are given in Table 5.

Effect of overfeeding is shown in Table 6, which presents results of a test on a rectangular settling tank 10×9 1/2×8 ft. (deep), center-fed, treating ANACONDA slime with 2.5% solids. Lead ores have been treated at the rate of 30 to 35 g p.m. of feed containing 1% solids, giving a spigot product with 25 to 40% solids and an overflow carrying 5 gm. per gal.

Table 6. Effect of overfeeding a cone-type thickener

Rate of feed, g.p.m. per sq. ft.	Solids recovered, % total feed
0.19	100
0.21	95
0.23	90
0.27	85
0.30	80
0.33	75
0.37	70

At ALASKA-GASTINEAU 8 1/2-ft. tanks were used for dewatering a feed containing 88.5% <200-m. at the rate of 20 tons solid per 24 hr. in a pulp containing 96% moisture. The spigot product contained 8.8% solids and 88.4% <200-m., the overflow 1.7% solids. At HOMESTAKE (*99 J 412*) 26-ft. conical-bottom tanks, 23 3/4 ft. deep, treated 406 tons of slime pulp (sp. gr. 1.036) per 24 hr., making 84 tons underflow containing 33 tons solid and 322 tons clear overflow. This pulp contained no reagent, and water was at winter temperature. Increase in the feed rate to 505 tons pulp per 24 hr. decreased the density of discharge to 33 tons solid in 86 tons pulp but caused cloudy overflow.

Use of cones. One of the objections to the use of cones for thickening is the fact that they cannot normally be built in large sizes on account of the great headroom required and the structural cost, so that a multiplicity of units is required. Also slimes build up on the sloping sides, causing irregular flow to the apex and making it difficult to maintain a uniform sludge discharge. On the other hand, cones are cheap and easy to support; they are definitely indicated when the gallonage to be treated is small.

Baffles set at an incline in a thickening tank increase settling capacity. Fig. 12 illustrates the action. The thickness of the layer of consolidating solid through which water must be expelled is lessened by inclining the container, and the number of surface pores available for egress of water is increased, both of which changes make for an increased rate of expulsion. Table 7 is a summary of the results of tests in a rectangular tank 3 ft. wide by 3 ft. deep by 9 ft. long at ANACONDA (*46 A 250*), with baffles of corrugated iron set at 45°, tops 4 to 6 in. below the overflow level and the lower ends about 9 in. from the tank bottom. The tank was fed at one end and overflowed the other; baffles were arranged in various positions without causing marked differences in result.

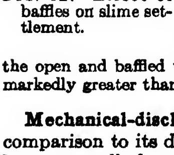

FIG. 12. Effect of baffles on slime settlement.

When high removal of solids is desired, there is little to choose between the open and baffled tanks, but with less complete solid removal the capacity of the baffled tank is markedly greater than that of the open tank.

Table 7. Comparison of baffled and open settling tanks at Anaconda (*After Hayden*)

Feed rate, gallons per foot of width per 24 hr.	Per cent. of solids settled	
	In baffle tank	In open tank
1,883 *a*	100.0	100.0
2,000 *a*	99.9	94.8
3,000	97.5	67.8
4,000	94.0	53.5
5,000	90.3	44.8
6,000	86.8	38.0
7,000	82.0	32.6
8,000	75.9	28.0
9,000	67.8	23.8

a Extrapolated.

Mechanical-discharge gravity-type thickeners comprise a cylindrical tank, shallow in comparison to its diameter, with peripheral overflow and a central bottom-discharge outlet; a centrally located feed well; and a power-driven rotary plow, positioned near the bottom, for moving settled solids to the bottom-discharge opening. Bottom discharge by gravity is unsatisfactory; modern installations almost invariably use pumps designed for constant volumetric displacement. A diagrammatic assembly is shown in Fig. 13. Tank *a* may be of wood stave or steel, as indicated, of concrete, or, rarely, is simply a pit dug in the ground, with suitable supports (usually on concrete piers) for the mechanism. Overflow launder *b* is generally an angle rolled to suitable radius, clipped onto the tank wall, and grouted tight, with a pipe outlet through the wall; a leveling strip *c*, comprising a rubber belt stretched around the upright leg of the launder angle, is adjusted with a wooden mallet

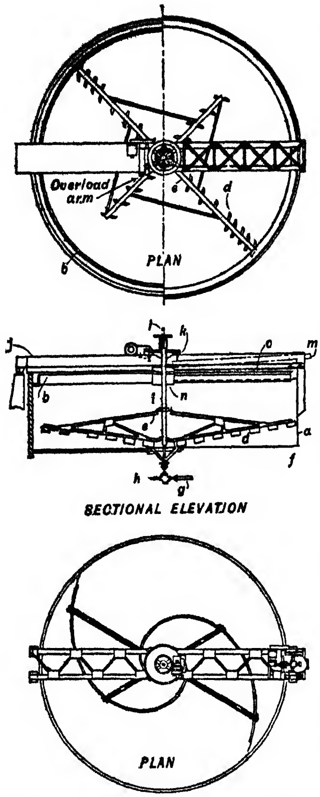

Fig. 13. Single-compartment rotary-rake thickener.

to equalize overflow from a full tank. In the type shown in the upper plan view (Dorr) blades *d* on the 4-armed rotating framework *e* rake settled solids to the central discharge cone *f*, whence thickened pulp flows through pipe *g*, with suitable valves *h*, to a pump, normally of diaphragm type (Sec. 18, Art. 19), located at one side at or near the overflow level. The lower plan view shows spiral rake arms, carrying a continuous spiral band for plowing. The raking mechanism is carried, in the smaller tanks, on a hollow vertical shaft *i*, which, in turn, is supported on a roller- or ball-type thrust bearing carried on support *j*, comprising a beam or truss diametrically across the tank, or a central pier. Rake arms are set on a slope. When the feed is low-grade, solid is allowed to build up in flat-bottomed tanks to the slope of the rakes, but if the feed pulp contains much value, as, for instance, flotation concentrate, the bottom is frequently filled in with cement concrete by pouring in a relatively stiff slow-setting mixture of sand and cement with rakes operating in the lowest position. When concrete tanks or concrete bottoms are used these are built to the desired slope initially.

Drive mechanism (Fig. 13, item *k*) is a worm gear on the central shaft *i*, usually driven by worm from the shaft of an individual motor. In the older forms of Dorr thickener and in some small modern thickeners overloads are absorbed temporarily and an overload alarm is given by the mechanism shown in Fig. 14. Block *b* abuts against the end of shaft *c*, which carries the driving worm. If the resistance of the plows, transmitted through the worm gear, is great, block *b* is pushed back against the pressure of spring *d* and pointer *e* is moved toward the left. Dangerous resistance causes the pointer to move over until a copper plate *f* closes an electrical circuit and an alarm bell is rung, or a light lighted, etc. Provision is made to raise the rakes, as by a hand wheel *l* on a threaded rod suitably attached. (See also Fig. 15.)

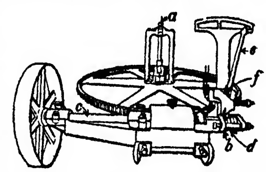

Fig. 14. Overload-alarm mechanism (*Dorr*).

Hardinge Auto-raise overload relief is shown in Fig. 15. Central shaft *a* is carried on rollers *b* which rest in spiral slots *c* in the downward extension *d* of drive tube *e*, which is supported, through the medium of gear *j* by ball bearings *f* in a ball-race in base *g* of the supporting casting. This casting rests on blocks *h* on main girders (or truss) *i* bridging the tank. Worm *j* rotates gear *j* (submerged in oil) in the direction shown in the arrow in Fig. 15, item *A*. When an excessive load comes on the rakes, rollers *b* roll along incline *c* and lift the entire rake mechanism. Link mechanism *l* operates a signal and/or automatic cutout on the driving motor when the rise reaches 3/4-travel.

A modification adapted for pier support of the mechanism is used for 100-ft. and larger tanks.

Dorr Torq thickener employs the resistance offered by an overload to cause the rake arms to rise as in Fig. 16 when an overload is encountered. A motor drive unit is mounted directly on top of a steel or concrete center column, a foot or so above the water level. This drives a turntable *a* from which is hung a revolving cage *b*, concentric with the column. Two, or in some cases four, radial arms, right-triangular in cross-section, are secured to the cage with the hypotenuse of the triangle paralleling the cage diagonal corresponding to *d* (assuming clockwise rotation in Fig. 16). Junction is effected by hinges at the upper leading and lower following corners. When resistance of the settled material exceeds the torque of

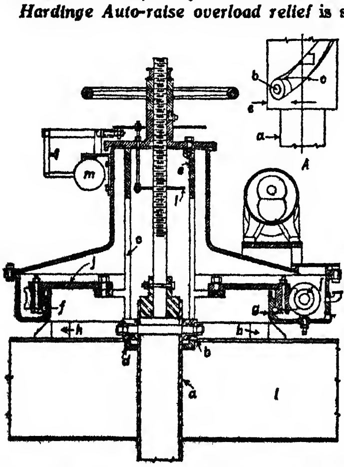

Fig. 15. Hardinge Auto-raise overload relief.

the arm, the latter turns on the diagonal hinge tilting upward and rearward to ride over the load. Normally the arms slope upward gradually at 1 to 1 3/4 i.p.f., but during overloads, they may take a position many times as steeply inclined, as shown in the figure. This arrangement has been used to drive thickeners up to 250-ft. diameter.

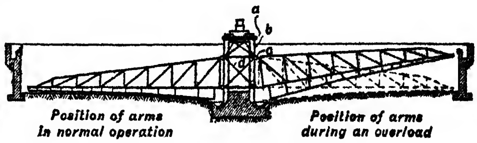

FIG. 16. Dorr Torq thickener.

Traction thickener (Fig. 17) is used for tanks upward of 200-ft. diameter. Driving force is applied at the outer end of the main rake arm *a* by a motor-driven carriage running on a rail mounted on the rim of the tank wall. The rake truss is suspended at its inner end from a turntable mounted on a central pier. Additional center raking is provided, if desired, by one or two stub arms *b* actuated by *a*. Stationary truss *c* carries the feed launder to a central feed well and provides a walkway.

Feed to thickeners is invariably at the center, through a simple feed well comprising an open-end cylinder (*n*, Fig. 13) in small center-drive machines, and through more elaborate adaptations of the same principle to accommodate center piers and drive cages in the large machines. In all feed devices the basic principle is reduction of velocity of the feed stream to such an extent that it will produce a minimum of local eddies and no main currents in the tank. This is accomplished in feed wells by bringing the feed stream against an imperforate splash board to dissipate most of the velocity and then flowing it through a perforated plate at or slightly below the water surface to distribute it in a number of small low-velocity streams within the well. The wall of the well is carried far enough below the surface, normally a few inches to a foot, to minimize radial surface currents and to insure that solid matter starts off with downward velocity.

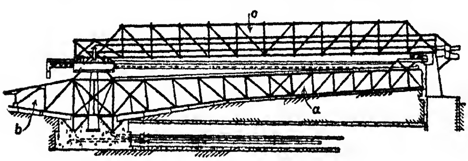

FIG. 17. Dorr traction thickener.

Sizes of single-compartment thickeners are designated normally by tank diameter; they range from 6- to 325-ft.

Tray thickener consists of two or more (usually 6 max.) thickening mechanisms in a single tank subdivided into shallow compartments by transverse obtusely conical septa or trays. In the Dorr balanced type (Fig. 18) the feed stream is divided by V-notch weirs in feed box *a* into equal streams which flow in parallel, as indicated, to centrally located feed points in the (three) different compartments. Sedimentation in each compartment is as in a single-compartment thickener. Overflow is by the usual peripheral weir in the top compartment; in the lower compartments it is drawn off by one or more pipes *b* from each compartment, the quantity drawn being controlled by adjustable slide-pipe weirs in the overflow boxes *c*. Settled material on the trays is raked to the center wells attached to the trays; these make a loose fit with upcast walls *e* carried on the raking mechanism and thus, in conjunction with the beds of thickened material on the lower trays and tank bottom, constitute a sealed central conduit through which thickened solid is led to the bottom-discharge cone, whence it is discharged by a diaphragm pump. In the Hardinge parallel-tray type the compartments are completely sealed off from each other and have, therefore, individual feed and discharge lines; the latter may be joined outside the tank, if desired.

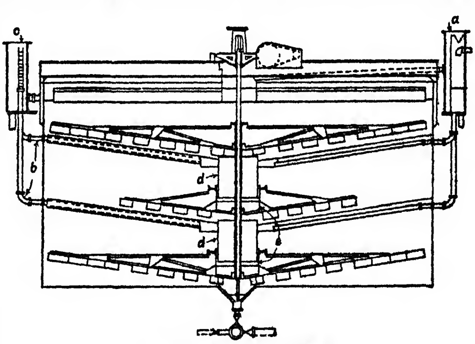

FIG. 18. Tray thickener (Dorr-type).

Sizes of tray thickeners range from 10- to 80-ft. diameter, with 2 to 6 compartments. Minimum tank depth required to accommodate mechanisms ranges from about 9 to 22 ft. for a 2-compartment thickener according to type and diameter, with from 4 to 11 ft. further depth required for each additional tray. Sedimentation requirements (Art. 6) may dictate greater depths.

Manufacturers. Denver Equipment Co., Dorr Co., Eastern Iron & Metal Co., Hardinge Co., Western Machinery Co.

Performances of mechanical sedimentation thickeners are shown in Table 8.

Operation of Settling-Type Mechanical Thickeners

Control of thickened product is usually effected, in the case of thickeners of 50-ft. diameter and smaller, by adjustable-displacement diaphragm pumps (Sec. 18, Art. 19). Spigot discharge tends to be irregular both in density and quantity, and spigots are also prone to clogging. Nevertheless, where close control of solid content or tonnage is not a factor, as in operating tailing thickeners, spigot discharge is usual (see Table 8).

Density of thickened pulp is affected by the size, specific gravity, mineralogical character, and state of dispersion of the ore; the detention provided, the depth of tank, and the action of the raking mechanism. In general, the discharge from a continuous thickener will be as dense as or denser than the long-time settlings from the same pulp in a beaker, graduate, or similar apparatus.

Ore. Coarse feeds of heavy ore settle to higher densities than feeds of fine, light material. Siliceous ores settle to higher densities than clayey and highly oxidized ores. Percentage of solids in thickener discharges can be run up to between 45 and 60% on normal feeds of 2.7 sp. gr. ground to 100- to 200-m. On clean, siliceous ores of higher sp. gr. ground to 48- or 65-m. the discharge may run as high as 65 to 70% solids.

Detention. Within limits, the density of the discharge is a function of the time (DETENTION PERIOD) during which the feed particles are retained in the thickener tank. A definite detention, differing for different ores, is required for a pulp of a given dilution to settle to the ultimate density. If the rate of sludge withdrawal is such that this time relation has not been allowed, the pulp discharges at less than the attainable density. With a given daily volume of feed, detention is a simple function of area and effective depth of consolidating pulp. (See Art. 6.)

Depth of tank. The effect of depth on density of underflow is small. The time during which consolidated pulp is compacting is the important element in determining discharge density. Shallow tanks ordinarily show slightly thicker discharges for a given time of settling, on account of the fact that compacting starts earlier therein. Table 9 is typical.

Table 9. Effect of depth on density of underflow (*After Coe and Clevenger, 55 A 356*)

Time of settling, hours	Depth of tank: 114 in. — Depth of clear liquor, inches	114 in. — Solids in settled pulp, %	45 in. — Depth of clear liquor, inches	45 in. — Solids in settled pulp, %	11 in. — Depth of clear liquor, inches	11 in. — Solids in settled pulp, %
0	....	22.5	....	22.5	....	22.5
1	1.5	....	1.5	....	1.56	26.7
5	9.4	25.3	9.75	28.8	3.92	33.6
23	45.5	35.5	19.5	37.1	5.25	39.5
29	51.5	38.2	21.0	39.1	5.39	40.1

Effective depth is total depth minus the depth of clear liquid extending from the surface to the lower rim of the feed well and minus the depth at the bottom of the tank occupied by the raking mechanism. The clear solution zone at the top may be a foot or two deep, while the raking zone at the bottom is equal to the radius of the tank in feet multiplied by $s/12$ where s is the slope of the rake arms in inches per foot. This effective depth, as determined by test (Art. 6), must be allowed for each compartment in tray thickeners; the total depth of the tank is the combined depth of the various compartments.

Raking mechanism. Many tests have demonstrated that the raking mechanism increases the ultimate density. All but the coarsest pulps settle to a higher ultimate density in continuous thickeners than in quiescent tubes or vessels. This is because, in quiescent settling, the individuals pack loosely in coming to rest, forming a structure, however, strong enough to resist the gently applied load of later-settled particles. The rakes exert greater pressure, in general, than gravity, and rabble the particles somewhat, thus compacting them. The rake arms of the type G Dorr thickener are provided with vertical fingers, resembling a picket fence, to accentuate this compacting effect. The action is paralleled by stirring settled sludge in a beaker, particularly if it is flocculent.

Distribution of solids in operating thickeners is shown in Figs. 19 to 21. In Fig. 19 the deep layer of clear solution at the top leaves a safe working margin for feed fluctuation and is a desirable condition. It also provides space that may, in emergency, be utilized for pulp storage. In Fig. 20, the thickener is being loaded heavily; if the feed rate were further increased, or settling rate should decrease, the clear zone would disappear and a cloudy overflow result. Fig. 21 shows the characteristic lateral size distribution during settling, with coarse heavy solids near the center and fine solids well out toward the periphery of the tank. The rakes, in plowing settled material to a central outlet, restore size distribution to that of the original feed pulp.

Capacity is normally expressed as sq. ft. per 24-hr. ton of settled solid. It depends upon the settling characteristics of the solid, *i.e.*, mineralogical character, size, and state of dispersion, and upon the moisture content of the feed and the density of underflow. (See *Density*, p. 22.) Moisture content of pulp together with volume and tank area determine

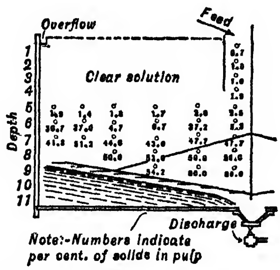

FIG. 19. Pulp densities in a thickener; low feed rate (*after Dorfman*).

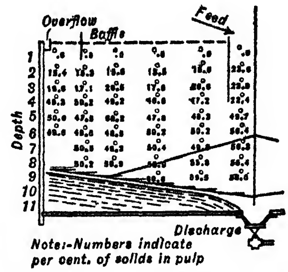

FIG. 20. Pulp densities in an overfed thickener (*after Dorfman*).

the rising current against which the solid must settle. Rising velocity in dilute pulps may be as great as 0.5 mm. per sec. Table 10 summarizes Table 8 and gives additionally rough average data from Dorr Co. files. The data are to be used with caution, and then only for check purposes; actual tests (Art. 6) should always precede specification. The soluble-salt content of ores and mill waters, and the reagents added for flotation, cyanidation, and the like, may have a tremendous effect on settling rates and, consequently, on thickener capacity.

At TUL MI CHUNG (*114 P 362*) addition of 2 lb caustic soda per ton of a calcitic ore decreased thickener capacity on a pulp containing 25% solids from 6 sq. ft. per 24-hr. ton to 36 sq. ft., or 500%.

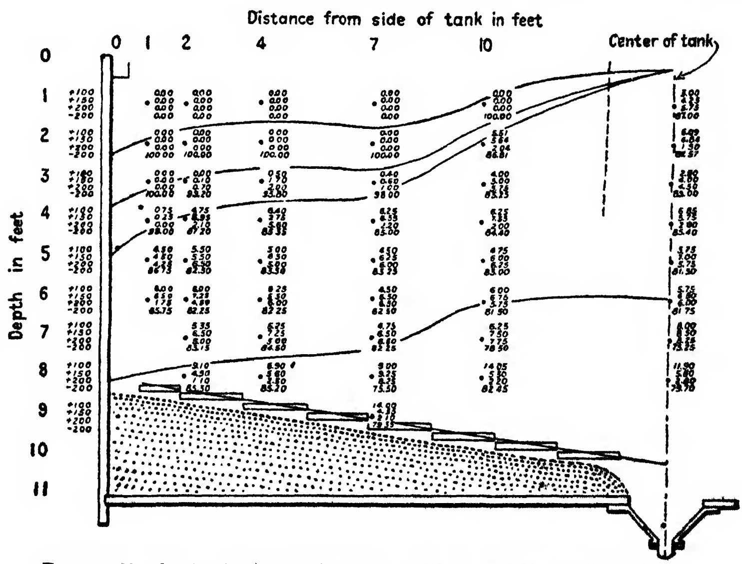

FIG. 21. Size distribution in a settling-type mechanical thickener (*after Dorfman*).

Concentrate thickening is ordinarily complicated by the presence of fine armored bubbles and fine-bubble agglomerates, and by the tendency of the pulp to refroth when or if it plunges into the body of pulp in the thickener. The best cure for frothing in the tank is prevention, *i.e.*, to introduce pulp at low velocity and at an acute angle to the surface. Frothing agents containing little or no insoluble oils normally make fragile froths.

Froth breaking. Surface froths can be broken by water. It is necessary to strike practically every bubble that is to be broken, hence the water must be projected at the froth as a multitude of small masses (SPRAY) or as a number of small streams (MULTIPLE JET) or as a sheet. The water must be under some pressure in order to be moving with sufficient velocity to break the bubbles, but the velocity should not be so high as to produce froth by cascade action (see Sec. 12, Art. 22). The sprays or water jets are applied in the launders leaving the flotation machines or are directed at the stream as it enters the thickener.

Pumps and bucket elevators have been used to break froth at several plants but neither is particularly satisfactory. If the froth is persistent and voluminous it will not enter these machines, but overflows the sumps, and water must be used to break it down. The cascade action at the discharge will cause considerable froth to form.

Table 10. Thickener areas required for settling typical pulps *a*

Type of pulp	Composition of feed pulp	Source of figure	Usual solid content of feed, %	Usual solid content of underflow, %	Unit area, sq. ft. per ton per 24 hr.

a The figures foot-noted *a* are by Dorr Co. and are given as normal ranges for illustrative purposes only; specific pulps should be tested (Art. 6) before a machine is selected.

b From Table 8.

c Some underloaded thickeners up to 63 sq. ft.

d One at 30 sq. ft., probably underloaded.

e One value at 88 sq. ft.

At CIA. COROCORO DE BOLIVIA (*112 J 983*) a very tough froth was broken by running it into the intake of a 4-ft.×6-in. ventilating fan running at 250 r.p.m. The fan handled more than 50 tons of froth per 24 hr. Blades lasted 4 to 6 mo. Only the foam was sent to the fan.

Soluble reagents that lower surface tension greatly in relatively low concentrations, such as pine oil, wood creosotes, and the like, have been mixed with the spray water at some plants. Water containing such reagents lowers the surface tension of the bubble films that it strikes to such an extent and so suddenly that the adjacent film contracts sufficiently to break the bubble wall at the point of low tension. The use of Wilfley tables as froth breakers is an application of the method of surface-tension change. Lime has been added at COEUR D'ALENE plants to break down froth (*105 J 716*), but the probability is rather that it promotes settling, since it has not sufficient effect on surface tension to act from that angle.

Frequently small-bubble persistent froth collects on the surface of concentrate thickeners and, if not confined, overflows. If it can be confined by a ring placed a few feet in from the overflow rim and extending down for several feet into the tank and up a foot or more above the overflow rim, it gradually dries out and compacts, and equilibrium is reached with settlement of the densest portion from the bottom near the periphery, balancing accession at the center. At MIAMI, when oil was used as a collector, this end was attained by using several tanks more or less intermittently and thus allowing sufficient time in each for the necessary compacting. At GOLD HUNTER (*107 J 889*) floating froth was scraped off into a special launder by arms connected to the revolving mechanism, and joined with the thickened product ahead of the filter plant.

Trouble with surface frothing has substantially disappeared from mills treating metalliferous ores, but is present in most nonmetallic flotation mills, if flotation feed is not deslimed.

Submerged air-mineral aggregates decrease sedimentation rates but do not affect moisture content of underflow materially. No general method of breaking such air-mineral contacts is known, although it is not impossible that with fatty-acid collectors a high hydroxyl concentration would be effective (see *153 A 500*).

Power consumption is so small as to be negligible from a cost standpoint. Installed horsepower is several times that consumed in normal operation in order to supply reserve force to overcome incipient stalls, and for starting without excessive lifting of rakes.

Attendance is a small item; attention is generally confined to pump adjustment, involving starting and stopping not over once or twice per shift, and to lubrication, which requires about 10 min. per day per thickener. Thus, except where a large number of tanks is in use, operators on adjacent machines can take care of them.

At MORENCI (old) one laborer devoted 3 hr. per 24 hr. to the operation of one 200-ft. thickener, handling 2,000 tons of tailing per day. At INSPIRATION one man per shift operated eight 60-ft., three 80-ft., and one 200-ft. thickeners. At ANACONDA one man, full time, took care of 40 @ 28-ft. tanks. At CHINO one man attended 21 tanks of 20- to 75-ft. diameter.

Repairs are substantially nil, barring accidents due to attempts to start after a shutdown when the rakes are imbedded in solid. Such accidents may be avoided by raising the rakes before shutting down and lowering them slowly on starting. Wooden tanks rot in course of time and should not be used if long life is desired, except where metal cannot be

Table 11. Operating costs of Dorr thickeners

a 1-tray. *b* 3-tray. *c* 2-tray.

used on account of the chemical character of the liquid and where concrete is not justified. Maintenance for a 2 1/2-yr. period at INSPIRATION was $208.56 total.

Costs. Operating costs at a number of plants are given in Table 11. Safe average figures for estimating are: 1¢ per ton of solid per thickening step for 100 to 300 t.p.d. per thickener; 1 1/2 to 2¢ for smaller operations, and 1/2 to 3/4¢ for large. INSTALLATION COSTS average about $70 per ton of mechanism, $30 per ton of superstructure and steel tank, and $80 per ton of wood tank. Concrete work for foundations and tanks: Excavation, $1 per cyd.; concrete in place, $30 per cyd.; supports in place: wood, $100 per M.B.M.; steel, $150 per ton.

6. DESIGN OF SETTLING TANKS

Coe and Clevenger method (*55 A 356*) is based on settling tests such as those described in Art. 1, carried out in detail as follows:

Apparatus: Glass cylinders 2 in. or more in diameter and 12 to 18 in. deep, preferably graduated; 2-liter graduates are excellent.

Testing: Two series of tests should be made, the first to determine the area required to obtain clear overflow, the second to determine the tank volume necessary to obtain a spigot discharge of the required density. In both series all conditions must be the same as will be encountered in practice, *e.g.*, the time that the ore has been in contact with water or solution; the kind and quantity of electrolyte or other reagent present, if any; the method of grinding and the temperature must be watched particularly.

Tests for area require from six to a dozen samples of pulp of varying consistency ranging from that of the original feed pulp to that of the thickest free-settling pulp (normally between 20 and 30% solids). The samples are best taken from a large batch which has been thickened to the desired consistency by decantation, then thoroughly stirred and sampled. Each sample, diluted to the desired consistency with decanted liquor, is allowed to stand until the upper surface of the solids has settled

about 1/8 in., then a reading is taken and the rate of subsidence for a period ranging from 2 or 3 min. for thin pulps to from 6 to 10 min. for thick pulps determined. With thick pulps intermediate readings should be taken to insure that the rate of subsidence is uniform. A decrease in rate indicates departure from free-settling conditions. The observed rates should be converted into feet per hour and tabulated as shown in the first three columns of Table 12.

Spigot-density test is made on the thickest free-settling pulp by reading the level of the surface of the subsiding pulp in the same cylinder as above used at intervals of several hours until subsidence ceases or until the required pulp consistency is reached. The overlying clear liquor should be removed often enough to keep the water surface near that of the subsiding solid. Table 13 shows the results of such a test on the same pulp as was used for Table 12.

Table 12. Results of tests to determine area of settling tank [a] (*After Coe and Clevenger*)

Design calculation

A Area in sq. ft. required per ton of dry solids fed per 24 hr. (24-HR. TON) to produce clear overflow, assuming free settling.

c Subscript indicating compression zone.

D Water-solid ratio by weight (DILUTION) of tank underflow; it is determined by spigot-density test, and may correspond to the ultimate density, or to some lower density dictated by other considerations.

D' Average dilution of pulp in compression zone, undergoing consolidation settling (p. 15–09).

d Required depth of compression zone, ft.

F Dilution of feed to a particular zone, the identity of which is denoted by a subscript.

f Subscript indicating free-settling (upper) zone.

R Rate of subsidence, ft. per hr., of top of solids in a pulp of dilution F_f.

T Weight of liquid, in tons, rising through any zone per 24 hr. per 24-hr. ton of settling through the same zone.

t Hours required for pulp to consolidate from F_c to D.

δ Average sp. gr. of solids in compression zone.

ρ Sp. gr. of liquor in which settling takes place.

ρ' Average sp. gr. of pulp in compression zone.

Area. Design, founded on the tests, is based on the assumption that the rising velocity of the water through each subsidence zone in the tank is equal to the settling velocity of the solid in still water through the same zone. Then $T = 24\,AR\rho\,(62.5)/2{,}000$. But $T = F - D$, by definition. Substituting this value for T in the preceding equation, and solving for A gives $A = 1.33\,(F_f - D)/R\rho$. Applying this equation to each settling test, *e.g.*, as in Table 12, values of A may be calculated for any selected value of D. The value $D = 1.12$ (see Table 13) was taken in deriving the values for Table 12.

Note that if the value of A in the tabulation (as Table 12) increases sharply in a zone of relatively low dilution, it is indicated that the pulp is undergoing consolidation settling. Consequently the equation for A does not apply.

From Table 12 it appears that, for the pulp tested, the maximum area required to be provided per 24-hr. ton is 4.31 sq. ft., corresponding to the zone in which $F = 4.00$. If less area is provided, the layer of pulp of this density will increase in thickness and solid matter will eventually overflow.

Capacity in the compression zone depends directly on the time required for the sludge to reach discharge density D, the time being a function of volume, which, for a tank of given area, is directly proportional to depth.

To calculate capacity in compression, the time required for a pulp, after it has entered the compression zone, to reach the discharge dilution required is taken from the spigot-density test records. Maximum economic density is usually limited by the pumping characteristics of the pulp, but cost of initial installation, limited space available, etc., may make it necessary or desirable to accept a more dilute discharge; character of the pulp determines ultimate density (see Art. 1).

From the spigot-density test, D' and ρ' are determined. Then the weight of solids in pounds in one cubic foot of pulp in the compression zone (average) is $62.5\rho'(D' + 1)$, whence the volume of pulp in this zone which contains one ton of solids is $2{,}000\,(D' + 1)/62.5\rho'$. The volume required to contain a 24-hr. ton of solids is $1/24$ of this or $4(D' + 1)/3\rho'$, and the volume required per 24-hr. ton to store for t hours is $V = 4t(D' + 1)/3\rho'$. But

(Sec. 19, Art. 24) $D' = \rho(\delta - \rho')/\delta(\rho' - \rho)$, and $D' + 1 = \rho'(\delta - \rho)/\delta(\rho' - \rho)$, whence $V = 4t(\delta - \rho)/3\delta(\rho' - \rho)$. But $d = V/A$, whence

$$d = \frac{4t(\delta - \rho)}{3A\delta(\rho' - \rho)}$$

From table 13, D' was 1.41 ($= 1/2\,[1.70 + 1.12]$). Assuming $\delta = 2.7$, $\rho' = 1.33$, whence $d = [4 \times 19(2.7 - 1)]/[3 \times 4.31 \times 2.7\,(1.33 - 1)] = 11.2$ ft. Add to this figure 1 to 2 ft. of clear solution for a margin of operating safety, and an additional allowance for the pitch of the rakes (p. 15). The total is the depth required with no allowance for storage, or variation in tonnage, character of ore or solution, temperature, etc. If the tank thus calculated is too deep, the necessary volume may be obtained by increasing diameter. Coe and Clevenger recommend a minimum area of 6 sq. ft. per 24-hr. ton for pulps composed of fine granular material with a considerable proportion of dispersed slime.

Table 14 compares capacities computed by the tests outlined with actual capacities at a number of plants. The great discrepancies at PORTLAND and PRESIDIO correspond to underloaded tanks, as shown by the excessive depths of clear solution. The NIPISSING excess of actual over calculated capacity appears to correspond to overloading. All of the pulps in Table 14 are cyanide pulps containing lime, which is an aid to settlement.

Table 14. Comparison of computed and actual capacities of thickeners (*After Coe and Clevenger*)

a Roasted ore.

7. WASHING IN THICKENERS

Counter-current decantation (C.C.D.) is the field name applied to continuous application of the familiar laboratory procedure of washing a fine solid by decantation. It is a common practice in hydrometallurgical operations. Fig. 22 is a typical installation in which items 1, 2, and 3 are agitators arranged for series flow, and X, Y, and Z are thickeners arranged for series flow of solid in the order named, with counterflow of removed liquid.

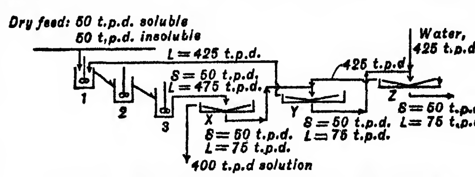

FIG. 22. Washing by countercurrent decantation.

Calculations. In Fig. 22 the feed assumed is 100 t.p.d. of solid, of which 50% is soluble in water; 425 t.p.d. of water is to be used as extractant; the insoluble residue settles under the conditions postulated to a pulp containing 40% solids. *Wanted:* (*a*) the solution concentration in all thickeners; (*b*) the amount of soluble material discharged in the underflow from Z; (*c*) the washing efficiency; (*d*) the extraction.

Tonnages. The underflow from the final thickener Z consists of 50 t.p.d. of insoluble solid (assuming complete solution in the agitators) comprising 40% of the discharge pulp; the accompanying liquid is, therefore, 75 t.p.d. On the conditions of the problem, the solid and liquid contents of the other thickener underflows are the same.

Total inflow to thickener Z is 500 t.p.d. of liquid and 50 t.p.d. of solid, wherefore the overflow to thickener Y is $500 - 75 = 425$ t.p.d. of liquid. Thickener Y receives the same quantity of liquid as Z and overflows the same quantity. Thickener X receives only from agitator 3, the discharge of which is equal in weight to the feed to agitator 1, or 425 t.p.d. of liquid, 50 t.p.d. of insoluble solid, and 50 t.p.d. of soluble solid, which dissolves in the agitators. Underflow from X carries away 125 tons of this total, including all of the solid; hence overflow from X is $525 - 125 = 400$ t.p.d. of solution.

Solution concentrations are calculated as follows: Let x, y, and z represent respectively the solution concentrations in the similarly lettered thickeners. Equate tons of dissolved salts in and out of each thickener and solve.

Thickener	*In*	*Out*	*Concentrations*
X:	$50 + 425y =$	$400x + 75x$	$x = 12.44\%$
Y:	$75x + 425z =$	$425y + 75y$	$y = 2.14\%$
Z:	$75y =$	$425z + 75z$	$z = 0.32\%$

Extraction is the percentage of the total salt fed that is contained in the overflow of thickener X, or $400\,(0.1244)100/50 = 99.5\%$. Given assays of feed and tailing (concentrate assay is 100%), extraction is obtainable by the usual recovery formula (Sec. 19, Art. 22).

Tailing assay (solid basis) is the salt content of the underflow of thickener Z divided by the sum solid plus salt in this underflow, or $75(0.0032)\ 100/[50 + 75(0.0032)] = 0.48\%$.

Filtration of tailing. Vacuum filters (Sec. 16, Art. 7) are frequently installed at the end of the C.C.D. system to dewater tailing. If the filters are arranged for spray washing, a smaller number of thickeners is required to give the same over-all washing efficiency.

Washing in tray thickeners. Fig. 23 shows the operation of a tray thickener arranged for washing, typified by series flow of solids and wash liquid in opposite directions through successive compartments, rather than by parallel operation of these compartments as in Fig. 18. The lower four compartments in Fig. 23 represent typical C.C.D. operation; feed enters the first washing compartment through feed box B, and solid progresses under gravitational influence through the successively lower compartments: wash water or other extractant enters the bottom compartment through feed box E and progresses via overflow pipe F, and feed box D to the overlying compartment, and thence similarly to a final discharge of enriched overflow from box A. The top compartment is superimposed as in Fig. 23, if treatment of the pulp prior to washing, as by agitation, and separation of original solution from wash solution are desired. This top compartment is actually a separate thickener, substantially sealed off from the first washing compartment by what is, in effect, a heavy-liquid seal.

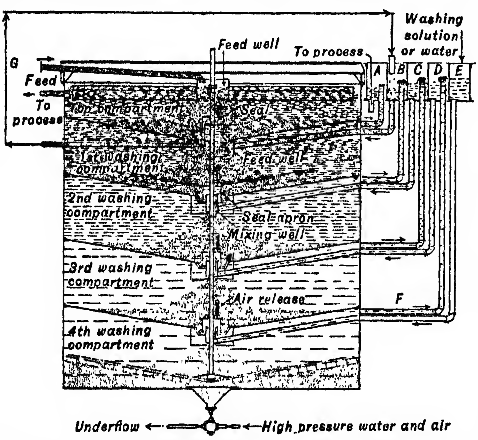

FIG. 23. Tray thickener with sealed-off primary compartment (*Dorr*).

8. FILTER THICKENERS

Filter thickeners depend primarily upon filtration (Sec. 16, Art. 1) to separate liquid from solid; they differ from filters in that the solid deposit on the filtering septum is not normally exposed to air drying but is dropped in the presence of the feed pulp, settling therein rapidly because of aggregation that survives the dropping.

They are particularly useful for thickening, washing, and leaching materials which do not settle readily from a suspending fluid, owing either to low specific-gravity differential between solids and liquid or to fine dispersion of the solid.

The usual filter thickener consists of a relatively deep tank provided with pulp-feed and sludge-discharge connections and a plurality of submerged filter elements connected to a source of vacuum. Filtration and droppage of cake are alternated automatically at short intervals, the wet cake being forced off by a counterflow of low-pressure air or water introduced behind the filter medium. The dropped cake is removed from the bottom of the tank, as a thick sludge, by spigot or pump.

Genter thickener (Fig. 24) consists of a cylindrical tank a, with obtusely conical bottom, in which are mounted a series of tube frames b radiating from a central structure c, the upper part of which is an automatic valve and the lower a filtrate receiver. The tubular elements, of which 4 to 16 depend from a manifold on each frame, are approximately 6 in. in diameter by 6 ft. long, made of corrugated iron or wood covered with filter medium. The filtering area of each tube is about 9 sq. ft. Timing mechanism d, which drives the auto-

matic valve, is motor driven; the same motor also drives rakes *e* at about 60 f.p.m. peripheral speed. Discharge of thickened product is effected by an intermittent valve driven from the timing mechanism. An annular overflow launder is provided. Frames are readily disconnected, one at a time, by means of a clamp, and may then be lifted out for inspection and/or repair. The individual filter units, weighing about 15 lb. each, are readily detached separately.

In operation the tank is kept filled to overflow to insure submergence of the filter elements, and the timer is set for a filtration period per frame of 1 to 10 min. (5 min. is usual), with 2 to 3 sec. flush-back period for discharging cake. The spigot-discharge timer is set to maintain the desired underflow consistency.

Sizes are rated on tank diameter and/or filter area as follows:

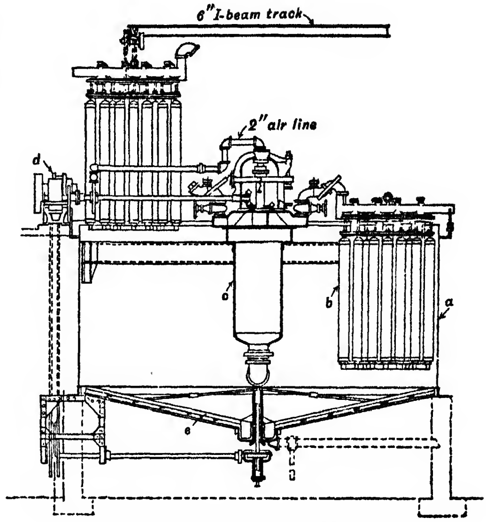

Fig. 24 Genter filter thickener.

a Leached. *b* Including vacuum pump. *FC* Flotation concentrate.

Oliver-Borden thickener has vertical filter tubes arranged in rows in a rectangular tank, the bottom of which forms a vee under each adjacent pair of rows. Tubes taper slightly downward. Alternate vacuum and blowing collect and drop cake into the vees, where it is re-pulped by a horizontal bladed stirrer and is then discharged by gooseneck.

Sweetland filter-thickener is similar to the Oliver-Borden, differing somewhat in tub construction, and in the fact that alternate vacuum and backwash water are supplied by a rotary pump driven by an automatically reversible motor.

Shriver filter-thickener is a modification of the Shriver plate-and-frame pressure filter (Sec. 16, Art. 6), so arranged that the flow of pulp is continuous from end to end, and the velocity is high enough to prevent cake formation by scouring. As a result the pulp is continuously thickened in its passage by removal of liquid, and there is continuous discharge of thickened pulp and clarified liquid at the end. Operating pressures range from 20 to 50 lb. per sq. in.

Hardinge Super-thickener (Fig. 25) is a combination of the usual settling-type dewaterer with mechanical removal of settled solids, and a sand filter. Its underlying principle is to increase the rate and extent of compacting of settled solid by making the direction of the currents of expelled water downward instead of upward. It does this by maintaining a head of solution on the sand-filter bottom,

either by suitable difference in elevation between the level of overflow and filtrate discharge or, if this is insufficient, by discharging filtrate by means of a vacuum pump. In Fig. 25 (*a*) is the thickener tank with overflow launder (*b*), spigot discharge (*c*) through a diaphragm pump, scraping mechanism (*d*) for moving settled solids toward the discharge spigot, a sand bed (*e*) through which filtrate is to be drawn, supported on the usual framework of studs, slats, cocoa-matting and burlap (*f*) (see Sec. 16). A pipe (*g*), connected to the space under the filter bottom, discharges filtrate either into the atmosphere or into a vacuum tank, according to the filtering duty required. The essential element of successful operation is the continuous removal of a thin skin from the top surface of the filter bed, thus maintaining this at full filtering efficiency. This is done by means of a thread (*h*) on the upper end of the drive shaft and a ratchet-driven feed mechanism (*i*) which lowers the scraping mechanism at the rate of 1/64 in. to as much as 8 in. per 24 hr., depending upon the amount of material present that tends to clog the filter. The thread (*h*) is 5 ft. long. The sand should be fine, granular, and of such a mixture of sizes as will give maximum porosity and yet permit minimum penetration of solid, as in Table 16. Power requirement for the scraper and diaphragm pump is about the same as for the usual rake thickener. If suction is used, more power, in accord with the suction requirement, will be needed.

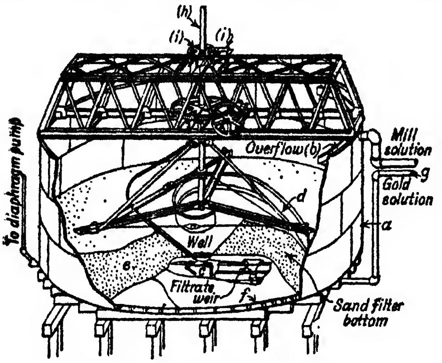

FIG. 25. Hardinge Super-thickener.

The underflow of the Super-thickener at GOLDEN CYCLE could be maintained at a much higher density than was possible in the usual type. When feeding cyanide pulp containing 20% solids, ground so that 95 to 98% was <200-m., the Super-thickener would discharge at 70% solids, working under a static head of 20 in. of water, but the diaphragm pump could not handle pulp of this thickness, so that density was lowered to 64% solids. This is to be compared with maximum operating thickness of 45% solids on the same pulp in the ordinary machine. (*Hardinge Co.*)

Applicability. The Super-thickener is particularly adapted to clarification and to production of exceptionally thick spigot products. For thickening service that is within the capacity of the ordinary thickener the latter is simpler to operate and probably cheaper, notwithstanding a somewhat lower capacity.

Centrifugal thickeners. The Bird centrifugal (Sec. 8, Art. 13) is used as a thickener in many nonmetallic milling operations.

Comparison of Thickeners

Continuous thickeners have greater capacity per square foot of settling surface than intermittent because the settling rate in the latter is slowed down, when they are nearly full, by the approach of thick pulp to the surface. Convenience in operation is, of course, all in favor of the continuous machines. Gravity-discharge continuous thickeners have the same capacity per square foot of settling area as the mechanically discharged machines, so far as settling alone is concerned, but on account of the difficulties in maintaining uniform discharge of thickened material by gravity, the practical effect is to cut down the capacity. The slow raking of the thick-pulp layer to the discharge opening aids and accelerates final compacting. Filter thickeners are superior to gravity thickeners for clarification, for treating very dilute pulps, and for making very thick spigot products. Centrifugal thickeners are outstanding in capacity per unit of area and of volume occupied. Both the filter thickeners and the centrifugals require more power, attendance, and maintenance than the gravity types.

SECTION 16

FILTRATION

REVISED BY DONALD F. IRVIN, ENGINEER,
OLIVER UNITED FILTERS, INC.

Filtration is employed in milling to separate liquid from solid more completely than is possible by settling alone. The principal applications are in dewatering flotation concentrate and, in the cyanide process, in removing pregnant solution from leached solid, washing the dewatered filter cake, clarifying decanted pregnant solution, and in collecting precipitate; other uses are for dewatering magnetic concentrate and various nonmetallic minerals in wet-treatment plants. A FILTER is a permeable septum so mounted that the material to be filtered can be brought to one side at a pressure higher than exists on the other side. Under such circumstances, if the pores in the filtering medium are of suitable size, the solid particles are held back while liquid passes through. After the first short period of filtering, the effective medium is the layer of solid deposited on the original septum.

1. PRINCIPLES OF FILTRATION

Sperry (*16 CME 198, 17 CME 161*) has determined experimentally that the velocity of flow of liquid through a filtering medium varies directly with the pressure and inversely with the thickness of the cake and that the character of the flow is, therefore, the same as that in capillary tubes under low pressure, which is expressed in the equation $v = \pi pr^4/8l\mu$, where p = difference in pressures at ends of tube, r = internal radius and l = length of opening, and μ = viscosity of liquid. The terms l and r in this equation cannot be determined for any practical filtering problem, but Sperry has expressed them in terms of a unit of resistance R, defined as the resistance of a filtering medium of such permeability that 1 sq. ft. 1 in. thick will pass 1 gal. of water per hr. at 68° F. under a pressure difference on the two sides of 1 lb. per sq.in.; and a unit of deposition or cake-forming ability K, possessed by the solid being filtered, which he defines by saying that a substance has a unit rate of deposition when, under standard temperature conditions, a 1% mixture of the substance with water produces a flow of 1 gal. per hr. over an area of 1 sq. ft. with a pressure difference of 1 lb. per sq. in. With these terms he has developed from the preceding equation the relation

$$Q = \left[\sqrt{\frac{2PKT}{RS} + \left(\frac{KR_m}{RS}\right)^2} - \frac{KR_m}{RS}\right]\frac{N_S(1 + at_1 + bt_1^2)}{N_0}$$

where Q = quantity of liquid passing the filter, P = difference in pressure on two sides of septum, R = resistance of filter cake to passage of liquid, R_m = resistance of septum, K = rate of deposition of cake, T = time, S = percentage of solids in feed pulp, N_S = coefficient of viscosity of liquid at standard conditions and $\dfrac{N_0}{1 + at_1 + bt_1^2}$ is Poiseuille's statement for viscosity at temperature t_1 compared with the viscosity at t_0, a and b being constants dependent upon the liquid. Sperry has verified this relation experimentally. The equation is not practically useful for purposes of design of filters but it shows that filtering rate increases when pressure and temperature increase and decreases with resistance of the

filter and increase in thickness of the cake. Hatschek (*27 SCI 538*) has shown experimentally that resistance to filtration increases rapidly with decrease in size of particle forming the cake. Hence the equation of capillary flow can be taken as indicative of the effect of variation in the several factors involved in filtration. Walker, Lewis, and McAdams (*Principles of Chemical Engineering, McGraw-Hill Book Co., 1937*) present a series of differential equations for filtration based on the fundamental equation $dV/dt = P/R$, in which V, t, P, and R are volume of filtrate, time, pressure difference, and resistance respectively. This is, of course, a summary of the indications of the Sperry formula. The authors give illustrative examples of the application of the derived equations to design.

Even granting the accuracy of the various theoretical equations presented, they are inadequate for practical design. A rotary vacuum filter usually makes 250 to 500 cycles per 24 hr., and the life of a filter cloth before discard may therefore be 50,000 cycles. Filter cloths diminish in capacity steadily, although slowly, owing to clogging by the finest solid particles, or incrustation by carbonate or sulphate scale; conversely the fabric may suffer actual wear, throughout the period of use. This means that the quantity R of the Lewis equation has a long-time variation that is certainly not determined by laboratory tests on new or comparatively new filter septa, and is probably not determinate even in the laboratory except by runs under conditions closely approximating plant conditions, including duration. Laboratory tests can indicate basic initial performances, but the results must be discounted on the basis of experience to obtain a dependable average output rating.

Young (*42 A 752*), working with vacuum filters and ore slimes, confirms the general trend of the theoretical equations. Fig. 1,*A*, shows the effect of cake thickness on filtering rate; Fig. 1,*B*, the effect

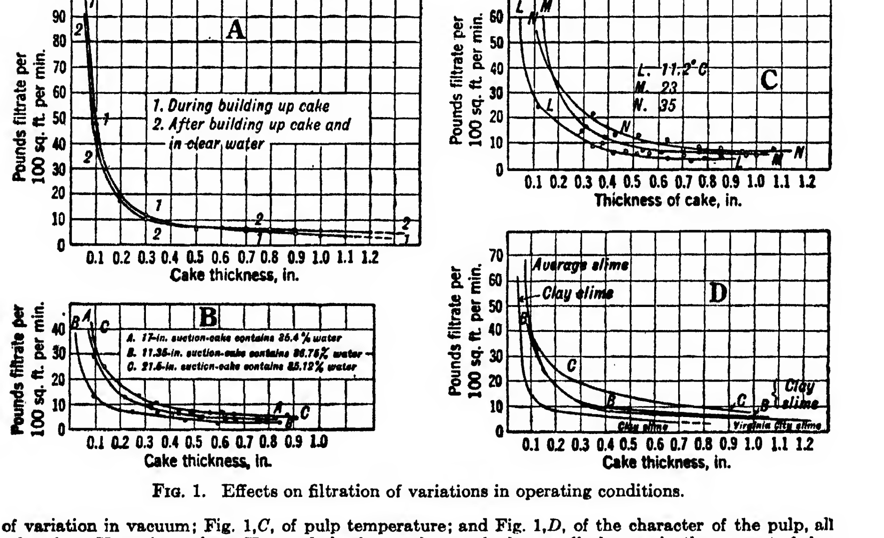

Fig. 1. Effects on filtration of variations in operating conditions.

of variation in vacuum; Fig. 1,*C*, of pulp temperature; and Fig. 1,*D*, of the character of the pulp, all taken from Young's results. He concludes from other work that small changes in the amount of clay in a pulp or in a cake have more effect on the filtering rate than much larger changes in the amount of sand.

2. FILTER MEDIUM

The filtering medium is composed of the porous septum itself plus the cake of filtered material held thereon. The septum may be a bed of solid grains merely piled together and, therefore, incapable of use in any position other than horizontal; it may be a porous slab of artificial material like Filtros; most frequently cotton cloth is used, but woolen, mineral-fiber, synthetic-fiber, and metallic cloths, and punched rubber sheeting are employed increasingly. The septum, in the size and spacing of pores and in the conformation of its surface, has a marked effect on the structure of the cake formed immediately adjacent to it. This follows from the mechanism of cake formation.

Cake formation. When a pressure is imposed on a body of pulp in contact with a porous surface, the liquid of the pulp begins to flow through the pores at a rate dependent upon the pressure differential on the two sides of the surface, and the frictional resistance

to flow. Liquid streaming to the pores carries solid with it, and the solid particles unable to enter the pores are held against the filter surface by the impulse of the liquid flowing against and around them. The phenomenon, and the magnitude of the forces involved, is familiar to anyone who has placed his hand or foot near the submerged outlet of a discharging tank.

If the particles in the pulp to be filtered are smaller than the pores, which is normally the case as to many, if not all, of the particles in the usual pulp with respect to the meshes in filter cloth, they go through, if they approach singly. If, however, as is ordinarily the case, there are so many in the pulp that they approach in a loose mass, they suffer the same fate as a crowd of people making a rush to get through a doorway amply wide to pass two or three or more abreast in orderly array. The result is as pictured diagrammatically in Fig. 2 by Hixson, Work, and Odell (*73 A 225*). An arched bridge of the coarse grains forms over each pore, the smaller being flushed through as the jam started, and this acts as a filter of much reduced pore space to form secondary bridges, etc., until the particles passing are so few and so small as to be invisible to the naked eye, and the filtrate becomes clear. Hixson *et al.* found that filtering surfaces were effective, *i.e.*, would build cakes that yielded clear filtrates, when the ratio of maximum filter opening to maximum particle size in the pulp did not exceed the ratios shown in Fig. 3. This relationship was found to hold for feed-pulp densities over the range of 20 to 60% solids (sp. gr. 2.7); for more dilute pulps smaller ratios were necessary. Over this range also, the thicker the feed pulp the more porous the cake.

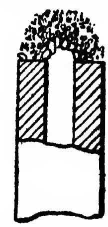

Fig. 2. Bridging of solids over a filter pore.

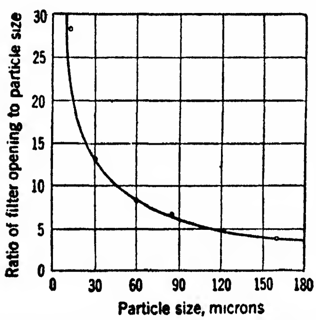

Fig. 3. Relation between filter opening and size of largest particle in pulp to be filtered (*after Hixson et al.*)

Structure of filter cloth. All fabric made from animal (wool, hair, silk) or vegetable (cotton, flax, hemp, etc.) fibers consists of a woven structure of threads, each thread comprising, in general, upward of 10 fibers, twisted together more or less tightly. The fibers range in shape from almost round to straplike, and in surface conformation from smooth to rough. Cotton fiber is straplike, relatively rough, and somewhat twisted.

The porosity and the nature of the surface of a cloth depend upon the size of the threads, how tightly they are twisted, the pattern of the weave, and its mesh. Cotton duck and canvas used for filtering are PLAIN WOVEN, *i.e.*, as a rectangular-mesh screen, of relatively coarse thread, tightly twisted, with warp and woof threads closely spaced. The resulting cloth is hard and strong, and the pores available for filtration are principally only those between the threads; the threads themselves are so tightly twisted as to make interfiber spaces too small for any material flow of liquid. TWILL is woven with two or more warp threads passed over and under one or more woof threads in a regular succession, thus producing the diagonal pattern. Even if the threads were as hard and tight as those of duck and canvas, the weave would be looser and the cloth more generally porous; usually the threads in cotton twill used for filter cloth are also more loosely twisted, making them readily permeable to water. Also the fiber ends, because they have longer projection from the threads (NAP), tend to become imbedded in the lower layers of the cake and thus hold cake to the cloth. This has an advantage when attempt is made to shave off cake and leave an under layer continuously available in place to produce clear filtrate.

Choice of a filter cloth is based on a balance between filtering performance, durability, and cost. Cotton cloth is almost invariably used in ore-milling practice, the usual exception being with acid pulps, which require an acid-resistant cloth such as wool. Cotton cloth has the advantages of great tensile strength, flexibility, durability, small weight, ease of handling and cleaning, and low first cost; it is obtainable in a great variety of weaves which make it adaptable to a wide range of filtering conditions. The cloth should be as permeable as is consistent with production of filtrate of the required clarity; it should be sufficiently tight and closely woven to exclude entry of particles into the interfiber spaces to clog it; it should be sufficiently strong to withstand the pressure differentials applied, and should not disintegrate under the flexure that accompanies cycle reversals; it should withstand chemical attack by the solution; be resistant to light abrasion; and finally should be as cheap as is consistent with the other conditions. Except for special cloths, however, price is usually of secondary importance.

Close-woven canvas duck is strongest. Soft twilled canvas is more porous but less durable. Woolley (*104 J 876*) recommends twill for fine concentrate that makes compact cake, and duck for more granular product for which the cloth itself must do much of the filtering. The fiber of cotton cloths swells materially when wet and fabrics that appear too porous when new may give entirely satisfactory service. Eight- to 10-oz. duck and 12- to 18-oz. twilled canvas are the commonest coverings in milling work. Most plants use from 15- to 17 1/2-oz. twill for the usual flotation concentrate or cyanide pulp. Duck is used for granular material, and, because of its greater strength, for pressure filters. The best covering can be determined only by experiment. This is particularly true when the pulp is highly abrasive, clayey, gelatinous, or chemically active (*e.g.*, pyrrhotite).

TYPES OF FILTERS

The cyanide process produced a large number of different kinds of filters that may be classified fundamentally as (1) vacuum and (2) pressure, depending upon the means employed for effecting the required pressure difference on the two sides of the porous septum. Vacuum filters may be further classified as (*a*) continuous and (*b*) intermittent. Pressure filters are usually intermittent.

3. CONTINUOUS VACUUM FILTERS

These filters are of the drum type, including the Oliver, Feinc, and Dorrco; and the disk type, such as the American. The horizontal revolving-leaf type, of which the Ridgway is best known, and the table type, such as the Caldecott, are little used. A variant of the Oliver filter is designed to receive the feed upon the upper half of the rotating drum surface; it is used for granular or crystalline nonslimy materials.

Oliver filter (Fig. 4) is typical of the drum machines with outside filtering surface (OUTSIDE-DRUM MACHINES).

Drum *a*, mounted on horizontal trunnions carried on tank *k*, is faced with longitudinal wooden staves *b* forming a tight shell. At suitable intervals longitudinal wooden partition strips *c* are fastened to the face of the shell, dividing it into a number of shallow

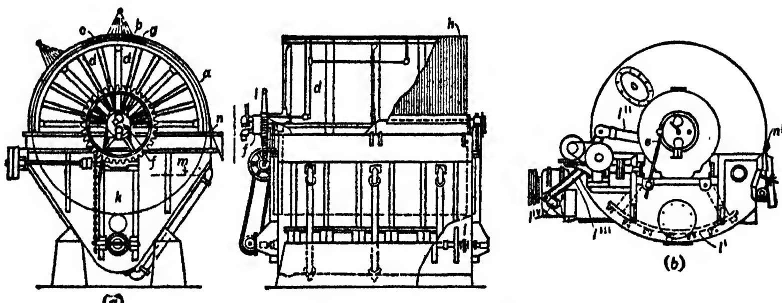

Fig. 4. Oliver continuous filter.

troughs which connect by pipes *d* or flexible rubber hoses with valve *f* (see Fig. 5) and thence with vacuum pump and compressor. The troughs on the face of the drum are filled with suitable backing to support the filter cloth *g*, which covers the entire drum. Cloth is held to the drum by wire *h* wound at 1/2-in. to 1 1/2-in. pitch, or by calking with rope into grooves cut in the upper surface of strips *c*, fastening at the ends of the cylinder by several turns of wire or by box-clamping strip. The wire winding affords considerable protection to the covering; the calked cover is more rapidly placed and removed, and makes the canvas more active. The ends of the drum are partially closed in later forms by an annulus of steel plate, extending above pulp level, which excludes pulp but permits inspection and entry to the interior. Drive is by a worm gear *i* from pulley *j* or from an individual geared motor. The drum revolves (in the view shown) in a clockwise direction with the lower segment immersed in pulp in tank *k*. Feed pulp is kept in suspension by a rotary agitator *l*, which is suited to the V-form of tank pictured, or, in cylindrical tanks (item *B*) by the arc-rake structure *l′*, carried on radial arms from hubs bored to turn on the trunnion shafts, and oscillated by arm *l″*, link *l‴*, and crank *l*^iv from an auxiliary gear.

Valve mechanism is illustrated in Fig. 5. It consists of a port plate *a*, valve seat *b*, and wear plate *c*. The port plate is held stationary by adjusting-rod pin *s* and a rod (*s*, Fig. 4*b*) therefrom attached to the

frame of the filter. Pipes from the filtering compartments on the drum face are connected to the valve seat, and the wear plate *c* is bolted through the valve seat to the trunnion in such a way that the peripheral holes in the two plates register. The valve stem *f* passes through hole *g* in port plate *a*, and the latter is held tightly against *c* by means of a coiled spring on the stem, which bears between a nut on the end of the valve stem and the ground surface *h* on the port plate. Tightness between the filter valve and its seat depends largely upon the pressure induced by vacuum within the filter. In simple filtering, a pipe from *i* runs to the vacuum receiver (Fig. 6), bridge *j* is removed, and solution outlet *k* is plugged. Under such circumstances that part of the drum surface extending from just below the pulp level on the downcoming side, at about point *m* (Fig. 4), to a point to the right of the top of the drum is in suction all the time. The three small ports in plate *a* (Fig. 5) provide for blowing the cake prior to its removal. Air connection is made at *l* and the number of compartments under pressure is regulated by stops *m* and *n*. Holes *p* are for gage connections. When washing is to be done, or if two different vacuum pressures are desired, bridge *j* is inserted and outlet *k* is connected to a second receiver. Wash solution is then withdrawn through the latter outlet. A grease cup at *r* supplies grease to the adjacent ground faces of plates *a* and *c*.

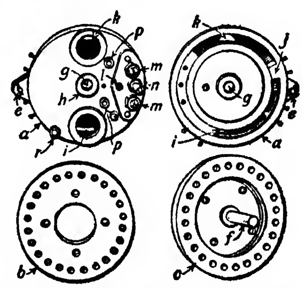

FIG. 5. Valve for Oliver continuous filter.

Cake is discharged by various combinations of compressed air, gravity, and mechanical scraping. In the older forms of filter a steel plate *n*, hinged along the lower edge, lay against the wire winding, and cake, already loosened by an air-blow on the downcoming side above the upper edge of *n*, fell on or was actually scraped away by *n*. In the later forms (item *B*) the position of scraper edge *n'* is from 12 to 24 in. below the drum axis and the air-blow plus gravity are the primary agents in removal; hence *n'* may be spaced a short distance from the drum surface and may act simply to knock off adhering lumps. Edge of *n'* is of rubber, grooved to slip on the scraper blade. Sometimes a taut wire in position *n'* replaces the blade scraper; this arrangement has been found particularly useful with very thin cake.

Sizes of Oliver filters are given in Table 1.

Filter-plant layout is shown diagrammatically in Fig. 6. Dry-vacuum pump *A* takes suction via pipe *B* on trap *C*, from which vacuum line *D* runs to one or two receivers *E*, *E'*. Lines *F*, *F'* are filtrate lines. Filtrate is discharged from the receivers by centrifugal pumps *G*, *G'*, taking suction through lines *H*, *H'*, which should have a minimum vertical length of 2 ft. The filtrate-pump discharge lines are provided with check valves to prevent runback in case of failure in filtrate supply. When more than 30 ft. drop is available below the receivers, filtrate may be discharged by a barometric leg, as shown on trap *C*. One receiver *E* only is needed when a single filtrate is to be made or a single degree of vacuum is sufficient. If, however, washing is to be practiced, or a low vacuum is required for a part of the filter surface, the second receiver *E'* with its connecting piping is installed. In this case a second vacuum pump with trap is needed, or the two receivers may be connected by a top crossover *I*, with vacuum regulator *H* to increase pressure in the second receiver. The vacuum receiver should be provided with float-head and vacuum-release valve at the outlet to the dry-vacuum pump to prevent liquid passing over into this pump, which is designed with small clearance and would be injured by liquid. For handling hot solutions tank *C* is made a condenser.

Reciprocating vacuum pump connected with the vacuum tank is commonly used to produce vacuum. The pump provided should ordinarily have piston displacement capacity ranging from 0.5 to 1.5 cu. ft. per min. per sq. ft. of filter surface. For very porous cakes as high as 5 cu. ft. per sq. ft. per min. may be necessary. ROTARY BLOWERS, with suction end attached to the vacuum tank, are sometimes used in place of a reciprocating compressor for dry-vacuum production, if low vacuum is sufficient. Wet-

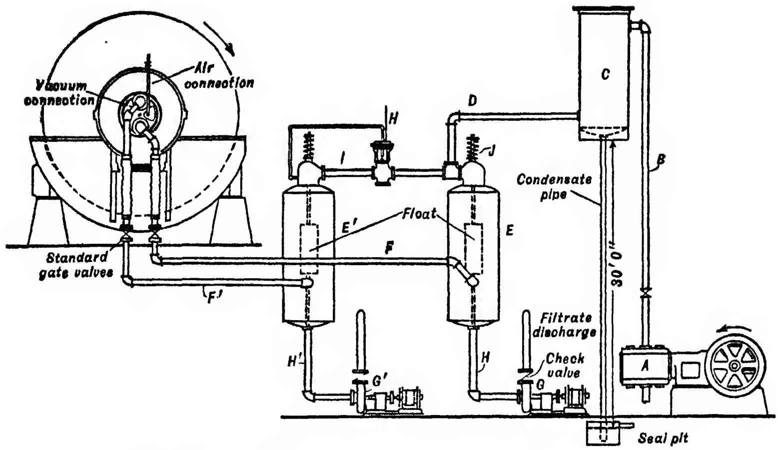

Fig. 6. Layout for vacuum filtration (*after Oliver United Filters*).

vacuum operation has almost ceased in metallurgical plants, because the separate handling of filtrate by centrifugal pumps is more satisfactory, dependable, and economical. Centrifugal pumps used for pumping out a receiver against a high vacuum within the receiver require special design. The pump impeller must be such as to avoid air-binding, and the stuffing-box assembly must be designed to prevent inward air leakage as well as needless filtrate drip.

Table 2. Power requirement of Ingersoll-Rand Type ER-1, 18×7-in. dry-vacuum pump at 350 r.p.m. and 720 cu. ft. per min. piston displacement

Inches of vacuum	Brake horsepower required
12	26.9
15	28.7
16–17	Peak
18	28.7
20	26.9
22	25.2
24	22.3
26	18.2
27	15.2

Power requirement for dry-vacuum pumps is computed from the same equation as that for air compression, with appropriate change of symbols. For a pump working adiabatically

$$\text{Hp.} = \frac{144}{33{,}000} \cdot \frac{n}{n-1} \cdot P_2V_2\left[\left(\frac{P_1}{P_2}\right)^{\frac{n-1}{n}} - 1\right]$$

in which P_2 = absolute pressure in vacuum produced in lb. per sq. in., V_2 = gas volume corresponding to P_2 in cu. ft. per min., P_1 = atmospheric pressure, and n is a constant ranging from a theoretical value of 1.406 down, probably, to 1.15 or 1.2 for ordinary vacuum-pump practice. Table 2 shows the estimates by Ingersoll-Rand of the power required for their Type ER-1 dry-vacuum pump, which is frequently used. By investigation of the power equation throughout the range of the theoretically possible vacuum production for any given conditions, it is found that the power requirement per cubic foot of gas exhausted from a given vacuum passes through a maximum, as indicated in Table 2.

Performances of Oliver filters are given in Tables 3 and 4.

Filter cloth. See Art. 2.

Re-covering, including removal of old cover and rewinding, requires a time and crew that depend principally upon the size of filter, wire spacing, and skill of the crew. From 5 to 8 hr. with a crew of 3 is about a minimum for a large Oliver unit; 36 hr. with a crew of 4 has been reported, but is excessive.

Scraper blade is ordinarily of steel; the edge should be kept smooth both to insure thorough removal of cake and to guard against tearing cloth. Wooden and rubber or rubber-edged scrapers have been used to reduce wear on the cloth. Experience indicates that the edge of the scraper should be a blunt bevel.

Portland filter is the predecessor of the Oliver.

Feinc filter (Fig. 7) is similar to the Oliver in general construction; it differs in the method of discharging cake. A plurality of parallel endless strings *a*, spaced about 1/2 in., runs around the drum and over discharge roll *b* and return roll *c*, the former being adjustable to maintain string tension. These strings are driven by the drum. At the line along the face of the drum where the strings leave the drum, cake is lifted and travels on the bed of suspended strings until they pass over the discharge roll; here the sharp flexure causes the cake to break away and drop. A comb *d* guides the strings evenly back onto return roll *c*, and also serves to scrape off lumps of adhering cake. The Feinc valve is simpler than that of the drum machines which utilize air pressure for loosening and discharging cake, and no air-compressing apparatus is necessary.

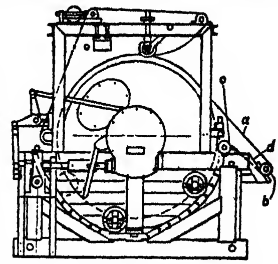

Fig. 7. Feinc filter.

Performances are given in Table 5.

Dorrco filter (Fig. 8) is of INSIDE-DRUM type, *i.e.*, the filtering surface *a* is on the interior surface of a drum comprising shell *b*, closed valve-head end *c*, and partly open discharge-end head *d*. The drum carries two riding rings *e* (these are rolled H-beams for 10-ft. diam. and larger) which rest on two pairs of rollers *f* and *g*, the former driven by sprocket *h* from a suitable source of power, the latter by sprocket and cross chain *i* from *f*. The automatic valve *j* (similar to Fig. 5) connects the suction pipes *k* successively with the vacuum system, and, through pipe *l* with compressed-air pulsator *m* driven by chain from a sprocket on the shaft of rollers *g*. Filter cloth *a* is supported on screen *n* and screen supports *o*; it is held on the edges by calking *p* and is secured longitudinally by further calking into division channels *q*. Feed is introduced by pipe at *r*, on the downcoming side. Spraying of cake is done on the upcoming side at *s*. Cake falls into chute *t* carried on outer support *u*, and an inner support *v* which rides on stub shaft *w*. If length of drum makes gravity discharge through

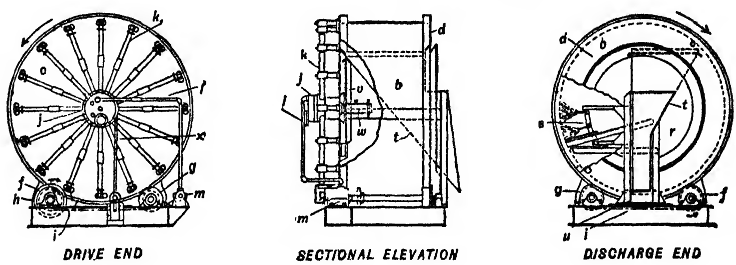

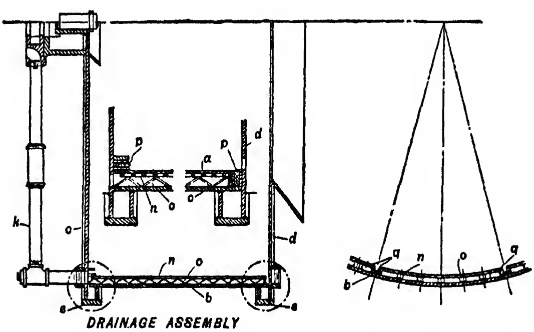

Fig. 8. Dorrco filter.

a chute impossible, the lower part of chute *t* is replaced by a screw or belt conveyor suitably supported outside. Rod *x* is for valve adjustment.

This filter is particularly adapted to use with coarse pulps that are difficult or impossible to maintain in suspension in the tank of an outside-drum machine; the rapid sedimentation aids in forming a porous-grain cake next to the cloth.

Performances are given in Table 6.

American Filter (Fig. 9) consists of a plurality of disk-shaped filter leaves *a* mounted on a heavy hollow shaft *b*, caused to rotate by means of the worm gear *c* and worm driven through gear *k* either by a motor-driven gear speed-reducer *e* and motor *l* or by pulley *f*.

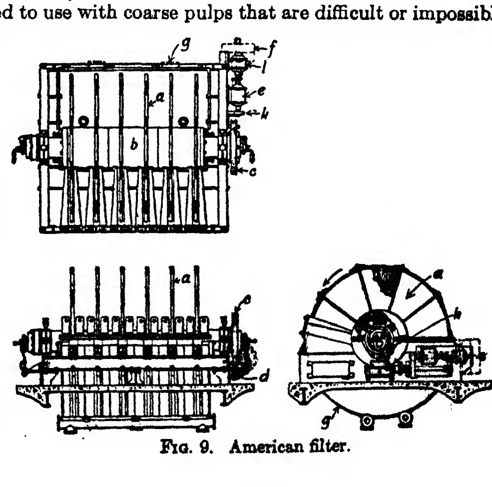

Fig. 9. American filter.

The lower parts of the revolving disks dip into a tank *g* which is partitioned on the front side of the central shaft in order to allow for discharge

of cake. Each filter disk consists of several sector-shaped units which connect by means of conduits in shaft *b* with a valve that is the same as that used on the Oliver filter. During the time that any given sector is submerged, and for a time after its emergence, it is connected with the filtrate outlet port through a conduit in the shaft and a corresponding channel in the journal. On further emergence it connects with the wash-water outlet port, if washing is required, and finally, just before it reaches the scraper, it connects with the compressed-air port and the cake is loosened.

Standard sizes are 4-ft. (disk diameter) × 1- to 4-disk, 6-ft. and 8 1/2-ft. × 2- to 10-disk, and 12 1/2-ft. × 5- to 12-disk.

Performance of American filters is shown in Table 7.

Ridgway filter consists of a number of horizontal filter trays carried on the ends of radial arms extending from a central revolving spindle. The trays travel over a series of annular tanks, a mechanism being provided to lift each tray over the partitions between the tanks. In cyanide work the first tank contains leached slime; the second, weak solution; a third, wash water; and the remaining 15 to 20° of arc constitutes the discharge hopper. The valve is similar in principle to the drum valve. Use of the filter has been principally restricted to So. African and Australian cyanide mills.

4. OPERATION OF CONTINUOUS VACUUM FILTERS

Elements of filter performance are dryness of cake, clarity of filtrate, rates of production, and power consumption, maintenance, and attendance.

Dryness is of major importance in dewatering concentrate, since saving freight on water is the primary purpose of the operation. Dryness is favored by high porosity of cake, uniformity of cake resistance, a relatively low pressure gradient, and a relatively small pressure differential.

Dryness in practice (Tables 3 to 7) does not differ materially as between the various filters. There is, however, a marked difference according to the pulps, as regards both nature and specific gravity. Cake made from fine cyanide pulps ranges from 13.5 to 25% moisture on 15 pulps, with the majority of the operations clustering around 20 to 22%; lead flotation concentrates carry 5 to 10% moisture normally, with the average about 7%; copper flotation concentrate ranges from 7 to 15%, average about 9.5%; pyrite flotation concentrate, 9 to 21%, average about 12%; bulk-flotation concentrate, 7 to 15%, average about 10.5%; and zinc flotation concentrate which, on a specific gravity basis, would be expected to be higher than pyrite, ranges from 7.2 to 15%, average from 9 to 10%. The relatively low moisture content in zinc cake is a reflection of the average longer haul to the zinc smelter. Lead table concentrate averages 3.2% moisture (range 3 to 3.5%) in four southeast Missouri lead plants.

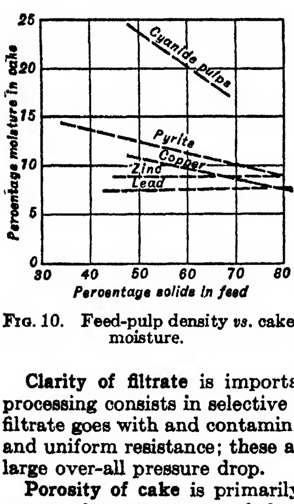

FIG. 10. Feed-pulp density *vs.* cake moisture.

While there is, for any given pulp, a definite relationship between cake moisture and density of feed pulp for a given submergence time, no such relationship may be asserted for the heterogeneity of pulps in Tables 3 to 7. When, however, these are sorted on the basis of general mineralogical character, the extremely approximate trends shown in Fig. 10 are discernible.

Clarity of filtrate is important in hydrometallurgical operations because subsequent processing consists in selective precipitation, and in general solid material in the primary filtrate goes with and contaminates this precipitate. Clarity requires low porosity of cake and uniform resistance; these are normally concomitants of a steep pressure gradient and large over-all pressure drop.

Porosity of cake is primarily a function of the size and size range of the solids; the coarser the aggregates and the shorter their size range the higher the porosity. Hence a granular pulp makes a dry cake; admixture of finely granular material with slimes, *e.g.*, fine gravity concentrate with flotation concentrate, tends to make dry cake; and flocculation (see Sec. 15, Art. 3), which, in effect, increases the size of the small particles and shortens the size range, also aids in drying. Porosity depends also on the way in which cake is formed (Art. 1); in a long-range pulp, anything that promotes early preferential presentation and deposition of granular material on the filter medium makes for relatively higher porosity of the system of cake and cloth.

Resistance of cake depends on its porosity and thickness and on the viscosity of the liquid withdrawn. Uniform resistance requires that the cake be uniform in thickness, uniform circumferentially in particle-size distribution, and that it be maintained free of cracks. Nonuniform resistance tends to correct itself by increased deposition in the parts of low resistance while the cake is submerged, but after emergence fluid flow in the areas of low resistance is much higher than elsewhere, with the result that a "dry hole" is soon

formed, the pressure differential falls, and there is insufficient pressure differential remaining at the wet areas to drive liquid through them.

Cracking of cake is caused by the shrinkage which develops in some fast-filtering pulps during drying. It may be lessened by speeding up the drum and making thinner cake. A mechanical device used in dewatering service on outside-drum types, called a FLAPPER, consists of a rotating shaft, parallel to and close to the drum surface, carrying strips of fabric, leather, or rubber that pound the cake surface with a rapid succession of sharp blows. The pounding compacts the cake, closes up cracks, and eliminates some moisture. In cyanide filtration the surface must be kept clear for best application of wash; cracking is prevented, in part, by the sheet of wash-liquid, and the liquid also tends to seal cracks and prevent excessive drop in pressure differential.

Another method of preventing cracking is to apply a canvas belt on the upcoming side just ahead of the line where cracking starts and to lead it away before the vacuum is released.

Pressure gradient. There is little or no exact knowledge available on this subject. It is inferable from the structure visible in long-range cakes (Fig. 2) that the gradient is steeper at a distance from the cloth than in the layers adjacent thereto. This inference is supported by Young's observation (*42 A 752*) that the outer layers of cakes made from slimy pulps are wetter than the inner. It is further inferable that the gradient becomes increasingly steep as the cake thickens, since the outer layers of the cake become increasingly finer owing to the inability of the inward currents to hold coarse grains.

Pressure differential is, in general, higher the finer the feed; it ranges, in the practice reported, from about 10 in. of mercury for fine gravity concentrate to 28 in. for slimy, platy native-copper flotation concentrate. The usual range for all types of flotation concentrate is 20 to 24 in. Filtering rate increases generally with pressure except that in pulps containing flocculated gelatinous matter (*e.g.*, ferric hydroxide), pressure sufficient to squash the flocs may decrease porosity and thus decrease filtering rate; and high pressures with pulps containing much very fine solid may drive solid into the cloth and, by clogging interfiber pores, decrease rate over a period of time. The best rule is to use the minimum differential that gives a reasonable flow of filtrate and to seek dryness by using a thinner cake or a longer drying time. The degree of vacuum obtainable in a given unit depends on the porosity of the cake and the size of vacuum pump available. Different pressures may be maintained on the submerged and unsubmerged parts of the drum by independent vacuum connections provided in the valve.

Thickness of cake made with a given pulp depends upon the pulp density, the time of submergence, and the pressure differential. For high capacity and dry cake the pulp should be as thick as possible.

Trauerman (*104 J 87*) reports a test on an 11.5×16-ft. drum machine on which 35 dry tons of cake containing 20% water were made in 8 hr. from a feed pulp containing 35% solids, and 51 tons containing 12% moisture were made in the same time from a pulp containing 55% solids. At SUNNYSIDE, with feed containing 30 to 35% water, cake was 1 1/4 in. thick and contained 8% water, while with feed containing 40 to 45% moisture, cake was 1/2 in. or less thick and contained 10% moisture. Thickening in tanks costs, in general, less than 1¢ per ton of solids; filtration costs, at the least, 1.5¢, and may cost upward of 25¢; hence the more preliminary thickening, up to the point where the time for further consolidation becomes excessive, the cheaper the whole operation. The filter tank may be shallower with thick feed than with thin, which gives more time for drying cake. It is also harder to maintain suspension of thin pulps.

In general the thinner the cake the drier it can be discharged. The relationship is, however, obscured when a number of pulps of different characteristics at different mills are compared (Fig. 11) because the filters tend to be run for maximum dryness, and cake is thinned to produce this result. Thus the majority of the copper mills reporting were apparently running to make 9 to 10% moisture, and they varied cake thickness from 3/8-in. to 1 1/4-in. to attain this result.

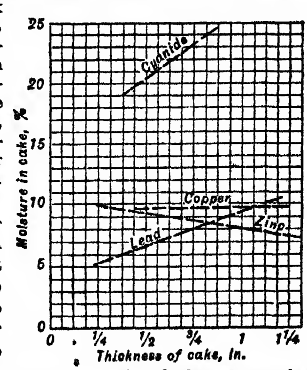

FIG. 11. Cake thickness *vs.* cake moisture.

Practice, as represented by Tables 3 to 7, shows a range of cake thickness for metalliferous flotation concentrates from 1/16-in. for one pyritic gold-ore to 2-in. for copper. Mean thickness is least for zinc (1/4-in.) and greatest for pyrite (5/8-in.); over-all mean is close to 1/2-in. The mean for cyanide pulps is also about 1/2-in. As between different filters, mean thickness is least on the Dorrco (3/8-in.); it is between 3/8- and 1/2-in. on the outside-drum machines, and 1/2- to 3/4-in. for the disk machines. Variation of cake thickness with approximate submergence time for all filters is shown in Fig. 12; the relationship is rough, since no account is taken of different types of pulp, or of the thickness of feed pulp,

but the dotted line approximates reasonably what is to be expected for an average pulp thickened to a consistency approximating that of 50 to 60% solids (sp. gr. 2.7) by weight.

Submergence time determines thickness of cake; it itself is determined by diameter of the rotary element, its speed, and the depth of submergence. Range of time (Tables 3 to 7) is from about 15 sec. for Dorrco filters dewatering table lead concentrates to about 5 min. on copper flotation concentrates; mean is about 1.2 min. for Dorrco filters, about 2 min. for outside-drum machines, and 1.6 min. for disk machines.

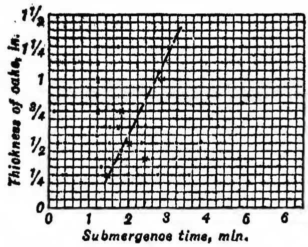

FIG. 12. Submergence time *vs.* cake thickness.

Recent designs of outside-drum filters placing the cake-discharge point below the drum axis have made it necessary to sacrifice depth of submergence. Instead of compensating by decreasing speed, speed has actually been increased. This takes advantage of the fact that the rate of increase in cake thickness falls rapidly with time after a short initial period, and by increasing the number of times that a square foot of cover is permitted to form cake at maximum rate, capacity is increased. The thinner cake dries faster and the decreased submergence and lower discharge point both contribute to longer drying time for a given filter at a given speed, thus permitting the higher speed.

Heating lowers the viscosity of the liquid and also tends to cause flocculation of fine solids. On both scores it increases filtering rate and it may also decrease the moisture in the cake. Heating to 100 to 120° F. is a common procedure in treating flotation concentrate. Heating of cyanide pulps is accepted practice in Canadian gold-cyanide plants to achieve good extraction. A temperature of 80° F. is considered desirable.

At AFTERTHOUGHT, heating pulp increased tonnage 17% to 750 lb. per sq. ft. per 24 hr. in a cake containing 15% water. Watt (*57 A 379*) stated that in treating lead concentrate in southeast MISSOURI, heating to 120° F. increased capacity 20% and decreased moisture in cake 2% (to 15% final). At UTAH COPPER Co. pulp is both heated and agitated by live steam injected into the filter tank. Experience shows that the hotter the pulp the drier the cake (*117 P 752*).

Cake-release pressure should be kept as low as possible; the usual pressures for the older outside-drum types are from 7 to 15 lb. per sq. in.; 2 to 5 lb. may be employed with the low-discharge outside-drum types, the inside-drum type, and the string type. High pressures keep the filter cloth cleaner, but excessive pressure is likely to cause the cover to split at the fastenings, especially when acid cleaning is used and the acid is not completely neutralized before operation starts again.

Agitation of some sort is necessary in under-fed filters to keep solid suspended in the filter tank. In the outside-drum machines it is effected by an oscillating stirrer, whereas in the disk types the pulp is up-fed through nozzles in the bottom of the tank at a sufficient rate to maintain suspension, even though this may involve overflow of some of the pulp and return to the feed surge tank, which should have about twice the capacity of the filter tanks. In the inside-drum machine settling is desirable, and agitation is, therefore, avoided.

When a plant makes both table and flotation concentrate, a good scheme for dewatering is to send the table concentrate to a mechanical classifier, join the overflow with the flotation concentrate, and thicken and join the granular discharge from the classifier with the spigot product from the thickener in a surge tank feeding the filters. The thickened slime concentrate readily keeps the granular material in suspension. The granular table concentrate will probably increase the capacity of the filter on the flotation concentrate.

Capacity of filters is expressed in terms of weight of dry solid filtered per unit of area per unit of time, or as volume of filtrate per unit of time per unit of area, according to whether drying or recovery of filtrate is the aim. Tables 3 to 7 show no certain correlation between unit capacity and type of filter, general mineralogical character of feed, or fineness of feed. The most that can be said on the basis of the figures reported is that on the average the filters are making from 0.030 to 0.040 dry ton of cake per hr. per sq. ft. of filtering surface on flotation concentrate and on cyanide pulps alike, with a range from 0.007 to 0.134; the performances bear no simple relation to size of feed or to moisture content thereof. Average for 15 performances on lead flotation concentrate is 0.032 and that for 7 on zinc is 0.031 ton per sq. ft. per hr.; the specific-gravity advantage of the lead is apparently balanced off by the fact that in differential flotation there is a tendency for dispersed clayey and micaceous slimes to go with the lead, leaving the zinc correspondingly more readily filterable. Confirmatory of this explanation is the average of 0.041 ton per sq. ft. per hr. for pyrite, which is doubly deslimed in lead-zinc-iron differential work. Lead

gravity concentrate, which is substantially completely deslimed, averages about 0.2 ton per sq. ft. per hr. AVERAGE FILTRATE RATE in g.p.m. per sq. ft. per hr. is numerically very nearly the same as the solid tonnage rate; it averages 0.035 for 13 generally siliceous cyanide pulps, and 0.176 for 3 lead gravity concentrates. With a given type of pulp, this figure definitely decreases with increase in solid content of feed, as is consistent with the parabolic character of the filtrate-time curve.

Blinding of filter cloth occurs both by mechanical entanglement of solid material in the pores and by incrustation of fibers by chemical precipitates, usually carbonates and sulphates. Carbonates can ordinarily be dissolved by an acid wash; calcium sulphate is soluble in water; the basic sulphates of the heavy metals, and ore particles, are not soluble to the extent necessary for removal by solution in either water or solutions against which the cloth itself is resistant. They must, therefore, be removed by scrubbing or other methods of washing.

Acid-wash solution is usually HCl, 1 to 2% maximum strength, but 5% solution was used at SLADEN MALARTIC, the wash being correspondingly shortened to guard against mercerization and attack on metal, and being followed immediately by an abundant water wash.

The abrasion in scrubbing tends to break the fibers of threads, weakening the fabric and shortening its life. Carbonate precipitation is most active at the surfaces of the cloth where the maximum contact of air (carrying CO_2) with solution carrying base- and earth-metal ions occurs. Hence if an acid-treat is given at short intervals (daily, if practicable) the cloth can usually be kept porous with subsequent hosing or light scrubbing, and the heavy scrubbing necessary to deform the threads to wash out internal dirt need be done only at long intervals. When acid-treating is required, the interval between treats should rarely exceed one week.

Life of cloth depends upon the kind of cloth and the mechanical treatment that it receives. A summary of the lives reported in Tables 3 to 7 (taken without regard to the covering used, on the assumption that in most cases that covering reasonably best fitted to the duty had been found) indicates clearly a longer minimum, mean, and maximum life in cyanide pulps (21, 60 to 90, and 360 da. respectively) than in flotation concentrates (30 da. mean); no material difference in life appears with different flotation concentrates, although a mean of somewhat over 30 da. is indicated for bulk concentrate; a definitely shorter mean life is indicated for disk-type (about 25 da.) than for the drum types (about 60 da.), owing, probably, to greater bellying of cloth against the scrapers.

The end of satisfactory life is reached when the cloth no longer gives the desired product, irrespective of its physical condition, and acid or other washing will not restore it.

Changing cloth on outside-drum machines involves removal of old cloth, cleaning channels, placing new cloth, and securing it. The new cloth is first wound on, stretched smooth, and secured by tacks. The drum drive is changed to winding speed (about 1 r.p.m. on modern machines). The wire is threaded from a braked reel through a lead die that travels on a sprocket-driven screw at about the level of and parallel to the drum axis along the back (upcoming side) of the tank. One end of the wire is fastened securely at one end of the drum; whereupon, when the drum is started, the wire is led on by the die, suitably spaced according to the speed of the die shaft, at a tension determined by the brake on the reel. A wire-wound cover can be removed and replaced, and the filter put into operation again in 4 hr., even on a large filter, with good planning and efficient labor, but the normal good performance is nearer 4 man-shifts, using 1- to 1 1/2-in. wire spacing; if the old wire spacings of 1/2 to 3/4 in. are used, winding time will usually be more than doubled. Winding devices with two lead dies, permitting simultaneous winding of two wires, are available for large filters. Calked covers can be installed more quickly than wire-wound. Price of a good twill cover for a 14×14-ft. drum (1938) was $60 to $70; wire, $3 to $4. Covers on disk filters are mounted on the sectors after removal of the frames from the disk.

Cost of continuous vacuum filtration depends upon the filterability of the pulp and upon the tonnage treated. Detailed preliminary estimates are practically impossible. Attendance requirements are low and attention to the filter is normally only part of one man's work, even in the largest plants. Thus at NORANDA attendance for 5 filters was reported as 0.49 man-shift; at AVALOS, 0.5 man-shift for 2 filters; at MUFULIRA, 0.66 man-shift for 2 filters; at CLIMAX one operator per shift attends 3 filters, 3 thickeners and 3 driers; at COMBINED METALS REDUCTION one man per shift attends 4 filters and 4 thickeners with the associated pumps; and at FALCONBRIDGE one man per shift operates 2 filters and 3 thickeners. Power consumption is the large item; a basis for estimate is given in Table 2 taken with the accompanying text and the performance tables (3 to 7). Maintenance, primarily renewal of covering, is very small (see *Changing cloth*, above). Over-all costs reported range from 1.5 to 2.5¢ per ton filtered at HOLLINGER and MADSEN RED LAKE on relatively large tonnages of easily filterable material; 3.5 to 5¢ per ton is about the range for medium tonnages of easy material or for large tonnages of material difficult by reason of fineness or mineralogical or other character; in small plants the cost will be 5 to 15¢ per ton under favorable circumstances, and may more than double if conditions are unfavorable.

First cost of continuous filters (1938 basis) ranged from $16 or $18 per sq. ft. of filter area for small simple dewatering filters, built of wood, steel, and cast iron, to $10 or $12 for the larger sizes. Special designs in wood for acid resistance and designs for caustic pulps ranged from $30 or $40 per sq. ft. for small sizes to about $20 for the large. Filters which require corrosion-resistant alloys or rubber-covered surfaces are highly special and cost rises correspondingly.

5. SAND FILTERS

Caldecott sand table is a revolving annulus about 25 ft. outside diameter by 3 ft. wide with horizontal porous top over suitable vacuum compartments. It is run at about 20 f.p.m. peripheral speed with a vacuum of 5 to 10 in. Thickened sand pulp from diaphragm cones or mechanical classifiers is fed at any given point in the revolution and removed, after filtration, by a diagonal plow just ahead of the feed point. About 0.5 cu. ft. per min. vacuum-pump displacement is required per sq. ft. of filter area.

At Simmer and Jack Proprietary Mines, Ltd., one such table handled 500 tons quartz sand per 24 hr. and reduced moisture from 30% to 15% (*RMP*). At New Jersey Zinc Co. 6-ft. tables with 21 sq. ft. of filtering area treat 6 t.p.h. of solid, of which 98.5% is >100-m. Feed contains 26% water and product about 13%. The layer of solid on the filter is about 3 1/2 in. thick. The table makes 1 1/3 r.p.m.; vacuum is 5 1/2 in. Hg; hose-duck covering has a life of 80 da.

Rotary hopper dewaterer is essentially a drum-vacuum filter with the sides of the filtering compartments extended beyond the filtering surface to form truncated-wedge hoppers with radial sides, into which granular materials are flowed and retained on the drum. The hoppers may be from a few inches to 18 in. deep. They are fed by overhead chutes on the upcoming side at a point 15 or 20° from the zenith, and discharge by gravity, aided by compressed air if necessary. A much larger inward air flow is usually provided for than is possible in the usual drum filter.

The usual size of the unit is 200 to 300 sq. ft. of filtering surface. Feed should not, in general, contain more than 20 to 25% water unless special arrangements are made to handle larger volumes. Filtered sands of normal sp. gr. contain 5 to 12 or 15% water, using atmospheric air (see below for use of heated air). Capacity ranges from 1 to 6 tons per sq. ft. per 24 hr. on slime-free pulps.

At New Jersey Zinc Co. a 6×?-ft. machine covered with Monel-metal cloth filtered 3.2 tons per 24 hr. of a feed 85% >100-m. containing 43% moisture, making a product containing 0.45% water by using air heated to 600° F. Speed was 1.2 min. per rev.; vacuum, 3 3/4 in. Hg, produced by a 20×24-in. Wilbraham-Greene exhauster; cloth life was 21 da.

Filter tanks are rectangular or cylindrical in shape, fitted with porous false bottoms, through which liquid passes by gravity, aided by vacuum toward the end of the draining period, if desired. They are used for sand-leaching in cyanide and copper-leaching plants and for more rapid and complete dewatering of granular materials generally than can be effected by simple draining (see Sec. 15, Art. 2). The filter bottom must be supported on a gridlike frame sufficiently close spaced to prevent harmful deformation of the filtering medium, which usually consists of a filter cloth laid over cocoa-matting or the like. A second grid is usually placed above the filter cloth to protect it when the filtered charge is shoveled out. Shoveling may be manual, or a mechanical shovel of the orange-peel or clamshell type may be used; at Chuquicamata a clamshell operated from a traveling bridge over the vats is employed.

In the Blaisdell system the tank is circular with a central bottom-discharge opening about 12 in. diameter under which a belt conveyor runs. The discharge hole is closed during filling by a downward-tapering hollow steel-plate plug extending to the top of the tank. When this is removed it leaves a steeply conical hole through the charge to which the filtered material is scraped by a revolving plow arm carrying a plurality of disk plows. A series of tanks is served by one plow mechanism.

At Shattuck Arizona (*110 J 761*) gravity concentrate containing 21% water was drained in concrete tanks with sand-filter bottom to a product containing 10% water.

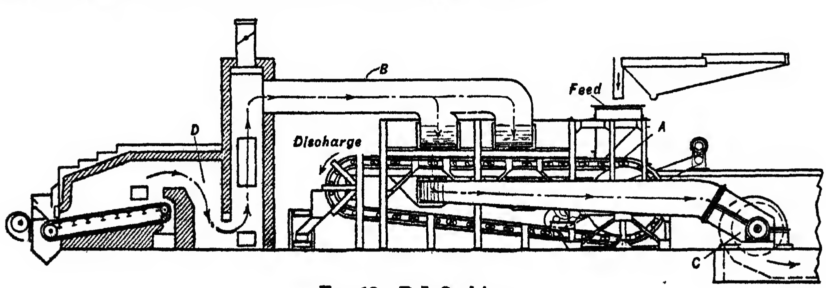

Fig. 13. D-L-O- drier.

D-L-O drier (Fig. 13), for granular material, consists of an apron conveyor *A*, with perforate carrying surface, so mounted under air hood *B* and over a conduit leading to fan *C* that hot gases from furnace *D* pass down through a bed of porous material on apron *A*

while under the downlegs of *B*, thus displacing and evaporating moisture. Essentially the apparatus is a Dwight-Lloyd sintering machine adapted to vacuum filtration with hot air.

At Friar Tuck mine, Linton, Ind. (*Bul. Oliver United Filters*), <3/4-in. bituminous screenings was dried from 15% water to 4 1/2% water at the rate of 70 t.p.h. with a consumption of 15 lb. coal fuel and 0.55 hp-hr. per ton of coal dried. The apron was 4 ft. wide and extended 20 ft. under the air hood; it ran at 40 to 50 f.p.m.; bed was 3 1/2 to 4 in. deep; temperature of inlet air was 400 to 700° F., and of exhaust air 100 to 120° F; volume was 200 to 400 cu. ft. per min. per sq. ft. of active bed (80 sq. ft.). Cost reported was 3¢ per ton for operation, 5.5¢ per ton total.

6. PRESSURE FILTERS

These are of two general types: (*a*) plate-and-frame presses and (*b*) pressure tanks. The first type is widely used in the chemical industry but has only a restricted use in milling for clarifying turbid pregnant-solution overflows from thickener tanks. The second type has been used to some extent on cyanide pulps.

There are many pressure filters in use for collecting gold and silver precipitate in cyanide plants. In recent years, this duty has been entrusted to a sock filter; the solution and precipitate are pumped into the several tubular socks, which retain the precipitate while the solution passes through the cloth-covered walls.

Plate-and-frame filter. A typical form is shown in Fig. 14. The essential parts are a framework consisting of two uprights *a* and two parallel tie-rods *b*, a fixed head *c*, a movable head *d*, and a plurality of plates *e* alternating with frames *f*. Plates are of cast iron, suitably perforated with ports *g* and slightly recessed at the center as shown. The recessed portions are grooved to allow passages for solution behind the filter cloth. Frames are similar to plates with the recessed portion removed. Both are practically square in the section at right angles to the plane of the drawing. Plates and frames have outside lugs which rest loosely on rods *b* when the press is open and they may be lifted out separately. When the press is being assembled for operation, filter cloths are draped over the plates, perforated to correspond with the opening *g*, are set on rods *b* alternating with the frames, and when the desired number are in place the movable head is pushed forward by power screw *h* until all joints are made tight by reason of the filter cloths serving as packing between the machined faces of plates and frames. Holes *g* in plates and frames, now registering, form a passage for feed pulp which is pumped in under pressure and passes through openings *i* into the space between the plates. Liquid passes through the cloth and along the faces of the plates to passages *k* which discharge through cocks *l*. When the chambers are filled or nearly filled with cake, wash water may be sent through the press to wash the cakes, finally compressed air or steam to dry them, after which the movable head is run back and cake is dropped out of the chambers one at a time.

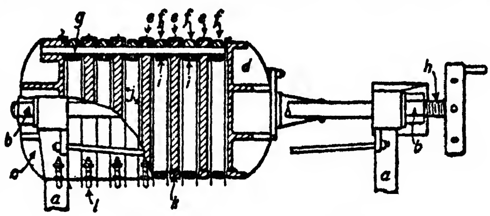

Fig. 14. Plate-and-frame filter.

Merrill press is the only plate-and-frame machine that has had any considerable use for pulp treatment in cyanide work. It has an interior passage along the bottom for discharge of cake and a high-pressure water pipe with jets into the individual compartments for washing spent cake into the discharge passage. Hence it may be discharged without opening.

At Dome 5 @ 4×6-ft. 90-frame Merrill presses are used for single-stage filtration of cyanide pulps, 85% <200-m. Feed pulp contains 49% moisture, and the 4-in. cake 20%, operating at 80° F. at a rate of 14 t.p.h. per machine or 0.0032 t.p.h. per sq. ft. of filter area. No. 8 cotton duck, acid-washed monthly, has a life of 130 da.

Shriver press is one of the best known of this type. When it is required to wash cake, two methods of operation are available. In solid filling, feed is run into the press until the frames are filled, which is indicated by cessation of filtrate. After an air blow, if this is desired to expel the last of the thus removable filtrate, wash solution is introduced behind the cloths (through the filtrate passages of alternate frames) and flows both ways through the intervening cakes and into the filtrate passages of the adjacent frames. In center filling, the flow of feed is stopped before the cakes meet in the frames and wash solution is turned in immediately behind the feed without any release of pressure that might permit

cake to slough. The path of wash is more than halved in this case, permitting quicker washing.

Merrill precipitation press is a plate-and-frame pressure filter with triangular plates and frames and with the feed-inlet pipes carried down to the lower vertices of the frames so that the rising currents of feed pulp therein keep the solids in suspension. It is used almost to the exclusion of all other forms in filtering zinc-dust precipitates in cyanidation.

Sizes. Plate-and-frame presses are rated by the size and number of plates. The usual sizes are 18×18-in., 24×24-in., 30×30-in., and 36×36-in. with 25 to 50 plates per press. Pressures depend on the filtering character of the material. They usually start at a low figure, say 5 to 10 lb. per sq. in., and finish at 50 to 60 lb. High initial pressure clogs the cloths and makes the initial layer of solid too compact; high final pressures are necessary to force liquid through the thick cakes.

Design of plates and frames is highly various. Complexity and number of ports depend on the number and kind of washes, whether blowing is to be practiced, and whether both air and steam are to be used. For considerable further detail as to construction and operation of presses see D. R. Sperry, vols. 18 and 19, *CME*.

Centrifugal pumps are the best type for forcing feed pulp into plate-and-frame presses, because pressure is low at the beginning and gradually increases as resistance builds up, and also there is no pulsation to compact cake as by tamping, which effect is distinctly noticeable with reciprocating pumps.

Pressure-tank filters are of several varieties, of which the Kelly and Burt are best known in milling work. The former has had considerable use in cyanide work and some use in concentrate filtration; the latter in cyanide work. At present neither is used in ore treatment, but the Kelly is rather widely used in petroleum refining and other high- or low-temperature, high-pressure work, while the Burt has been adopted for the hot corrosive liquors in electrolytic-zinc work.

Kelly pressure filter (Fig. 15) consists of a basket *a* of filter leaves, carried on a frame *b* that can be slid in or out of a pressure tank *c*. The tank is inclined so that gravity aids egress of the loaded basket. One end of the movable frame forms the closing head *d* for the pressure tank. Each filter leaf consists of a bag or slip carried on a rectangular pipe frame. Collapse of the covers under pressure is prevented by spacers of wood, wire cloth, or coarse fiber held between the walls. The lower pipes of the frame are perforated within the slips and are extended outside the slip covers through the movable head and terminate in cocks *e*. When the tank is closed, pulp is introduced under pressure, filtrate passes through the canvas and out through cocks *e* while a cake of retained solid builds up on the leaves. When sufficient cake has built up, judged by the pressure on the gage and the rate of flow of filtrate, air is introduced to displace the remaining pulp through drain pipe *g* and to maintain pressure within the tank and hold the cakes in place, then water or dilute solution may be pumped through for washing or air or steam for drying. Finally the leaves are run out and cake forced off by steam or compressed air introduced within the covers through pipes connecting with header *f*. Gravity pressure may be used instead of pumps, if sufficient head is available.

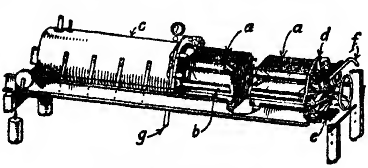

FIG. 15. Kelly filter.

Sweetland filter is similar to the Kelly except that the leaves are transverse and stationary, the tank is jointed along a cylindrical element, and the bottom swung open for discharging cake. It is unimportant in ore treatment.

Burt revolving filter (Fig. 16) consists of a steel-plate cylinder *a* similar to a tube mill or rotary kiln, one end supported by a hollow trunnion *b*, the other on a tire and rollers *c*. The cylinder is closed by hydraulically operated toggles *d*. The interior of the shell is lined with filter mats bolted on. The whole is revolved about 15 r.p.h. by means of gear *e*. Feed is introduced through feed valve *f* until a proper charge has entered, when the air pressure is turned on. Filtrate is forced through filter mats and out through holes in the shell. Wash liquid is then introduced, as desired. Finally the closing head is withdrawn and the charge is tumbled out, sluicing water being used if necessary.

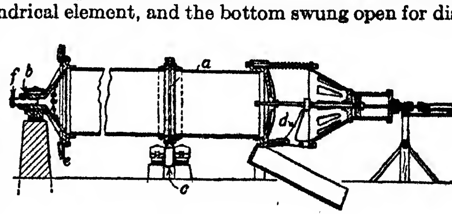

FIG. 16. Burt revolving filter.

7. VACUUM-LEAF FILTERS

Moore filter (Fig. 17) consists of a basket *a* formed by a plurality of individual filter leaves *b*, all suspended from a traveling crane over a compartmented tank *c*. Leaf (Fig. 18) consists of a canvas bag *a* slipped over a rectangular pipe frame *b* and stitched between wooden separating strips *c*. The bottom pipe of the frame is perforated and is connected to header *d* and thence to a vacuum pump. In operation one of the tank compartments is

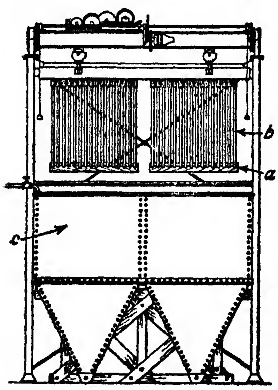

FIG. 17. Moore filter.

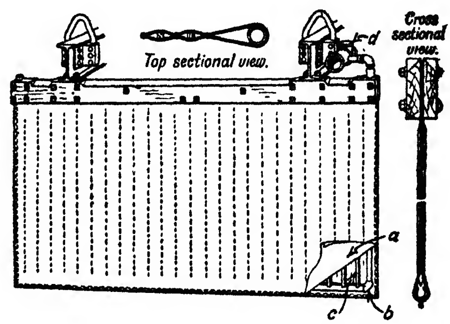

FIG. 18. Detail of Moore filter leaf.

filled with pulp and the filter basket is lowered therein and allowed to remain under vacuum until a cake of the desired thickness, usually 1 to 2 in., has built up. The basket is then lifted to an adjoining compartment and immersed in wash liquid and finally, after washing in one or more compartments, as desired, is transferred over a discharging hopper, where the cake is blown off by compressed air admitted inside the filter leaves.

Butters filter is similar except that the filter basket is stationary in one tank, into which are pumped in succession feed pulp and wash liquids. Finally the cake is blown off into the same tank and flushed away. Cake in this type of filter must be at least 0.5 in. thick to insure clean discharge.

Performance of Butters and Moore filters on cyanide pulps is given in Table 8.

Table 8. Performance of Butters and Moore filters handling cyanide pulps (1925) *a*

a These plants have either ceased operation or are now using continuous-vacuum filters. Very few filters of this type are now (1943) used in cyanide work.

8. CENTRIFUGAL FILTERS

Centrifugal filters are essentially the familiar basket centrifuge of the chemical laboratory adapted to large-scale continuous operation. They are used to dewater granular materials only, *e.g.*, to dry fine granular bituminous coal as an alternative to gravity draining.

Carpenter centrifugal filter (Fig. 19) consists essentially of the conical step screen *a*, mounted on vertical shaft *b* within an enclosure comprising frame *c* with annular launder *d* and conduit *e* for leading away filtrate, feed hopper *f*, and hopper *g* for filtered and dewatered solid. The conical shape of the filter basket causes the filter pressure to increase as the water content decreases with travel toward the bottom. Usual peripheral speed at

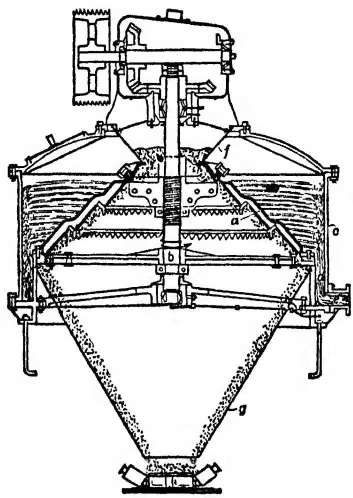

FIG. 19. Carpenter centrifugal filter.

the lower edge of the cone is 7,500 f.p.m. The machine is used for fine ($<^5/_{16}$-in.) bituminous slack; it is claimed to make a discharge containing <7% moisture from a feed carrying 30% moisture. Size: 78-in. rotor diameter; capacity, 40 t.p.h. on $<^3/_8$-in. coal 40-hp. motor.

At PITTSBURG COAL Co. (*40 CA 407, 458*) it was found that the machine tended to break >4-m. coal: that the filtered coal was lower in ash and sulphur than the feed; but that the reduction was effected at the expense of the percentage of >48-m. material.

Cost of centrifugal coal drying is said to be less than $0.02 per ton (*23 CA 784*).

9. COMPARISON OF FILTERS

Continuous filters have the surpassing advantage of continuous operation, with consequent low attendance charge and non-necessity for provision for storage of thickened feed pulp or alternative intermittent operation of thickeners. They are and should be used whenever a cake of $^1/_4$ in. upward in thickness can be built in 2 to 4 min. under the vacuum available, and when sufficient washing can be effected. Intermittent filters of both vacuum and pressure types have the advantage of lengthy and independent cake-making and washing periods, they can wash more thoroughly and with less water than the continuous machines, and they have greater filtering area per unit of floor space. Disadvantages are the intermittent operation, invisibility of cake during making and washing, and impossibility of applying mechanical preventives for cracking. Pressure filters are better than vacuum when the cake has low porosity, but the cake is less uniform and consequently not equally washed, wear on filter cloth is greater than in vacuum filters, and, in those pressure filters in which pulp is introduced by pump, the high wear on the pump is a charge against filtration. Porous-bottom tanks, filter tables, and rotary dewaterers can be used only on highly permeable granular pulps. Centrifugal filters are used only in drying granular materials, notably bituminous coal.

SECTION 17

DRYING

REVISED BY

FRANCIS E. FINCH, FORMERLY

HEATING ENGINEER, HARDINGE CO.

DRYING is the process of removing water from solid or semifluid materials by vaporization, as opposed to mechanical dewatering such as by draining, decantation, pressing, or centrifuging. Drying is employed in mill operations (1) to save freight charges where the material has to be shipped long distances; (2) to facilitate handling in cars, bins, conveyors, feeders, etc.; (3) to increase values where ores or concentrates are sold at a sliding value per weight unit; (4) to increase capacity of and/or reduce fuel or power consumption in nodulizers, roasters, and electric furnaces; (5) to increase efficiency of dry processes such as screening, air separation, and electrostatic separation.

1. PRINCIPLES

Wetness of a mass of comminuted mineral is expressed numerically as the percentage of its wet weight that is lost when the mass is heated to some temperature a few degrees above the boiling point of water for some specified time (see Sec. 19, Art. 4). The weight lost is normally evaporated water. The time required for the evaporation is dependent upon the way in which the water is distributed in the mass. SURFACE WATER is visible water on the surface. INTERNAL WATER is water within the pores of the mass. THIN-FILM WATER (ADSORBED WATER) is water on either the outer or the internal surface of a particle in the form of an invisible film, a few molecules thick at the most, held tenaciously by molecular attraction between the solid and water. Surface water and internal water are relative terms when applied to comminuted material in that they describe the position and state of the water not only with respect to the solids but also with respect to the adjacent gaseous phase. Thus for an individual wet particle surrounded by gas, surface water is the visible water between the solid surface and the gas, and internal water is the water in the pores of the particle. But for a mass of wet sand in a pan, surface water is only the visible water above the general surface of the mass, and internal water is that in the interparticle spaces plus that within the pores of the individual particles. The importance of the distinctions lies in the fact that evaporation rates for the three kinds of water are markedly different.

Evaporation is the change from liquid to gaseous state which a liquid undergoes when the vapor pressure of the liquid exceeds the partial pressure of the vapor of that liquid in the gaseous phase in contact with it. The VAPOR PRESSURE of a liquid is that pressure which the vapor of the liquid exerts, at equilibrium, on the walls of a vessel containing only the pure liquid and its vapor. The PARTIAL PRESSURE of a vapor in a space containing other gas is that part of the total pressure in the space which is exerted by the vapor; it is directly proportional to the mol fraction or volumetric fraction of the vapor present. At equilibrium the vapor pressure of a liquid is equal to the partial pressure of its vapor in the surrounding space; the surrounding space is then said to be SATURATED with the vapor. The vapor pressure of any liquid increases with rise in temperature; the relationship for water is shown in Fig. 1.

Rate of evaporation from a mass of wet solid depends upon (*a*) the porosity and, to a minor extent, other physical characteristics of the individual particles; (*b*) the state of wetness of the solid mass, primarily the ratio of surface water to internal water; (*c*) the temperature, both that at the surface and that within the body of the mass; (*d*) the pressure; (*e*) the capacity of the adjacent gas phase to take up and hold water; (*f*) the relative motion of the solid and gas phases; (*g*) the method of heating.

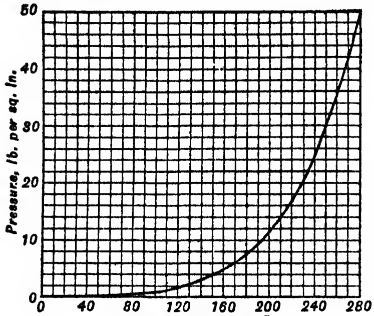

FIG. 1. Vapor pressure of water.

Solid. The important properties of the solid material from the standpoint of drying it are its porosity, specific heat, heat conductivity, and, less frequently, the chemical nature of its surface. Porosity determines the state of wetness (see below). SPECIFIC HEAT determines the relative temperature rise that can be effected by a given quantity of heat input. Specific heats of most nonmetallic minerals fall in the range 0.20 to 0.25; those of sulphide minerals are much lower. The specific heat, s, of any substance can be estimated generally within 10% by Kopp's law, which states that $s = \Sigma na/M$ where a is the atomic heat of an individual atom, n is the number of such atoms in the molecule, and M is the molecular weight. The atomic heats of the elements found in solid compounds are: B = 2.7, C = 1.8, F = 5.4, H = 2.3, O = 4.0, P = 5.4, Si = 3.8, all others 6.2. Thus for galena $s = (6.2 + 6.2)/(207 + 32) = 0.051$ (0.047 experimentally); and for calcium carbonate $s = (6.2 + 1.8 + 3 \times 4)/(40 + 12 + 3 \times 16) = 0.20$ (0.21 experimentally). HEAT CONDUCTIVITY is a measure of the relative rates at which heat flows from the exterior to the interior of a drying mass. Conductivities for some familiar materials at ordinary temperatures are: Air, 0.000057; brick, 0.0015; chalk, 0.002; granite, 0.0045 to 0.0050; graphite, 0.012; gypsum, 0.003; marble, 0.0071; mica, 0.0018; quartz, 0.03 to 0.16 according to crystallographic direction; sandstone, 0.0055; dry sand, 0.00093; slate, 0.0047; soil (dry), 0.00033; water, 0.0014. Conductivities of the metals are of the order of 0.1 to 1.0, and those of the metallic sulphide and oxide minerals are correspondingly higher than those of the nonmetallics. Chemical nature of surface is important in determining the attractive forces of the solid for water molecules. So far as knowledge of materials dried in ore-dressing is concerned, surface nature is important only as to flotation concentrates, and to certain other minerals such as talc that take on hydrocarbon coatings (Sec. 12, Art. 3) with extreme ease. The effect of these coatings on drying is discussed in the paragraph ***Drying curve*** below.

State of wetness. It has been found that, in the drying of any solid, the rate of evaporation of uncombined water varies according to the quantity of water present and/or its position with respect to the solid mass. Surface water evaporates most readily and, therefore, most rapidly, with a given rate of heat input. Thin-film water evaporates most slowly; the last traces cannot ordinarily be removed except at high temperatures and high vacua. Internal water evaporates at an intermediate rate which, in any given case, depends upon the porosity of the solid mass and the continuity of liquid water in the pores. A diagrammatic representation of these facts is given in Fig. 2.

Constant-rate evaporation. When a solid is so wet that its entire surface is covered by visible liquid, evaporation occurs as from a free surface of liquid, and, with a constant temperature differential, proceeds at a constant rate according to the general evaporation equation $w/\theta = KA(h_s - h_g)$, in which w/θ is the weight of water evaporated per unit of time, h_s is the saturation humidity at the temperature prevailing at the saturated surface, h_g is the absolute humidity of the gas surrounding the evaporating surface, A is the area from which evaporation is occurring, and K is a constant.

Falling-rate evaporation begins as soon as the surface of a solid becomes free of visible water. From this time on evaporation is at a decreasing rate until bone-dryness is achieved. Two factors are involved in the decrease. (*a*) The water in the invisible film at the solid surface is held to the solid by molecular attractions greater than those of water molecules for each other; hence more energy (heat) must be put into the system to release them. (*b*) Internal water in the pores of the solid is in contact with gas that is substantially saturated except as its temperature is raised by increase in temperature of the surrounding solid. The water content of this pore gas can be decreased only by diffusion the length of the gas-filled pore and thence to the surrounding atmosphere—a tremendously slow process. Liquid water may, however, be, and is, moved to the surface by raising the temperature of the solid, whereupon gas and water vapor precipitate from the body of the water onto the solid surfaces, and the resultant bubbles grow, pushing the liquid toward the surface, where it evaporates from a concave surface, relatively slowly as compared with a plane or convex surface, but much more rapidly than from a liquid surface within the solid mass. This process is effective until such time as the internal liquid ceases to be continuous across pore spaces, and the residue becomes drops and films on the walls of these spaces. Then a further drop in rate occurs, limited by gaseous diffusion rates and by film adhesion, as above discussed.

Drying curve. In Fig. 2, from A to B free water covers the surface and, with a constant supply of heat, the water attains a constant equilibrium temperature at which, if the water vapor is removed

from the surface as formed, evaporation proceeds at a constant rate. B marks the point at which apparently dry solid breaks through the water film. With respect to the uncovered surface the evaporation rate falls, and, the area of free-water surface being decreased, the evaporation rate for the total area falls, at an increasing rate as the free-water surface decreases, until at C free water has disappeared from the surface entirely. From C to D drying proceeds largely by extrusion followed by evaporation at or near the solid surface, the rate falling rapidly as the continuity of the liquid pore fillings is broken, and the extruding capacity of water evaporated within the general mass decreases for lack of confinement. From D to O droplet and thin-film evaporation in the pores, with vapor diffusion to the gas-swept surface, prevails, and the rate decreases slowly to very low values.

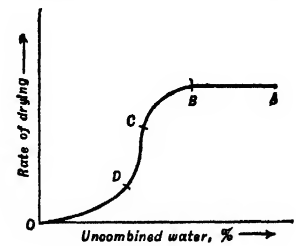

FIG. 2. Drying curve.

The significance of hydrocarbon surface films on flotation concentrates, etc., lies in the fact that air and water vapor precipitate readily from liquid water at such surfaces with a small rise in temperature (see Sec. 12, Art. 11), while without such surface coating the temperature must be raised much higher before gas precipitation occurs. Concentrate is often dried in a mass to prevent the dusting that occurs when it is dropped through a current of hot gas. Under these circumstances the enhanced extrusion from interparticle pores due to precipitated gas is important in accelerating the drying rate.

Temperature affects evaporation rate because of its effect on both vapor pressure (see Fig. 1) and the moisture-carrying capacity of the gas phase in contact with the evaporating surface (see Table 1). Further, the higher the temperature of the heating medium (solid surface or gas) the greater the temperature differential between surface and interior of the mass of solid; since conductivity varies as this temperature differential, with high temperature the internal water is heated and driven out more quickly.

Pressure. Reduction in the pressure on an evaporating surface reduces the partial pressure of the vapor of the evaporating liquid in the gas phase without affecting the vapor pressure of the liquid. Since rate of evaporation is proportional to the difference between these quantities, it is thereby increased. This phenomenon is utilized in evaporating substances that would be harmed by high temperatures; it is more expensive than heating and is not, therefore, used with ores and concentrates.

Gas velocity. Transport of moisture away from the evaporating surface is essential to maintenance of a high difference $h_s - h_g$ in the evaporation-rate equation. Water molecules leaving an evaporating surface must diffuse through the gas film, statistically stationary, in contact with the surface. At constant temperature this diffusion rate is dependent on the thickness of the gas film, which decreases with increase in gas velocity across the solid surface. Furthermore, the shorter the time that any volume of gas is near an evaporating surface the less vapor it picks up and hence the lower its absolute humidity (h_g). On both scores, therefore, the higher the gas velocity past the wet surface the higher the drying rate. Sherwood (*Perry*) proposes the formula $G = 0.021V^{0.8}$ to represent the relationship between evaporation rate and gas velocity during the constant-rate period. G is lb. of water evaporated per hr. per sq. ft. of free-water surface per mm. of difference between the vapor pressure of the evaporating water and the partial pressure of water in the surrounding gas, and V is the mass velocity of the gas (lb. per sec. per sq. ft. of evaporating surface); the limits of applicability are given as 180 to 1,200 f.p.m. gas velocity.

Heating. The minimum quantity of heat necessary to be supplied for evaporation of liquid from a solid mass is the sum of the latent heat of the liquid evaporated (see Table 1) and the sensible heat required to raise the temperature of the system to the temperature of evaporation. In any practical operation an additional quantity of heat, amounting to 50 to 100% or more of the minimum, must be supplied to make up for heat losses (see Art. 5).

Heat required to raise the temperature of the solid is given by the equation $H_s = W_s h_s(t_e - t_i)$, where H_s is the required number of B.t.u., W_s is the weight of solid heated in lb.; h_s is the specific heat of the solid in B.t.u. per lb. per deg. F.; t_e is the exit and t_i the inlet temperature in deg. F.

Heat required to raise the temperature of the water is obtained by the equation $H_w = W_w(t_e - t_i)$, where H_w is the required quantity of heat in B.t.u., and W_w = total weight of water entering. The specific heat of water is practically 1.0, so it does not need to appear in the equation.

Heat required *for evaporation* (H_e) is the product of the weight of water evaporated (W_e) and the latent heat of evaporation of water at the outlet temperature (h_l). $H_e = W_e h_l$. See Table 1.

Heat transfer occurs both by conduction and by radiation. The fundamental equation for conduction in solids is the integrated form of Newton's equation, $Q/\theta = kA(\Delta T)/L$, where Q is quantity of heat, θ is time, ΔT is the temperature difference, A is the area over which conduction is taking place, measured at right angles to the direction of flow; L is the length of path, and k is a coefficient of conductivity which varies markedly for different materials and is different at different temperatures. The Stefan equation for transfer by radiation is $Q_n/\theta = A(T_1^4 - T_2^4)$ in which Q_n is the net heat loss of the hotter body, and T_1 and T_2 are the absolute temperatures of the hotter and cooler bodies respectively. Data are never available in any particular drying problem for quantitative application of either of these equations. They are useful, however, in that they point

out that whether transfer is by radiation or conduction, the rate of flow of heat (Q/θ) increases with increase in the difference in temperature between the heating medium and the solid to be dried, and that the rate at which a particle becomes heated through is an inverse function of its diameter.

TYPES OF DRIERS

Driers are of a variety of types. They have been classified loosely, and on different bases, as (*a*) hearth-type, (*b*) shaft-type, (*c*) film-type, (*d*) spray-type, etc.

2. HEARTH DRIER

This type is characterized by the fact that the material to be dried is supported on and receives its principal heat supply through a floor or hearth. The earliest form was the drying floor. Modern forms are typified by the Lowdén type (*post*). Wedge and Herreshoff roasters normally utilize the upper hearths for pre-drying. The simplest drying operation consists in spreading material on floors, protected from the elements but

open to free circulation of air. Under these circumstances drying takes place even with freezing temperature, although very slowly. The rate is increased by turning material over from time to time. This type of drier is used in certain small and crude nonmetallic milling plants, *e.g.*, tripoli, bauxite, etc. It is applicable only where labor is the cheapest commodity entering into the treatment process, tonnage is small, and time is not an important element.

Heated floor was used at Tui Mi Chung mill (*119 P 814*) for drying flotation concentrate. The floor was of concrete (1 of cement, 2 of washed sand, 4 of 3/4-in. gravel), 2 1/2 in. thick, reinforced with barbed wire laid in 3-in. squares 3/4 in. from the bottom of the slabs. Checkerwork flues underlay the floor. The slope toward the stack end, which was also the loading end, was 1 in. per ft. for the last 3 ft. and 1/4 in. per ft. for the rest of the length. Concentrate was brought in cars from the thickeners, dumped at the stack end, and allowed to drain. Material was then raked by hand toward the fire end, where it arrived dry. Six floors, each 15×40-ft., were needed for 30 to 35 t.p.d. of concentrate 97% <200-m. Fuel consumption ranged from 0.1 to 0.2 cord of wood per ton dried, summer and winter respectively, and averaged about 0.14 cord. Cost of drying, sampling, sacking, and weighing was $0.90 per ton with wood at $3.60 per cord and labor at $0.25 per day of 10 hr. At Tonopah Mining Co. (*91 J 1214*) fine gravity concentrate was drained in an 8-in. layer on sloping (3/8 in. per ft.) plank floors to 15% moisture in 20 hr., then dried to 3.4% on a steel-plate floor. With coal at $13.50 per ton and wood at $9.50 per cord the total cost of drying 4 tons per day was $0.84 per ton.

Mechanical hearth driers comprise troughs of various shapes along which the material to be dried is conveyed by mechanical means while it is being heated. The primary source of heat is by conduction through the trough. When gas is used to heat the trough, it may later be flowed over the material. In some forms the trough is steam jacketed. The conveying means should be and ordinarily is arranged to rabble the material at the same time that it conveys it; usually chain drags or reciprocating rakes are used, but screws or spirally placed blades (logs, Sec. 10, Art. 4) have been employed.

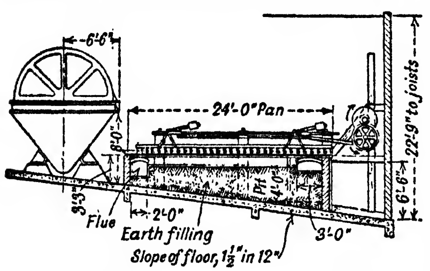

Fig. 3. Lowden drier with Oliver filter.

Lowden drier (Fig. 3) is the best known of the hearth type. It consists of heavy cast-iron plates resting on brick or concrete checkerwork heated by gases of combustion, waste-heat gas, or steam. Feed is introduced at the firing end of the hearth and slowly advanced and rabbled by a series of reciprocating rakes operating on the bell-crank principle (Sec. 8, Art. 2); length of stroke is adjustable, but is less than the distance between the rabbles. Speed is 1 to 3 s.p.m. The hearth may be open or hooded; in the latter case vapor is removed by means of a fan or stack. Hearths are 4, 6, 9, and 12 ft. wide and 24 to 60 ft. long. The machine is recommended by the manufacturer (Colorado Iron Works) for drying very fine materials that would give off excessive dust in other types of driers and for sticky materials that clog other types.

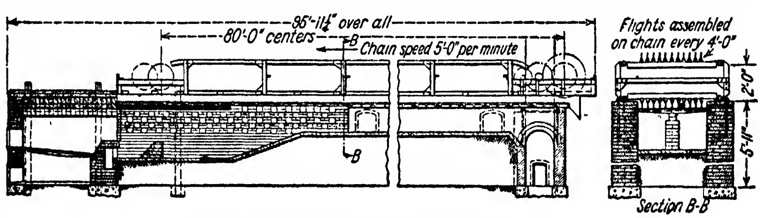

Fig. 4. Hearth drier with chain-drawn rabbles.

Most other designs of hearth driers in use have been designed by the users. C. O. Bartlett & Snow Co. build a chain-drag type (Fig. 4). Trouble is usually encountered with the drag type when drying sticky materials owing to the tendency of the material to adhere to the rabble or to build up on the hearth and allow the rakes to ride over it.

Performances of rabble driers are as given in Table 2.

Table 2. Performances of rabble-hearth driers

Material	Zinc flotation concentrate	Lead flotation concentrate	Copper sludge	Washed plastic kaolin

a Per lb. *b* Per gal.

Watt reported (*57 A 385*) that Lowden driers require 70 to 120 lb. of coal per ton of lead-flotation concentrate to dry from about 14% to about 6% moisture; and that the usual size allowance is 10 sq. ft. of hearth area per ton of concentrate to be dried per 24 hr. At FEDERAL LEAD Co. Mill No. 4 one 12×24-ft. machine dried 50 t.p.d. of <80-m. flotation-lead concentrate from 15 or 16% moisture to 4 to 6% with a consumption of 2 tons of soft coal. The machine was run at 2 1/2 s.p.m. and consumed about 6 hp. Lost time for tightening rakes, replacing crank pins, and repairing furnace hearth and arch amounted to about 2%. A common set-up, with gravity feed from filter and gravity discharge to a car-loading hopper, is that shown in Fig. 3. At HAYES MILLING Co. (*111 J 909*) a 5×17-ft. Lowden drier, oil-heated, dried 175 tons per month from 35 to 15% water at a cost for fuel of $6.90 per ton of water evaporated. Reynolds (*116 P 745*) gave data on FUEL CONSUMPTION in drying flotation concentrate at three different plants as follows: (1) 56 tons (dry weight) per 24 hr. from 15 or 16% to 4% moisture with 3 1/2 tons of coal; (2) 30 tons (dry weight) per 24 hr. from 15 to 16% to 5% moisture with 1 3/4 tons of coal; (3) 31 tons (dry weight) per 24 hr. from 29% to 13% moisture with 2 tons of coal. At LIBERTY BELL two steam-heated rabble-type hearth driers, with 4×10-ft. drying surface, were used in series to dry 12 tons of 300-m. flotation concentrate per 24 hr. from 20% to 10% moisture; fuel consumption was estimated at 0.5 ton coal per 24 hr. for the two machines.

Evaporation on hearth driers ranges, in general, from 1 to 5 lb. of water per hr. per sq. ft. of hearth; and from 1 to 4 1/2 lb. per lb. of 13,000-B.t.u. coal.

3. SHAFT DRIERS

Shaft driers operate on the principle of showering moist solid material through a current of hot gas moving at 90° to 180° to the stream of falling material. There are two main forms, *viz.*, (*a*) tower driers and (*b*) rotary driers.

Tower drier is, as the name implies, a shaft- or chimney-like structure, ordinarily vertical, connected at the bottom to a furnace or other source of heat. Feed is introduced at the top and flows downward by gravity, usually over baffles; at the bottom it discharges 90° or 180° from the fire box. This type of drier is usually constructed without any moving parts. The walls are built of brick, of concrete lined with brick, or of insulated steel. Baffles are arranged to retard the fall of material; they are usually steel angles, channels, or other shapes so set that material does not build up on them. When steam is used as the source of heat, the steam pipes take the place of, or are additional to, the baffles.

Fig. 5 shows two different forms of tower drier in use at the Franklin mill of NEW JERSEY ZINC Co. The stack is usually laid up of three or four courses of common red brick, bound both ways at about 3-ft. intervals with tie-rods laid in the brickwork, or with buckstays and tie-rods. The sides and arch of the firebox and the first few feet of the stack are lined with one course of fire brick. Racks for T-bar grids are carried on the inner walls or, as at the EMPIRE IRON & STEEL Co. mill (*99 J 560*), carried on independent hollow sectional cast-iron columns, built up like tile pipe, set in the corners of the stack. If shelf baffles are used, they are usually carried on the stack walls and may be made of adjustable slope. At EMPIRE IRON & STEEL Co. the stack was 5 ft. square and 45 ft. 4 in. high, set on a concrete block 10 × 10 × 10 ft. The baffle bars were arranged in 10 sections or groups. The lowest 7 sections consisted of 5 tiers of 5 bars each, the bars in alternate tiers at right angles. The upper surface of the bars (the crossbar of the T) was 6 in. wide and 3/4 in. thick. The bars were set to give 6 in. clear horizontally and 8 in. vertically. In section 8 there were 4 tiers of 4 bars per tier, each bar 9 in. wide and 1 in. thick. This left 7 in. clear between bars horizontally and 10 in. vertically. In section 9 there were 3 tiers of 3 and 4 @ 9-in. bars per tier, leaving 10- and 10 1/2-in. spaces horizontally and 12 in. vertically. In the top or No. 10 section there were 2 tiers with 3 and 4 @ 9-in. bars per tier, leaving the same horizontal spacing as in No. 9 but 15-in. vertical spacing. The web of the bars fitted loosely into the supporting racks. Doors were provided at each section for ease in changing. The firebox was 6 ft. 9 in. × 7 ft. 6 in. with grate for burning No. 2 buckwheat coal under forced draft. Additional air was furnished by a No. 80 American Blower Co.'s steel-plate exhaust fan; it was pre-heated by drawing it over the arch of the furnace, then under the arch, where it joined the gases of combustion. A 30-in. (diam.)×20-ft. stack was provided, having a damper arrangement to cut in the blower or the stack for draft, as necessary. Feed was through a 1 1/8×2 1/2-in. slot and averaged 14% moisture. Average feed rate was 25 t.p.h., maximum 35 t.p.h. Product was substantially dry. At NEW JERSEY ZINC Co. the double-furnace drier shown in Fig. 5 dries 100 t.p.h. of <1-in. feed from 3% moisture to apparent dryness. Fuel consumption is 700 lb. anthracite buckwheat per hour. The air used amounts to 20,000 cu. ft. per min. and the blower draws 30 hp. The single-furnace drier is fed 6 t.p.h. of <10-m. material containing 8% moisture; discharge is substantially dry. Coal consumption is 250 lb. per hr. (anthracite). The blower supplies 5,500 cu. ft. of free air per min. with a consumption of 10 hp. A similar drier at the same plant with a stack 3 ft. 6 in. square and 32 ft. high handles 11 t.p.h. of 6~35-m. feed carrying 10% water and brings it to substantial dryness with a coal consumption of 170 lb. per hr., air consumption of 3,200 cu. ft. per min., and power draft of 15 hp. At the Ogdensburg mill of the same company 20 t.p.h. of <1-in. ore is dried in a stack 3 ft. 6 in. square and 40 ft. high from 10% water to apparent dryness. Fuel consumption (anthracite) is 450 lb. per hr., air consumption 10,000 cu. ft. per min., requiring 10 hp. at the blower motor. In the same mill a double-stack drier, each stack 3 ft. square and 38 ft. high, dries 3 t.p.h. of 8~35-m. feed from 15% moisture to apparent dryness. Fuel consumption is 200 lb. per hr. of powdered bituminous coal, air consumption is 8,000 cu. ft. per min., and power consumption about 10 hp. In all of these New Jersey Zinc Co. driers the attempt is to keep the exit gases down to 200° F. At WITHERBEE-SHERMAN, Mill No. 3, <3/4-in. roll product (mag-

netite gneiss) was dried from 3% to 0.2% moisture at the rate of 50 t.p.h. in a stack 4 ft. 9 in. square × 50 ft. high. Coal consumption was given as 1 ton of anthracite (birdseye) per 24 hr., but this is undoubtedly below the actual consumption for the reduction in moisture stated.

The DISADVANTAGE of the tower drier is the difficulty of regulating the rate of fall and, consequently, the amount of drying. In driers with adjustable-shelf baffles some regulation may be effected by

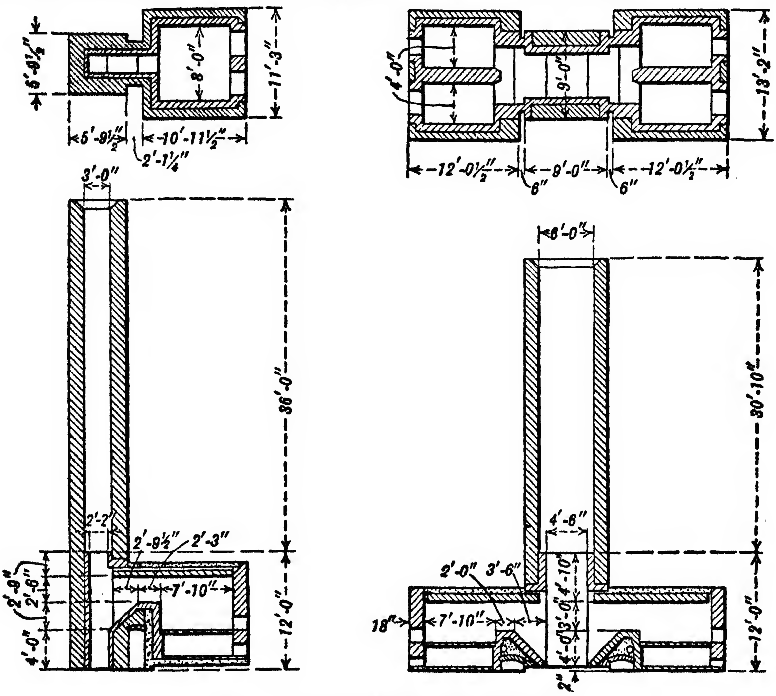

FIG. 5. Tower driers at New Jersey Zinc Co.

changing the inclination of the shelves, but not much is to be gained here because, if the shelves are made flat enough to retard flow materially, the wet material sticks and piles up and substantially all drying effect of the shelf surface is lost. Another disadvantage is the large loss in headroom. Hence these driers are used mainly for materials having a small, constant amount of surface moisture only, or when it is desired to reduce surface moisture by a small, constant amount. The ADVANTAGES are simplicity of design and operation. Average evaporation in tower driers is between 3 and 8 lb. of water per lb. of 13,000-B.t.u. coal.

Rotary drier is the commonest form of mechanical drier. It consists essentially of a long cylinder mounted on a slight incline (acute cones and horizontal cylinders with internal spirals are also used), revolved slowly while the material to be dried and the heated gases pass therethrough. *Lifting angles* on the interior of the shell lift the drying material and drop it substantially at right angles to and through the current of gas, thereby both spreading the material out in a manner favorable to evaporation of the contained moisture and aiding its progress through the shell. Stationary heads with suitable sealing glands at the ends of the cylinder provide for inlet and outlet of solid and heated gas with minimum infiltration from the atmosphere.

Direct-heat cylindrical drier (Fig. 6) is the simplest form. The essential parts are the drying cylinder (*a*), furnace (*b*), exhaust chamber (*c*), and driving mechanism (*d*). Feed

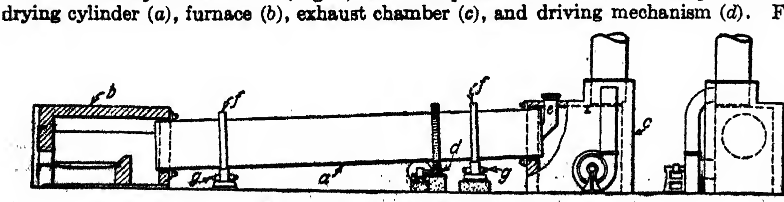

FIG. 6. Direct-heat cylindrical drier.

enters through spout (*e*) and is discharged into a suitable receptacle or conveying mechanism at the other end of the shell. The shell is made of heavy steel plate with riveted joints. Longitudinal lifting angles are riveted to the inner surface. Heavy steel tires (*f*) bolted to the shell ride on hardened-steel rollers (*g*). Various methods are employed to resist end thrust. Fig. 6 shows flanged rollers used at the head end. Fig. 7 shows a more efficient, although more expensive, form with horizontal rollers (*a*) that bear against the sides of the tire. A gear drive is usual, although chain-and-sprocket drive is used on some small, light machines. Coal is the usual fuel, but any fuel may be used. The use of a blower in addition to a stack is wise, since it gives positive control of draft and increases thermal efficiency. The furnace is placed at either end of the shell, as desired. The arrangement shown in Fig. 6 is the usual one, as combustion is not checked by contact of the gases with cold wet material and dust losses are less because the sheet of wet solid at the feed end serves as a sort of filter for the dust-laden gases.

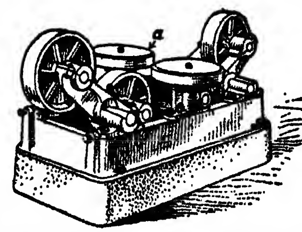

FIG. 7. Roller bearing for rotary drier.

Cylinder sizes range from 2 to 12 ft. diameter and 8 to 160 ft. in length. Usual SPEEDS are 60 to 80 f.p.m. peripheral. POWER required for drier cylinder and fan averages about 10 hp. for a 3×25-ft. machine; 15 hp. for a 4×30-ft., 25 hp. for a 5×35-ft., 35 hp. for 6×40-ft., 50 hp. for 7×50-ft., and 70 hp. for 8×60-ft. (*C. O. Bartlett and Snow.*) Fuel consumption averages about 1 lb. of 13,000-B.t.u. coal per 5 lb. of moisture evaporated (range of 4 to 8 lb.).

Direct-indirect-heat cylindrical drier (SEMI-DIRECT-HEAT) is built either in the brick-enclosed form shown in Fig. 8 or in the double-shell form (Fig. 9). The elements of the shell in Fig. 8 are the same as those in Fig. 6, but the circulation of hot gases is first around

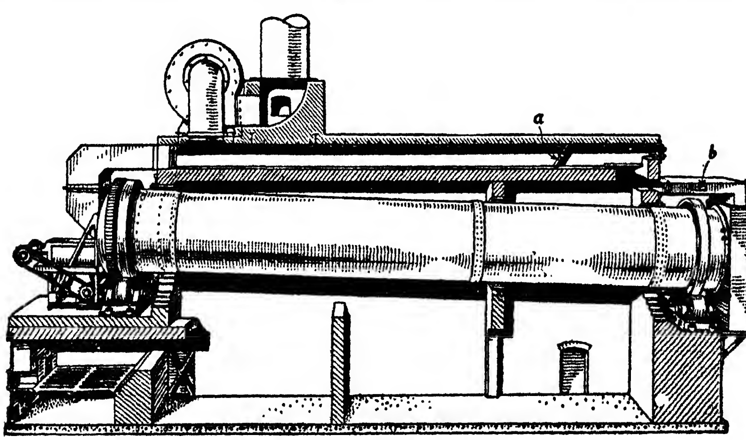

FIG. 8. Brick-enclosed cylindrical drier.

the outside of the shell, then through the shell. Dampers *a* and *b* determine the proportion of gas passing through the shell interior. By closing *b* and opening *a* the machine becomes an indirect-heat drier. Cylinder sizes are the same as those of the preceding machine.

This machine utilizes heat more completely and efficiently than the direct-heat machine, both on account of the enclosure of the shell, which decreases radiation losses, and the longer time that the gases are in contact with surfaces to be heated. Fuel consumption is 1 lb. of 13,000-B.t.u. coal to 6 or 6 1/2 lb. of water evaporated.

Double-shell drier (Fig. 9) is arranged so that hot gas directly from the furnace passes through the inner shell and returns between the two shells, as indicated by the arrows. Feed enters at the furnace end of the outer shell, is lifted by the ribs of the outer shell, showered through the stream of hot gas onto the ribbed outer surface of the inner shell, held for a while in contact with this hot surface, and then showered again through the gas stream onto the outer shell. This cycle is repeated many times in the passage to the

discharge-end head, where the material is finally picked up by buckets on the inner surface of the outer shell, dropped onto the fluted discharge cone *a*, and carried out through the discharge trunnion.

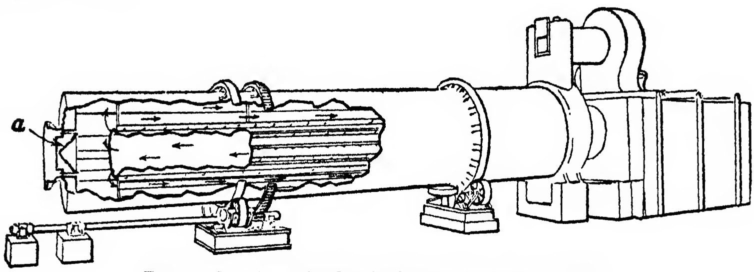

FIG. 9. Ruggles-Coles double-shell semi-direct-heat drier.

Sizes are from 3- to 12-ft. diameter and 10- to 125-ft. lengths. EVAPORATION ranges from 4 to 11 lb of water per lb. of 13,000-B.t.u. coal.

Cylindrical driers in concentrating mills are usually of the direct or direct-indirect type, since discoloration and overheating are of no importance. Their use is ordinarily limited to granular materials, however, on account of the high dust losses with finer feeds.

Rotary louvre drier (Fig. 10) consists of a cylindrical shell *a* with a conical inner space *b* enclosed by louvres *c*; the entire structure is mounted on rollers and is gear driven. A stationary head *d* with suitable seal provides for entry of wet feed and heated gas. The space between the inner face of shell *a* and the outer faces of the louvre plates *c* is divided by radially placed plates *e* into longitudinal flues, open at the head end and along the louvred side, but closed by the discharge-end wall of the cylinder. The hot-gas inlet is so arranged that only those lower flues on the upcoming side that are at any given time under louvre plates covered by the bed of material are in registry with the inlet. The gas

there introduced under pressure follows generally the paths indicated by the arrows in Fig. 10. The diameter of the discharge opening is adjustable to permit variation in depth of bed. Normal gas exhaust is at the discharge end.

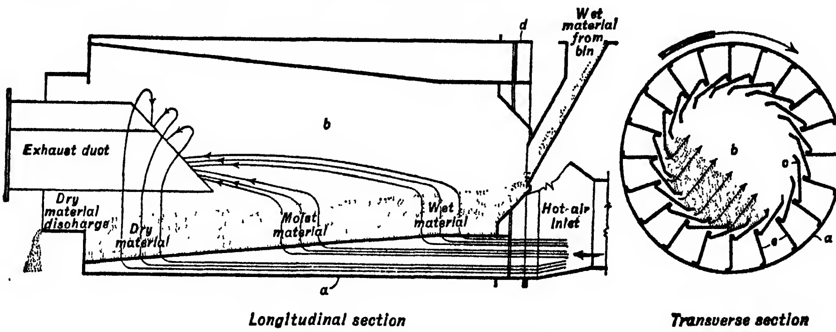

FIG. 10. Rotary louvre drier.

Sizes range from 6- to 35-ft. length to evaporate from a few pounds to 12,000 lb. of water per hr. Evaporation is stated to be 5 to 11 lb. per lb. of 13,000-B.t.u. coal.

Indirect-heat rotary driers are used when discoloration or contamination of the solid would occur from contact with combustion gases, and when dusting would be excessive with a large flow of gas through or over the material. The drier in Fig. 8 may be run as an indirect-heat machine by closing damper *b* and opening damper *a*. Fig. 11 diagrams a 3-shell machine which has two heated surfaces, *a* and *b*, supported within and revolving with shell *c*, and gas flow as indicated by the arrows. In both types a small amount of air is forced through the cylinder carrying the material, or this is put under a slight vacuum, in order to exhaust evaporated water.

g BS, Brick-sheathed; CF, Counter-flow; DS, Double-shell; IH, Indirect-heat; PF, Parallel-flow; SD, Semi-direct; SS, Single-shell; TT, Tube-type.

i Reported by Hardinge Co.

Sizes of the 3-shell machines are 3- to 10-ft. diameters by 10- to 80-ft. lengths. EVAPORATION rates are 2 to 6 lb. of water per lb. of 13,000-B.t.u. coal.

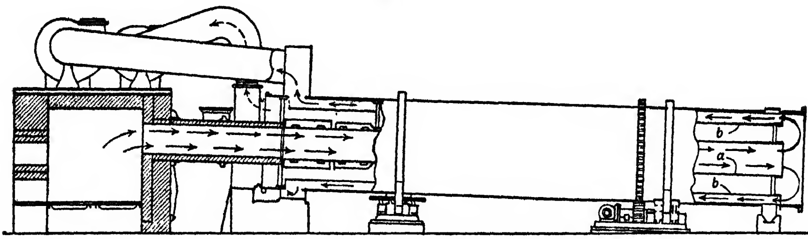

FIG. 11. Indirect-heat rotary drier.

Multiple-tube drier is a form of cylindrical drier with the shell replaced by a number (usually 3 to 5) of parallel tubes aggregating in outside diameter the usual 3 to 8 ft. of the single-shell machines. Various arrangements are shown diagrammatically in Fig. 12. Sufficient space is maintained between the tubes to allow free circulation of hot gases. The machines may be run either indirect-heat or semi-direct. Advantages asserted are greater heating surface for indirect heating, and reduction in power consumption from 70 to 80% of that required for a single-tube drier owing to distribution of the ore stream around the axis of revolution. Bartlett & Snow claim an average of 8 lb. of water evaporated per pound of 13,000-B.t.u. coal in their multi-tube drier operated with both direct and indirect heat.

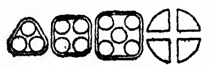

FIG. 12. Arrangements of tubes in multi-tube revolving driers.

Steam-tube rotary drier is used for many of the materials dried in indirect-heat driers and also for those materials that must be dried at relatively low temperatures. By using low-pressure or exhaust steam the greatest temperature any part of the material can reach will be slightly less than the temperature of the steam used. The cylinder is similar to that of single-shell direct-heat driers, but steam pipes take the place of the internal baffles and vanes. SIZES range from 2- to 8-ft. diameter by 10- to 80-ft. length. EVAPORATION rates vary greatly, but approximately 1 lb. of water is evaporated per 1 1/2 lb. of steam at 10-lb. pressure.

Manufacturers of rotary driers: Allis-Chalmers Mfg. Co.; C. O. Bartlett & Snow Co.; Buffalo Foundry & Machine Co.; L. R. Christie Co.; Hardinge Company; Louisville Drying-Machinery Co.; Stearns-Rogers Mfg. Co.; Struthers-Wells Co.; Traylor Eng. & Mfg. Co.; Vulcan Iron Works Co.

Performances of rotary driers of various types are given in Table 3.

In PHOSPHATE WASHING (*50 A 929*) a 5×40-ft. machine dries 135 to 165 tons of <1/4-in. slime-free gravel per 24 hr. from 20% to 2 or 3% moisture with a consumption of 75 lb. bituminous coal per dry ton and 15 to 20 hp. for driving the shell and fan. At the U. S. SMELTING, REFINING & MINING Co., Midvale plant, a 5×30-ft. Ruggles-Coles (double-shell) machine dried 90 tons of <16-m. table middling per 24 hr. from 14.5% moisture to bone-dryness with a consumption of 3 tons of bituminous coal per 24 hr. Temperature of exit gases was 350° F. Speed, 5 r.p.m. Power consumption: driving shell, 6 hp.; fan, 4 hp. About 5.5% possible running time was lost owing to shell repairs. At AFTERTHOUGHT COPPER Co. (*119 P 154*) a 5×30-ft. oil-fired machine was used to dry about 150 tons flotation concentrate per 24 hr. from 15% to 5% moisture. About 10 tons of flue dust was collected monthly. Some caking occurred near the feed end when concentrate was sticky.

On the basis of the reported figures, THERMAL EFFICIENCIES range from about 40 to 75%, and B.T.U. PER LB. OF WATER EVAPORATED from 1,500 to 3,700, for a considerable variety of materials. High fuel consumption correlates, in general, with fine grain sizes and/or drying to a fraction of 1% of moisture.

4. MISCELLANEOUS DRIERS

Screen-type driers consist of screens over which wet material travels while subject to a down-draft of heated gas (see D-L-O drier, Sec. 16, Fig. 13). Such driers are not suitable for fine material (<1/4-in.). See also Sec. 16, Art. 5.

Utah vibrating drier is a Jeffrey-Traylor-type conveyor (Sec. 18, Art. 23), heated underneath and boxed in above and below and run semidirect. A 2×30-ft. machine dried 30 t.p.d. of molybdenite concentrate from 15% moisture to 0.5%.

Centrifugal driers. See centrifugal filters, Sec. 16, Art. 8.

Electrical driers. At GOLD HUNTER (*111 J 909*) eight coils of high-resistance wire wound on 1-in. iron-pipe supports were spaced at 1-ft. intervals across and near the face of an Oliver filter. Each unit consumed 3.95 kw. The filter handled 30 t.p.d. of mixed table and flotation concentrate. The cake without the drier averaged 11% water; with the drier, 8.7%. The cost per ton of water evaporated

was \$6.86. At BUNKER HILL & SULLIVAN (*ibid.*) a rotary drier consisting of a piece of 12-in. iron pipe 10 ft. long, covered with 3/8-in. asbestos, was wound with 205 turns of bare No. 4 hard-drawn copper wire (90 lb.) terminating on collector rings. A current of 82 amp. at 282 volts was supplied and heat generated by hysteresis and eddy-current losses in the pipe walls. The pipe rotated 7 r.p.m.; spiral rabbles inside, turning 1.4 r.p.m., moved the ore through. Pre-heated air was forced through countercurrent. The capacity was 17 t.p.d. of flotation concentrate from 11.4 to 6% moisture; cost of power, \$5.66 per ton of water evaporated.

Cylinder or film driers (ATMOSPHERIC DRUM DRIERS) consist of one or more revolving, hollow, metal cylinders internally heated by means of steam. The material to be dried must be more or less fluid; suitable feeding arrangements deposit it as a thin film on the cylinder. Dried material is removed by scrapers before completion of a revolution. Speed of rotation of the cylinder governs the time that the film is in contact with heat. These are rarely used in ore dressing.

Spray driers. Various atomizing devices spray liquid into a heated chamber. Dry products collect at the bottom and in dust collectors.

Vacuum driers consist essentially of heated chambers under vacuum, with means provided for introduction of feed and discharge of product; numerous mechanisms have been devised for the purpose. They are used only when the heat necessary to dry the solid at atmospheric pressure would injure it; this is rarely the case in ore dressing.

Comparison of driers. The SINGLE-SHELL ROTARY drier is cheaper in first cost and maintenance per unit of capacity than other rotary types, and is satisfactory for metallic ores. It is generally favored because it affords ready control of temperature and drying time. The TOWER drier has lower maintenance costs but consumes more fuel per unit weight evaporated than the rotary; it is better adapted to a crowded mill, but control of time-factor is practically nonexistent. The DOUBLE-SHELL DIRECT-HEAT and the LOUVRE types have the lowest fuel costs, and can be used to dry many materials that must not be subjected to the high temperatures prevailing in direct-heat single-shell machines. HEARTH, VIBRATING-CONVEYOR, and INDIRECT-HEAT ROTARY driers are used for drying fine materials to a low moisture content when dust losses would be high in other types; also for materials which must not be contaminated by the products of combustion. STEAM-TUBE drier eliminates dust loss and contamination, but sticky materials tend to pack around the pipes.

5. OPERATION OF DRIERS

Dewatering of feed should always be practiced if the material contains free surface moisture that is removable by draining or filtration; these methods of water removal are usually much cheaper than drying, especially when large tonnages are involved.

Dusting. Operation of a drier on a material containing valuable fines involves a continuous compromise between fuel consumption and dust loss.

Dietz and Keedy (*43 A 342*) give the data shown in Table 4 for operation of a 4 1/2×24-ft. rotary drier running at 8 r.p.m. with light draft, the feed carrying 5 to 8% moisture. At a dry-crushing cyanide plant, drying <2-in. material in rotary driers that needed strong draft, 5 to 6% of the feed, which assayed 0.31 oz. Au and 0.15 oz. Ag, was lost as <150-m. dust that assayed 0.48 oz. Au and 3.48 oz. Ag. In an elaborate test with a 4×30-ft. drier, sloped 1/4 in. per ft., they found that, in drying <2-in. zinc ore, about 12% of the feed was reduced from >16-m. to <16-m. by the tumbling action in the drier and that this 12% carried 19% of the zinc. In a dust-collecting system in the same plant substantially 16% of normal drier feed was collected carrying 19% of the total zinc; the more gritty part of the collected product had the higher assay.

Table 4. Dust loss in a rotary drier (*After Dietz and Keedy*)

Products	Weight, per cent.	Assay		Percentage of total	
		Pb, per cent.	Ag, ounces	Pb	Ag
Total feed	100	10.35	9.68	100	100
Dry discharge	96.2	9.77	9.34	90.7	95.40
Settled in chamber	1.77	35.30	10.30	6.04	1.94
Settled in smokestack	0.76	18.50	8.60	1.36	0.69
Lost in gases	1.27	14.30	15.20	1.75	2.04

Dust losses can, in any given case, usually be reduced by reducing the velocity, and hence the volume, of gas through the evaporating zone, but this expedient involves increase in fuel consumption in order to raise the temperature and corresponding moisture-carrying capacity of the gas. Gas velocity should be kept down to about 80 f.p.m. when the dusting tendency is serious; normal velocities are from 200 to 400 f.p.m.

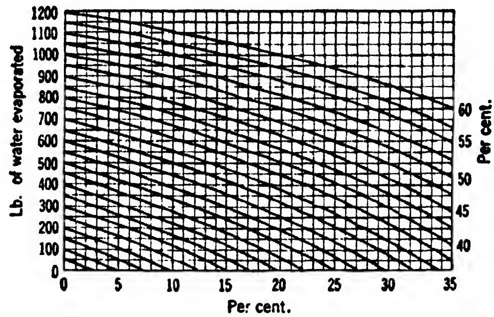
Efficiency of a drier is commonly defined as the ratio $E = 100(H_s + H_w + H_v)/H_f$, in which H_f is the total heat in the fuel and the other H values are defined as on p. 08 for an evaporating temperature of 212° F.

Example. To calculate the efficiency in drying a zinc concentrate (58% Zn, quartz gangue) from 14.5% to 3.5% moisture at the rate of 7.4 tons wet feed per hr. with a consumption of 39 gal. oil per hr. (138,000 B.t.u. per gal.). Initial temperature of feed, 50° F.

Weight of dry solid (W_s) = 7.4(0.855) = 6.3 t.p.h.

Weight of water in feed (W_w) = 7.4(0.145) = 1.1 t.p.h.

Weight of water evaporated (W_e) = (Fig. 13) 230 lb. per wet ton = 7.4(230) = 1,700 lb.



Enter chart on diagonal representing percentage of moisture in feed, follow diagonal to intersection with ordinate representing moisture in product and read on left-hand scale pounds of water to be evaporated per ton of wet feed.

FIG. 13. Weight of water evaporated per ton of wet feed from a given inlet to a given outlet moisture percentage (*after Ruggles-Coles Eng. Co.*).

Specific heat (h_s) of concentrate from Kopp's law (Art. 1): Assuming concentrate assayed 58% Zn, the percentage of sphalerite in it is 58/0.67 = 86.7%; quartz, 13.3%. Sp. ht. of sphalerite = (6.2 + 6.2)/97 = 0.13. Sp. ht. of quartz = (3.8 + 2 × 4)/(28 + 32) = 0.20. Sp. ht. of concentrate = 0.87(0.13) + 0.13(0.20) = 0.14.

$$
\begin{aligned}
H_s &= 6.3(2{,}000)(0.14)(212 - 50) &&= 286{,}000 \text{ B.t.u.}\\
H_w &= 1.1(2{,}000)(212 - 50) &&= 356{,}000\\
H_e &= 1{,}700(970) &&= 1{,}650{,}000\\
&\text{Total} \ldots\ldots\ldots\ldots &&\ 2{,}292{,}000 \text{ B.t.u.}\\
H_f &= 39(138{,}000) &&= 5{,}382{,}000 \text{ B.t.u.}\\
E &= 229/538 &&= 42.6\%
\end{aligned}
$$

This method of calculation is a rough approximation only. Its value, if any, is for comparison of different machines when the same assumptions are made in all cases as to temperatures. Error is greater the drier the discharged material, because of the degree of superheat necessary to drive off thin-film moisture. For this reason estimation of the quantity ($H_s + H_w + H_e$) from Table 5 is justified in efficiency calculations generally, even though the item H_s in the total will be high for metallic concentrates.

a Based on feed temperature of 60° F. and discharge at 212° F.; specific heat, 0.21.

Heat losses are caused by imperfect combustion, radiation from the structure, leakage of gas, and heat in the exit flue gas and in the discharged solid. Efficiencies of operating driers in ore-dressing plants (Tables 2 and 3) indciate that total losses range from 25 to

60%, with the average expectable loss between 40 and 50% in single-shell rotary driers. No accurate breakdown is possible. Table 6 can be used to estimate radiation losses, from which the possible economies flowing from insulation may be judged. Metal extending from the heating zone through an insulated covering causes surprisingly large losses, even when only a bolt. Leakage loss may amount to 10 or 20% of the sum of the useful

Table 6. Heat loss by radiation from drier walls (*After Buck, 29 CME 626*)

heat and the radiation loss; it should, therefore, be guarded against by making all seals as effective as possible. Flue-gas losses are due to the sensible heat in these gases above that required to prevent condensation in the drying zone. They depend, therefore, on both the weight and temperature of the flue gases. Generally the loss is inversely proportional to the percentage of saturation and directly proportional to the rise in temperature of the EXCESS AIR (air above that required for combustion). The relationships between these quantities are such that, with saturated gas leaving, the loss passes through a maximum at an exit temperature of about 110° F. Since this temperature is lower than must ordinarily be maintained to prevent condensation, except when the humidity of the exit gases is low, it follows that minimum loss of heat through the flue will correspond to relatively high temperatures coupled with a high percentage of saturation. Losses of sensible heat in the exit solids and increased radiation losses militate against carrying this conclusion into practice. Usual exit temperatures of gases in ore driers are in the range of 100° to 200° F.; the solids leave at 150° to upward of 300°, according to the extent of drying.

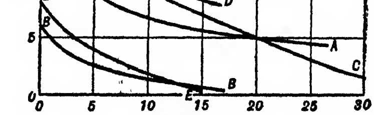

FIG. 14. Time required for drying in continuous rotary driers (from commercial operations).

Capacity of a drier is not expressible in any useful general form related to size of machine. The basic element in capacity is time-factor. Some rough data on time-factors are presented in Fig. 14. No coefficients of rate, universally applicable, have been established, although the parallelism of the curves in Fig. 14 indicates some promise for such a coefficient for the early stages in the case of relatively nonporous materials, *i.e.*, those in which surface moisture predominates. The porous materials (curves *C* and *E*), which contained, presumably, the most internal moisture, are remarkable for their maintenance of higher rates than the others; this is not improbably due to friability in the rotary driers used. In general, sized material dries faster than unsized, coarse faster than fine, nonporous faster than porous.

Operating costs are extremely variable. Depreciation, fuel, power, maintenance, and labor are the chief items. Different relative humidities and different altitudes cause different power and heat requirements, hence correction for these factors must be made in comparing and estimating costs. Fuel and fuel-handling charges are rarely the same even for identical driers on the same material. Power consumption varies with the material and the type of drier. Maintenance varies with the design and construction of the drier, particularly as to internal and moving parts, and with the abrasiveness and other physical and chemical properties of the material and its water content. Depreciation is about 10%. Table 7 gives reasonably typical costs for operations.

Table 7. Operating costs of driers

Material	Zinc conc.	Lead conc.	Coal, 1 1/2-in.	Sand	Washed clay	Zinc conc.	Molybdenum conc.
Type of drier *a*	SS, DH	SS, DH	DS, SD	DS, SD	TT, IH	RH	RH
Moisture, %: Original	13.8	14.3	9.8	6.2	24.3	14.5	16
Final	4.2	4.8	1.2	0.6	0.8	6.0	2.5
Tons per month	2,210	2,008	2,030	9,560	792	2,736	496
Hours operated per mo.	408	442	228	352	212	568	442
Costs, dollars per ton:							
Fuel	0.082	0.073	0.052	0.031	0.204	0.108	0.119

a DH, direct-heat; DS, double-shell; IH, indirect-heat; SD, semidirect-heat; SS, single-shell; RH, rabbled-hearth; TT, tube-type.

6. DESIGN OF DRIERS

Driers are designed, as to both mechanical and thermal features, by a method of cut-and-try which disguises the baldest empiricism under a cloak of seeming fundamental attack.

Elements of design are (*a*) heat supply, (*b*) heat transfer, (*c*) rate of evaporation, and (*d*) transport of feed and products.

Heat supply. Theoretical total heat is estimated for the given conditions from Table 5 or, with an appearance only of greater accuracy, by calculation (see ***Efficiency***, Art. 5) based on a determination of the mean specific heat of the material, and a guess or a laboratory test (see ***Rate of Evaporation*** below) as to the temperature of evaporation. Total heat necessary is then estimated on the basis of another guess as to probable heat losses. Since these cannot be broken down and estimated in detail, the usual method is to divide theoretical heat by an estimated over-all efficiency (Art. 5) expressed as a decimal fraction.

All heat to perform the estimated computed heating duty must be supplied by gas passing around and through the heating zone. The heat balance equation is

$$W_G h_g (t_I - t_E) = \text{Theoretical heat} + \text{heat loss}$$

in which W_G = total weight of gas required in lb., h_g = specific heat of the gas (0.23, for air, is sufficiently accurate, since air predominates), and t_I and t_E are inlet and exit temperatures of the gases respectively. With this gas there will pass through the exit passages of the drier the vapor of the evaporated water. The DEGREE OF SATURATION may be determined by adding to the evaporated water the water entering with the inlet air. Compare the ratio of total pounds of water in exit gas to total pounds of dry air therein with the column headed "Ratio, vapor/air" in Table 1. If the corresponding temperature in the table is well below the exit temperature, no precipitation need be feared.

Volume of gas. To determine the volume of gas to be handled by the blower, take the reciprocal of the corresponding value in the column headed "Weight in lb. per cu. ft. of saturated mixture" and multiply by the ratio $(t_E + 491)/(t_t + 491)$ where t_t is the tabular temperature corresponding to saturation, as above.

Velocity of air leaving the drier shell should not exceed 300 to 400 ft. per min. if dust loss is an important consideration. If a drier, calculated as above, shows greater velocity than this, and dust loss must be prevented, higher initial and lower final temperatures should be investigated. If such change in conditions does not reduce velocity sufficiently, a dust collector is probably the cheapest method of overcoming the difficulty.

Amount of fuel required is determined by dividing the total heat requirement ($H_s + H_w + H_e + \ldots$) by the heating value per pound of the fuel that is to be used. See Table 8.

C. O. Bartlett & Snow estimate the consumption of 13,000-B.t.u. coal as 1 lb. per 5 lb. of moisture evaporated in an exposed-shell direct-heat revolving drier, 1 lb. per 6.5 lb. of moisture in an enclosed-shell indirect-direct heat machine, and 1 lb. per 8 lb. of moisture in the enclosed-shell, indirect-direct heat, multi-compartment machine, when the final moisture content required is not below 3 or 4%. See also Tables 2 and 3.

Table 8. Approximate heating value of various fuels

Fuel	B.t.u. per pound
Anthracite......	12,000 to 14,000
Bituminous.....	10,000 to 15,000
Lignite.........	6,000 to 12,000
Air-dried peat...	5,000 to 9,000
Dry wood......	8,000 to 9,000
Fuel oil........	18,000 to 19,000

Temperature. When no limits are set by the requirements of the material itself, the attempt should be to make the temperature drop of the gases in passing through the drying zone as great as possible. The temperature limit is then imposed by the amount of heat that the drier shell itself can stand. The strength of steel plate reaches a maximum at about 600° F. and falls very rapidly at higher temperatures until at about 660° it is the same as at ordinary temperatures. At 1,000° the strength is only 40% of maximum, at about 1,200° F. the plate becomes dull red and hereabout the susceptibility to corrosion increases greatly. Hence the temperature of the incoming gas should never be as high as this unless the gas-inlet end of the shell is protected by very moist, cold ore, and even with this protection the shell should not be called upon to support any great load at the heated portion.

High inlet temperatures with direct-heat driers almost invariably result in high exit temperatures, hence if large temperature drop is to be attempted, the drier should be of the semi-direct type, with the hot gas entering under the feed-inlet end.

The lower temperature limit may be anything desired, except that it must be borne in mind that the volume of gas necessary to carry the heat to effect evaporation will be very great when the inlet temperature is low, that as a result the heat loss in the outlet gases will probably be greater than when a smaller volume of gas at higher temperature is used, that the power required to move the larger volume of gas will be greater, and that dust loss will be increased. On the contrary, radiation loss will be less and the life of the drier shell will be longer with low inlet temperature. (See *Heat losses,* Art. 5.)

Combustion structure. Firebox in rotary driers is usually placed directly at the end of the shell, so that furnace design is relatively simple. Countercurrent flow of gas and material is commonly used in single-shell direct-heat machines in order to utilize the sheet of wet material at the feed end to knock down dust, and also to prevent checking of

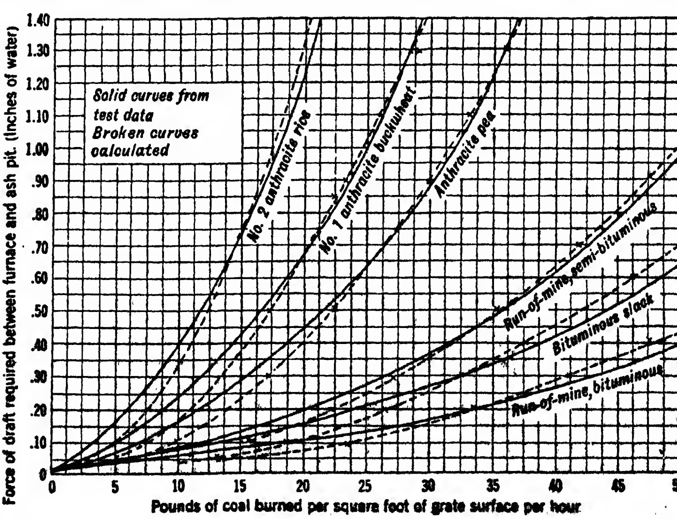

FIG. 15. Size of grate required for different kinds of fuels (*after Lucke, Engineering Thermodynamics*).

combustion by the cold feed. Countercurrent flow is necessary when material is to be dried to a low moisture content. It has the disadvantage that the discharging solid is subjected to maximum temperatures and carries away much heat. Double-shell machines are usually fired from the feed end, since this does not involve direct contact of burning gases with cold wet feed and yet does make for maximum heat flow by reason of the large temperature difference prevailing here. Forced draft, usually by exhauster fans, is almost universal; suitable flues and dampers are normally provided to permit the desired apportioning of air to the burning zone and to the combustion gases. Use of a pressure fan as well as an exhauster makes it possible to maintain substantially atmospheric pressure in the gas system, thus minimizing leakage. Fig. 15 gives data for estimate of grate areas.

Firebox in tower driers is always at the bottom, *i.e.*, the arrangement is counterflow.

Heating arrangement for hearth driers is much more complicated than for shaft types. The basic requirement is a checkerwork arranged for maximum absorption of heat from the flue gases, and for maximum radiation of heat to the underside of the hearth plates. This is a special problem for which solution should not be attempted without reference to works dealing especially with furnace design.

Heat transfer. For general discussion of the problem see Art. 1. In hearth driers provision for transfer to the hearth is a matter of furnace design (see preceding paragraph). Transfer to the solid is principally by conduction. This is slow through quiescent gas, such as in the pores of a bed; hence the bed should be continually turned to bring all solid particles repeatedly in contact with the hearth plates. Practice indicates that the best bed thickness for flotation concentrate is from 3 to 4 in., but this is a compromise between requirements for evaporation and those for heating.

In shaft driers all heat is brought to the solid through the medium of hot gases. In direct heating the essential requirement is direct contact of particle with gas. This is attained by dropping the material through the gas stream; the aim of the designer is to make the contacts as frequent and long-lived as possible. In tower driers this is accomplished by frequent stoppage of the stream by shelves or perforated plates, which also serve to increase relative gas-particle velocities (see Art. 3) as the two stream through the constricted throats in opposite directions. In rotary driers showering is effected by lifting the solid on lifter shelves attached to the interior of the shell. These should be so placed as to lift the solid as high as possible before beginning to discharge, and should be of such depth as to aid in effecting individual-particle discharge. When material is granular and tends to fall in masses the lifters should be of small capacity and closely spaced, but this expedient is not applicable with material that cakes; with such material larger pockets, with heavy chains in the bottom (see Sec. 18, Art. 14) may be needed to prevent entire loss of lifting capacity.

Rate of evaporation. For governing factors see Art. 1. Laboratory tests to determine time-factor are substantially useless except on a relative basis, *i.e.*, a known and an unknown heated under the same conditions, with an attempt to simulate, as much as possible, conditions in an actual drier of the type proposed. Such tests are useful principally, however, to indicate caking tendencies and to classify the proposed drying as generally quick or the reverse, whereupon an estimate of time is made from experience.

Transport. Once the question of drying time is settled, the proper size of cylinder for a rotary drier can be determined as follows: If the drying time is between 20 and 30 min., it is usual to make the volume of the shell (V) five times the volume of material in it at any one time, or $V = 5tTc/24$, in which t = drying time in hours, T = tons feed per 24 hr., and c = cu. ft. of feed per ton. The diameter d and length l of the shell may be found from V through the relation, ordinarily prevailing, that $l = 7.5d$, from which $V = 6d^3$ (approx.). This value of d must be such as to accommodate the minimum gas velocity that will be required.

Usual commercial cylinder diameters are 3 to 12 ft. (in 1-ft. steps) and the usual corresponding lengths are the nearest even 5-ft. multiple to 7.5-times the diameter.

Slope and speed (r.p.m.) may next be settled from the relation $l = tnsd[d/2 + \sin(\alpha - 90)]$, where l, t, and d have the significance already assigned, n = r.p.m., s = slope in ft. per ft., and α = the average angle, reckoned in the direction of revolution, from the bottom of the shell to the point where the lifters discharge. With radial lifters, α may be taken as 112°, with U-shaped lifters at 135°. The usual speed ranges from 60 to 100 f.p.m. peripheral, the higher figure corresponding to the larger diameters; the limit is primarily structural. The usual slope is 1 : 24. With α fixed, setting either n or s obviously sets the other.

Costs of installation (approximate, 1938) are given in Tables 2 and 3. Manufacturer's prices on iron and steel parts furnished range from 8¢ to 27¢ per lb., the lower prices corresponding to the simpler types. Installation of some of the lower priced types,

e.g., brick enclosure of a revolving shell, may make the total installed cost the highest. Installed cost per unit of capacity is lower the larger the unit. Cost of dust-collection equipment and of gas or oil burners and stokers will be additional to the costs given.

Average prices, weights, and recommended power installation for rotating the shell, from four manufacturers of similar types of single-shell, direct-heat driers, are given in Table 9. The factory prices do not include motors, power transmission equipment, or brick.

Table 9. Prices of direct-heat rotary driers (1938)

Size of shell, ft.	Price, f.o.b. factory	Shipping weight, lb.	Installed hp. for rotation
3×30	$1,560	12,600	5
4×40	1,990	18,700	7
5×50	3,180	33,200	12
6×60	5,050	61,000	20
7×75	7,950	92,000	30

SECTION 18

STORAGE AND MILL TRANSPORT

STORAGE

REVISED BY

E. J. TOURNIER, ROBINS CONVEYORS, INC.

AND

E. K. JUDD, MINING ENGINEER, NEW YORK, N. Y.

1. INTRODUCTION

Necessity for storage arises from the fact that different parts of the operation of mining and milling ores are performed at different rates, some are intermittent and others continuous, some are subject to frequent interruption for repairs and others are essentially batch operations, so that unless reservoirs for material are provided between the succeeding different steps the whole operation is rendered spasmodic and, consequently, uneconomical. Storage bins are the best means of distributing the product of a crusher of high capacity to several machines of low capacity, as, for instance, jaw-crusher product to stamps or finely crushed products to a battery of screens and, in the same way, crushing-plant product to grinding mills. Large bins are desirable because they allow mill feed to be well mixed and tend toward uniformity. When a bin is fed with undersize from run-of-mine ore and crushed oversize, these products should be delivered at the same point in the bin or segregation of sizes, and probably, of values, will be unavoidable in drawing.

Surge bins, *i.e.*, small bins of 5- to 50-ton capacity, are commonly placed ahead of fine crushers, screens, or any other machines, the efficient operation of which is dependent upon uniform feed rate. They should be provided with feeders especially designed to deliver at a constant rate by weight (Art. 23), irrespective of the head of crushed material on the discharge gate. Wet-pulp storage is secured in tanks with agitating means (Sec. 12, Art. 7); such storage is provided when time is needed for a chemical reaction; it may be made to serve also, however, to equalize pulp flow.

Amount of storage necessary is ordinarily considered and expressed in terms of the daily tonnage capacity of the plant. It depends on the equipment of the plant as a whole, its method of operation, and the frequency and duration of regular and unexpected shut-

downs of individual units. At many mines ore can be taken out during only a part of each day on account of the necessity for getting supplies into the mine through the same opening; on the other hand, concentrating mills are most efficient when continuously operated, because of the unavoidable tailing losses in shutting down and starting up the machinery. Mine operations are more subject to unexpected interruption than mill operations, and coarse-crushing machines are more subject to clogging and breakage than fine crushers, grinding mills, and concentrating machinery. Consequently both the mine and the coarse-crushing plant should have greater hourly capacity than the fine-crushing, grinding, and concentrating units, and storage reservoirs should be provided between them and the mill proper. Ordinary mine shutdowns, expected or unexpected, will not generally exceed 24 hours' duration, and ordinary coarse-crushing plant repairs can be made within an equal period, if a good supply of repair parts is kept on hand. Therefore, if a 24-hour supply of ore that has passed the coarse-crushing plant is kept in reserve ahead of the mill proper, the mill can be kept running independently of shutdowns of less than 24 hours' duration in mine and coarse-crushing plant. It is wise to provide for a similar shutdown of the mill. In order to do this the reservoir between coarse-crushing plant and mill must contain at all times unfilled space capable of holding a day's tonnage from the mine.

Ore-storage reservoirs ordinarily are not of such shape that they can be filled or emptied completely without shoveling and, since to incur the expense of shoveling would to a large extent defeat the purpose of storage, additional storage room must be provided so that a day's tonnage may be *drawn* into the mill proper, in case the ore supply stops for a day, and the same tonnage may be discharged into the partly filled bin in the usual way, in case the mill ceases to draw. The amount of space that must be provided for undrawable material and the additional amount that cannot be loaded without shoveling depend upon the shape of the bin, the method of drawing, and the method of loading. In ordinary rectangular bins it will amount to something more than that necessary to hold a day's supply of ore. Hence a bin, to fulfill the conditions set down, must have a volume equivalent to something more than 3 days' ore supply and should be run about half full to provide against unexpected shutdowns at either end of the plant. Similar methods of analysis are applicable at other points in the path of the ore. The average of present-day practice is about 3 days' storage capacity; individual figures range from 1 hr. to 16 days (Sec. 20, Table 13). These figures in many cases include both coarse- and fine-ore storage, *i.e.*, between mine and coarse-crushing plant and between coarse-crushing plant and mill. Peculiar conditions, such as long and uncertain haul from mine to mill, great variety in character of ores treated in a given mill, and the like, give rise to special storage problems, resulting in the provision of storage in excess of the average.

Methods of storage. Considerable storage is usually provided in the mine itself, in stopes and skip pockets, thus allowing actual breakage of ground and some underground haulage to proceed even after available surface storage space has been exhausted. When for any reason an extended mill shutdown is incurred and it is particularly desirable that underground breaking be carried forward in excess of the underground storage capacity, stockpiles may be built on the surface in a location convenient both for building and subsequent excavation. This may be the solution when extensive exploration work is carried forward during the building of a mill. STOCKPILING OR GROUND STORAGE is resorted to when winter conditions are such as to prohibit excavation in open-cut mines and the year's mill supply must be taken out in the open months; or when transportation is stopped during the winter, though mining can be carried forward, as is the case in some of the Lake Superior iron mines; or when the product of a milling operation is bulky, as in the case of coal or crushed stone, and the demand is seasonal and in excess of mine or mill capacity. RAILROAD CARS may form a considerable part of the storage system; particularly when the haul from mine to mill is long. BINS are the commonest type of ore-storage reservoir. They are built in several different shapes, of masonry, concrete, steel, and wood. Shape is determined primarily by the service the bin is to render, secondarily by the materials of construction. Wooden bins are ordinarily cheapest in first cost and easiest to construct. Masonry and concrete bins have the longest life. Steel bins are lightest and occupy the least space for a given capacity. They can be built in shapes that better withstand the pressure of the filling material and they maintain their original rigidity much better than wooden bins. Fire hazard is great in wooden bins, and, if the ore is wet, the bottom rots rapidly unless well ventilated. If bins are loaded by trains they are subjected to much vibration and heavy racking strains. Under these conditions the tension rods in wooden bins must be continually watched and tightened; yet the bins will, in time, become so rickety as to be dangerous. The large sticks of timber needed in high and wide wooden bins are becoming so scarce and expensive that the cost of such bins approaches more and more closely that of the other types.

2. SHAPE OF BIN

Common shapes are shown in Fig. 1.

Flat-bottom bin (Type *a*) is suited to timber, steel, or concrete construction. It is the cheapest type of all to build and in it the ore forms its own bottom so that there is no wear on the bin bottom in drawing.

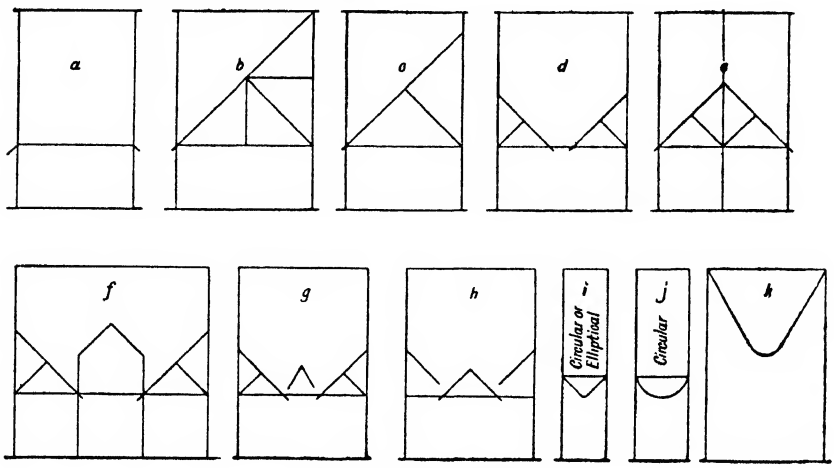

FIG. 1. Typical bin shapes.

Of 50 mill bins reported in 1939 (*Q*), 28 had flat bottoms. Of 66 bins (all flat-bottomed) in the N. J. ZINC Co. mill, 44 are of steel, 21 of wood, and 1 of concrete.

DISADVANTAGES are (1) that the bin cannot be emptied without shoveling, and (2) that the angle of repose of material in the dead part of the bin may be as great as 60° when the ore contains a large amount of fines and an appreciable percentage of moisture, so that the free-running (LIVE) bin capacity is much less than in a sloping-bottom bin of the same horizontal cross-section. A flat-bottom bin is not suitable for service where material must be treated in lots, as in custom plants. Flat bottoms are frequently filled with waste, particularly if the ore is high-grade, so that interest will not be lost on high-grade ore locked up in bottom filling. But if the mill is working to capacity in any case, treatment of material that would otherwise form bin filling leaves a corresponding amount "locked up" in the mine. The loss with high-grade ore by passage of fine material down into the waste filling may well exceed an actual interest loss. If the dead space in a flat bin is filled with ore, this ore forms a reserve if the emergency justifies shoveling, but after the bin has been thus emptied no ore can be drawn therefrom until an amount substantially equal to that shoveled out has been replaced. Anthracite coal should not be handled through flat-bottom bins because of breakage of coal in the dead space by pressure of the coal above.

Slanting-bottom bins. Type *b*, Fig. 1, is typical of small bins that it is desired to empty frequently, such as shipping bins and concentrate bins. Type *c* is perhaps the commonest around milling plants. It is suitable for distributing to and feeding rolls, ball mills, gravity stamps, or other multiple units. Completeness of discharge depends upon the spacing of gates lengthwise of the bin and the bottom slope. The minimum slope upon which material will slide depends upon the kind of material, size of pieces, percentage of fines, percentage of moisture, and surface of bin bottom. Minimum sliding angles for dry materials containing only a small percentage of fines, on steel-lined bottom, are given in Table 3. The slope of the bin bottom should be at least 2°, better 5°, greater than these figures. In general, 45° is sufficient to move any ordinary ore (besides favoring the design of joints and members) but sticky ores may need 50° to 55°; however, too steep a slope may do more harm than good, by wedging and compressing the ore as it approaches the outlets. Fine, wet, and sticky ores sometimes move less freely on a smooth (steel-lined) than on a rough plank bottom at the same slope. Designers with the Southwestern Engineering Co. (*139 #1 J 66*) recommend the shape shown in Fig. 2, in which *a* indicates the surface of repose; the floor, at 45° for convenience in framing, occupies the position and is supported in the manner shown. The residual

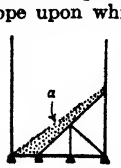

FIG. 2. Slant-bottom bin with ore-layer protection.

wedge of ore avoids abrasion on the bottom. Type *e*, Fig. 1, which is a modification of type *c*, is rarely used on coarse feeds, but is sometimes used for fine-ore and shipping bins. It saves timber for a given capacity, and is useful when delivery on two sides can be utilized.

Hopper-bottom bin (type *d*, Fig. 1) gives the highest percentage of gravity delivery of any of the first five types. Discharge must ordinarily be collected and transported to the following machines by a conveyor or cars. This type is particularly suitable for long bins of large capacity. When complete gravity discharge from a rectangular bin is desired, a common expedient is to add crosswise false bottoms diverging upward from both sides of the discharge opening. In such construction, it should be remembered, however, that the slope of the valley between two intersecting inclined bottoms is considerably less than that of either bottom and may cause much ore to hang back. For example, if two planes, both pitching 45°, intersect at right angles, measured horizontally, the slope of their intersection will be only 35 $^1/_4$°. Types *f*, *g*, and *h* are typical coal bins. They give a relatively high percentage of discharge by gravity, are shallow and do not cause the coal to crush, yet are of good capacity per foot of length. All of these types, while best adapted to timber construction, may be built of steel or reinforced concrete.

Steel bins. Forms *i*, *j*, and *k* are particularly adapted to steel construction, although both *i* and *j* have been built with reinforced concrete. Wood-stave circular tanks with flat bottoms have been used for both coarse-ore and concentrate-storage bins, but the gravity-discharge percentage is low. Circular and elliptical shapes are particularly suitable for deep bins, since the metal of the walls is under tensile rather than bending stresses and the pressure on the bottom is relatively small. Such bins with conical bottoms will draw practically clean, if the ore is not too moist. For complete gravity discharge of a given ore, the slope of the conical bottom must be considerably greater than would be necessary on the sloping bottom of a rectangular bin, similarly lined. If, for example, a rectangular bin requires a bottom slope of 45°, that of a conical bottom should be at least 55° for the same ore (*136 J 223*). Stress in the hemispherical bottom *j* is less for a given loading than in a conical bottom, hence lighter material can be used, but the gravity drawoff is not so complete. When a number of such bins are necessary, as in cement storage, they are placed close together, and the space between is floored and utilized for additional storage (see Sec. 3A, Fig. 15).

Suspension bunker (Fig. 1, item *k*) puts all of the wall in tension and can be extended indefinitely at right angles to the section shown without any increase in weight of section, and without the loss in storage capacity that is attendant upon placing circular or elliptical bins side by side. It has been used extensively in fuel storage and handling plants; its use in milling work is increasing. It warrants investigation when the amount of storage needed per foot of length of mill is within the limits of its capacity. See Sec. 2, Figs. 20, 24.

Segregation within a bin occurs unavoidably when the material contains mixed sizes, coarse particles tending to roll outward on the cones or ridges of the more sluggish finer material while the bin is being either filled or discharged. Such segregation affects the weight per unit volume of material issuing from the bin, by amounts which may reach 20 to 30%, and usually (especially in the case of brittle ores) affects also the assay; both effects are detrimental to many milling and metallurgical operations. A mixture of coarse and fine is heaviest, all-fines is next, and all-coarse is lightest. Means for regulating bin discharge by weight are described in Art. 23. Segregation is least apt to occur (*a*) when material is all finer than about $^1/_4$-in.; (*b*) when discharge is continuous at about the feed rate; (*c*) when the bin is so shaped as to avoid accumulation and packing of fines in corners and valleys, and to prevent bridging of damp or of de-aerated dry material over the discharge openings. None of the numerous mechanical devices intended to correct this latter difficulty is wholly satisfactory; jets of compressed air playing into the space adjacent to the bin outlet is one of the best means for preventing bridging of fine ore, but is ineffective with coarse material. Segregation due to irregular discharge may be diminished by providing hopper bottoms with unusually steep slopes (say 60°); a square bin with two adjoining vertical and two sloping walls, discharging at one corner, has some advantages, although it is more expensive per unit of capacity than a hopper with a central opening. A flat-bottom bin with closely spaced floor outlets discharging simultaneously or in rotation also reduces the opportunity for segregation, but it requires auxiliary collecting conveyors. Segregation of feed into a bin may be partially offset by providing aprons to transform a single cone into a ring, or a single ridge into two ridges, so that some of the coarse particles will roll toward the center of the bin.

3. DESIGN OF BINS

This problem involves the usual elements of determination of loads and design of members to bear them. Wear due to passage of material through the bin must be anticipated and structural members guarded against blows and abrasion that would weaken them. Determination of loads is by the same methods that are employed in the design of retaining walls. Many formulas and graphical methods have been proposed. Those

by Rankine, Coulomb, and Cain, summarized by Ketchum (*Design of walls, bins, and grain elevators*), are best known and should be investigated in the case of large and elaborate structures. The graphical method given below, based on Coulomb's theory of "maximum wedge thrust," is satisfactory for most cases.

Preliminary considerations are (*a*) required capacity in tons; (*b*) corresponding cubical content based on weight of filling (Table 1); space that cannot be loaded nor emptied

Table 1. Weights of bin-filling materials

Material	Condition	Weight per cubic foot, pounds
Ashes, coal	Dry, packed	40 to 45
Barite	Broken, loose	180
Cement	Clinker, broken	95
Cement	Ground, loose	50 to 56
Clay	Moist	120
Coal	Any size, broken, loose	45 to 60
Coke	Loose	23 to 32
Earth	Slightly moist	70 to 90
Earth	Soft, flowing mud	104 to 120
Gravel	Dry	120
Iron ore (hematite)	Loose	150
Lime, quick	Ground, shaken	64
Phosphate, rock	Ground, loose	75
Quartz	Pulverized, loose	90
Quartz	Pulverized, well shaken	105
Sand	Dry, loose, even sizes	90 to 106
Sand	Dry, loose, uneven-sized grains	117
Sand	Even sizes, voids full of water	118 to 120
Slag	Granulated	53 to 60
Slag	Bank, crushed	80
Stone, average	Crushed	95 to 100
Stone, heavy (trap, greenstone)	Crushed, loose	107

Note. Volume of broken rock in dumps and bins is from 1.6 to 1.9 times volume in place.

Table 2. Angle of repose of bin fillings = ϕ

Material	Condition	Angle ϕ, degrees
Anthracite	Broken, loose	27
Ashes	Dry	40 to 45
Cement	Dry	40
Cement	95% through 20-m. screen	37.5
Cement	96% through 100-m. screen, piled	*a*
Cement, clinker	Through 1 1/2-in. screen	33

a With grain.
b Angles are increased by presence of large amount of fine, damp material. Range of figures, where given, represents limits of authorities.

Lateral pressure against bin walls, although not accurately computable on hydrostatic principles (due to internal friction and to friction against the wall), may be approximated by representing the contents of a bin as an EQUIVALENT LIQUID, of such specific gravity as will make allowance for internal friction. (Wall friction becomes an important factor only in deep, narrow bins, and is often neglected in design—see below.) C. O. Sandstrom (*45 CME 684*) offers the formula: $L = w(1 - \sin \phi)/(1 + \sin \phi)$, where L = weight per cu. ft. (or sp. gr.) of the equivalent liquid, w = that of the bin filling, ϕ = angle of repose of the filling. On this basis, weights of equivalent liquids for some common substances are given in Table 4. This approximation applies only to the vertical walls and not to the bottom of a bin.

Table 4. Equivalent-liquid weights of bin fillings (*Sandstrom*)

Graphical method of determining pressures on bin walls. If $ABCD$ (Fig. 3) represents a transverse section of a flat-bottomed bin, broken rock, when poured therein, along the center line, will come to rest with inclined surfaces BE and EC. Angle EBC is known as the angle of repose (ϕ). Its magnitude depends on the friction between the particles of material and is different with different substances, sizes, mixtures of sizes, and moisture content. (See Table 2, compiled from various sources.) A heap of ore with cross-section BEC will exert no pressure on walls AB and DC. Side pressures are all taken up within the pile of material itself. Herein lies one of the differences between such materials, known as semifluids, and true fluids. If bin $ABCD$ is charged level full, the mass of material will tend to rupture by sliding of the upper part over the lower along some plane such as BF, lying between AB and BE. The thrust of wedge AFB against wall AB is the pressure against the bin front, according to Coulomb's theory. This thrust is a maximum when BF bisects angle ABE. If wall AB is considered displaced a small distance to the left, wedge ABF will slide a small amount along BF and in coming to rest will exert a force P on AB that is the resultant of a force N, normal to the wall, and another, F, acting vertically downward in the plane of the wall. This latter force is due to friction between the material and the wall. The ratio F_1/N_1 is equal to the coefficient of friction of the filling on the bin wall. (See Table 3.) To determine P, consider a wedge of material having the section AFB and 1 ft. in thickness along the length of the bin, in equilibrium under the action of forces exerted by the wall AB and the

material lying to the right of BF. Lay off AN proportional to the weight of block AFB. The resultant of the reaction of the material to the right of BF on ABF acts in a direction inclined ϕ below the normal to BF. This will be $45 + \phi/2°$ below AF. Draw AX making angle FAX equal $45 + \phi/2°$. Through N draw NY so that angle θ is equal to the angle of friction ($\tan \theta = \mu$ = coefficient of friction) between the material and the bin wall. (See Table 3.) NJ is the total pressure in 1 ft. length of wall AB, in magnitude and direction. The point of application is K located $2h/3$ downward from A. Normal pressure N_1 is the horizontal component of $P_1(=NJ)$. Pressures on CD are the same. Total pressure on BC is the weight of block $ABCD$ and is uniformly distributed along BC. The distribution of pressure along wall $DC(=AB)$ is determined by placing $N_1 = 1/_2\overline{CL} \times h$, solving for CL and completing the triangle as shown. Unit pressure at any point along DC can then be read off directly.

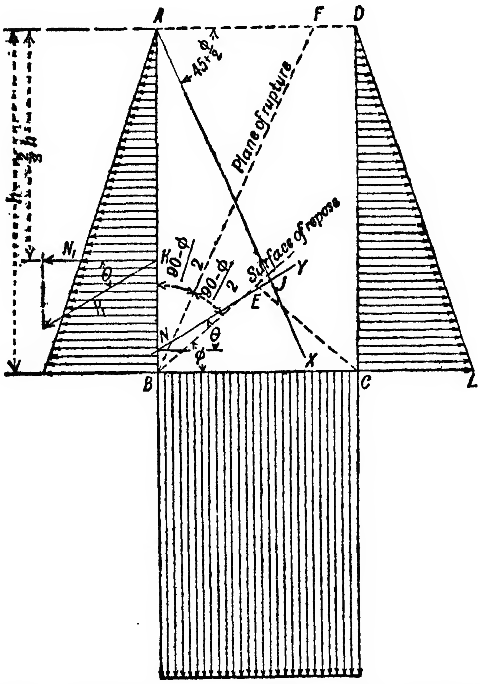

FIG. 3. Solution of stresses in flat-bottom bin, based on Coulomb's theory.

In a slanting-bottom bin (Fig. 4) take $\phi = 40°$, $h' = 8$ ft., breadth of bin = 12 ft., weight of bin filling = 100 lb. per cu. ft., and $\theta = 30°$. Solve for P_1 as described in the preceding paragraph. To determine P_2, draw $CN = RQ$, determine area DCN and lay off N_2 through the point of application, $2h'/3$ down from D. Through this point draw the line of action of P_2, making an angle $\theta(=30°)$ with N_2, then complete the triangle of forces. Consider block $ABCD$, weighing W, in equilibrium under the action of the forces P_1, P_2, W, and P_3, P_3 being the total reaction of the bottom to the load, unknown in magnitude and direction. W acts through the center of gravity of $ABCD$, located at T. To solve for the magnitude and direction of P_3, lay off TS to scale, equal and parallel to W; SV equal and parallel to P_1, and VU equal and parallel to P_2; UT, closing the force polygon, determines P_3 in magnitude and direction. The line of action of P_3 is determined as follows: Choose any point O so that angles between lines OT, OS, OU, and OV are as large as conveniently possible. Choose any point such as b on the line of action of P_1 and draw lines vo and so parallel to OV and OS, respectively. Produce so to intersect TS, produced if necessary. Through this intersection draw to parallel to OT. Produce vo to meet line of action of P_2. Through the intersection draw uo parallel to OU. Produce uo and to to intersection. Through this intersection draw ut parallel to UT; ut is the line of action of P_3. To determine N_3(= normal component of P_3), lay off P_3 along line ut from the point where ut cuts the bin bottom. Project this length onto a normal to the bin bottom through the same point and scale off N_3. To find the distribution of N_3 along the bin bottom, lay off the pressure trapezoid $BCaZ$ so that the area = N_3. Now $1/_2(BZ + Ca) \times BC = N_3$ (Eq. 1). If BC and Za were produced they must meet at Y on AD produced, then

$$Ca/BZ = YC/YB \qquad \text{(Eq. 2)}$$

Scale YC and YB and solve for Ca in Eq. 2. Substitute in Eq. 1 and solve for BZ. Lay off $\overline{BZ}$ and ΔYBZ. Lay off Ca parallel to BZ and scale off or solve by the preceding equations.

Ketchum gives another method for this solution in which friction between the walls and material is disregarded. In bin $ABCD$ (Fig. 5) the total normal pressure on wall AB is $P_1 = 1/_2wh^2 \dfrac{1 - \sin\phi}{1 + \sin\phi}$, acting through a point $2h/3$ below A, where w = weight of material in lb. per cu. ft. Similarly $P_2 = 1/_2wh'^2 \dfrac{1 - \sin\phi}{1 + \sin\phi}$. To find total pressure on BC, produce BC and AD to intersect at J. Calculate weight of wedge $ABJ = 1/_2\overline{AB} \times \overline{AJ} \times w = W$. This acts vertically downward through the center of gravity of triangle ABJ. Produce the line of action P_1 to intersect the line of action of W at K. Lay off KL to scale equal to W. Lay off LM equal and parallel to P. $MK = P_3$. Construct the normal component of $P_3 = N_3$. Construct ΔJBO so that area $= N_3$. CQ = unit pressure at point C. Area $BCQO$ = total normal pressure on the bottom per foot of length of bin. Lay off $CH = FG$. Complete the pressure triangle DCH. Area DCH = total normal pressure on CD. Note that the assumption of smooth walls results in larger values for the pressures on walls and bottom than does the preceding solution.

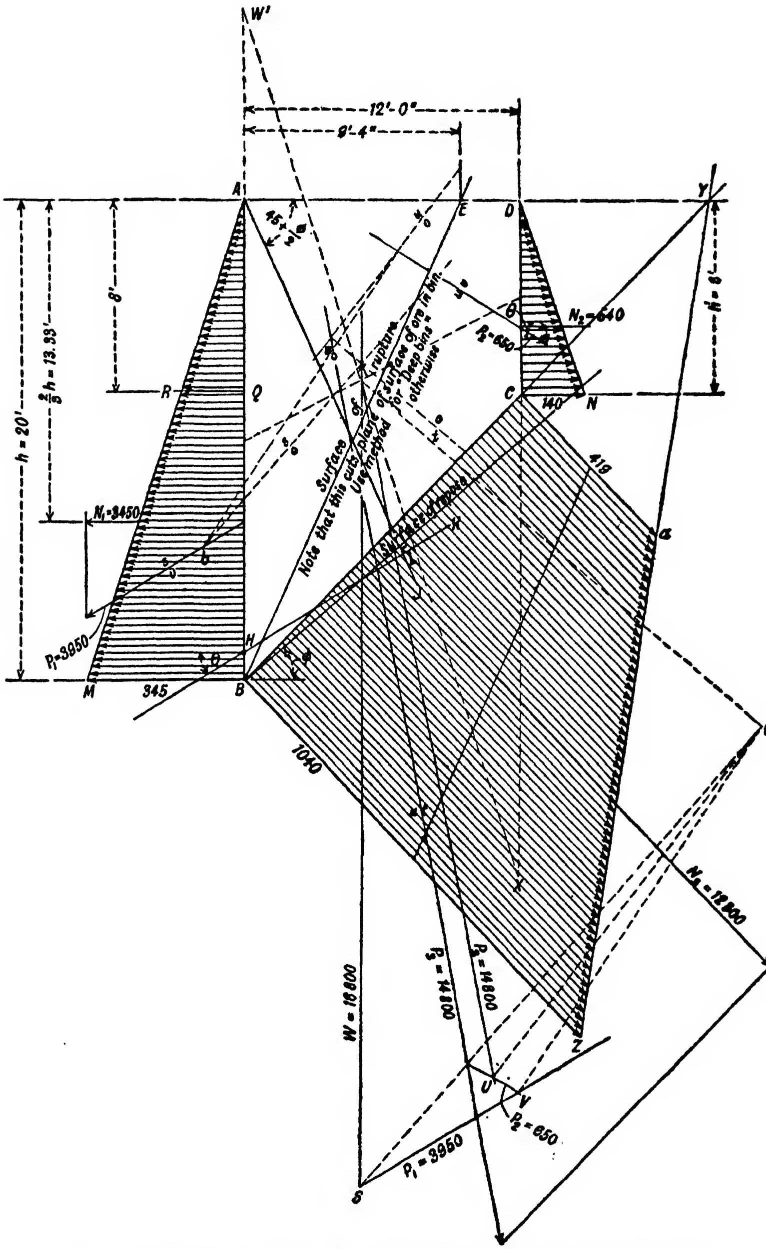

FIG. 4. Solution of stresses in slanting-bottom bin, based on Coulomb's theory.

Surcharged bin. Pressures on the walls of a surcharged bin are much greater than in one level full. Fig. 6 gives the pressure analysis for such a bin assumed surcharged at an angle equal to the angle of repose of the material ($= \phi$). Weight of filling = 100 lb. per cu. ft.; dimensions are shown; $\phi = 40°$. The resultant pressure on the bin wall for this condition is a maximum and is inclined parallel to the surface of the ore.

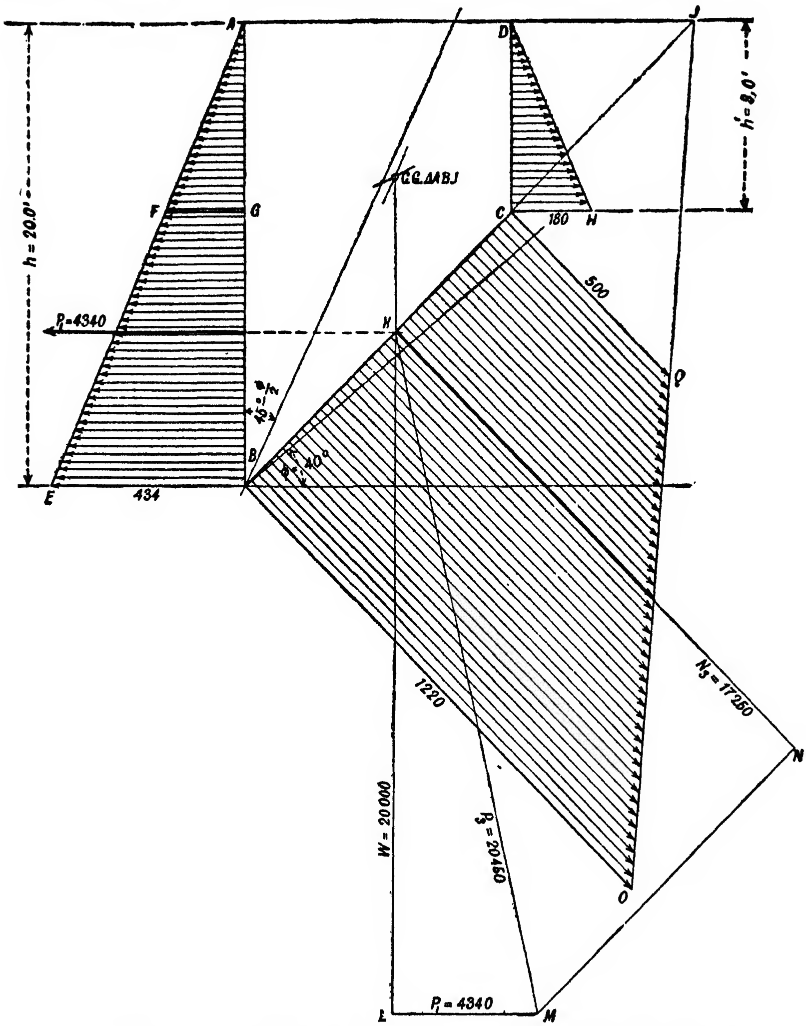

FIG. 5. Graphical solution for slanting-bottom bin, neglecting friction against walls.

TO DETERMINE THE PRESSURE AGAINST AB: Lay off BX parallel to AM. Draw AE perpendicular to BX and lay off AF so that angle $EAF = \theta$ = angle of friction between wall and filling. From F as a center with radius FA strike arc AG and draw the straight line AG. $P_1 = \Delta AGF \times w$. The point of application is $2h/3$ down from A. Lay off P_1 and the normal component N_1 in the usual fashion. Lay off the pressure triangle $ABH = N_1$. Lay off $CL = JK$ and complete the pressure diagram DCL. Area $\Delta DCL = N_2$. P_2 acts parallel to MD and is determined from N_2 as shown in Fig. 6. TOTAL PRESSURE ON BOTTOM may be calculated by assuming block $ABCDM$ as a rigid body in equilibrium under the action of the nonconcurrent forces $-P_1$, $-P_2$, W($=$ *area* $ABCDM \times w$), and P_3. The method of solution is as described for Fig. 4 and is shown in Fig. 6, taking the center of force polygon $SUQR$ at T. This assumption results in a value for P_3, in a bin of a given size, less than the value for P_3 in a bin level full, when calculated as in Fig. 5. FOR MAXIMUM PRESSURES ON BOTTOM, assume block

ABCDM in equilibrium under the nonconcurrent forces N_1, N_2, W, and P_3 and solve for P'_3 and N'_3, as in Fig. 4. (To determine the center of gravity of block *ABCDM*, determine the centers of gravity of *ABCD* (see Fig. 4) and *ADM* separately. Take moments around axes at right angles, for instance, lines *HB* and *DC*, and solve for the resultant moment arms.) To DETERMINE DISTRIBUTION OF NORMAL

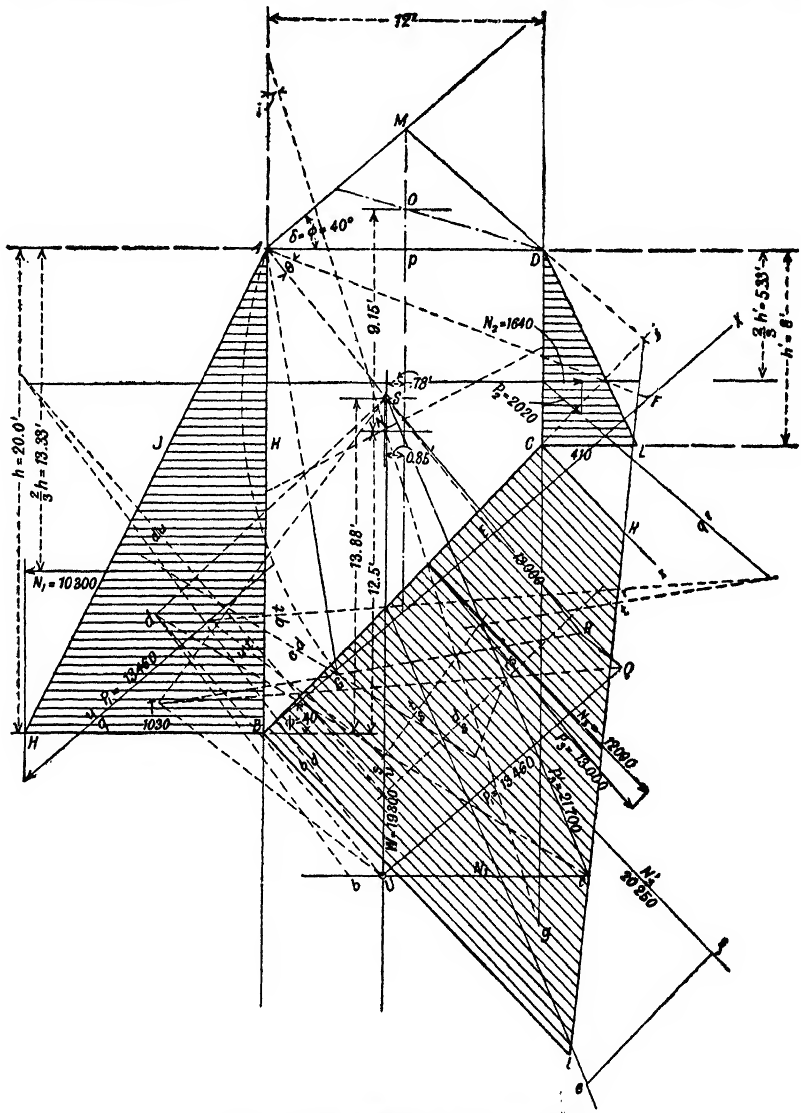

FIG. 6. Graphical solution for surcharged bin.

PRESSURE ON BOTTOM, produce *MD* and *BC* to intersect at *j*. Lay off the trapezoid *BCkl* to equal N'_3 as follows: $Bl = \dfrac{2N'_3}{BC\left(\dfrac{jC}{jB} + 1\right)}$. Lay off *Bl* to scale, draw *lj*. Point *k* is determined by the intersection of *Cx* (parallel to *Bl*) with *lj*. The bottom pressure may also be determined by assuming a block *ABjM* in equilibrium under action of forces W'' (= weight of this block), N_1 and P''_3, as in Fig. 5, and solving for P''_3, N''_3, and the pressure trapezoid as in that figure.

Deep bins. The preceding methods apply only to shallow bins, *i.e.*, those in which the plane of rupture cuts the surface of the filling material. In deep bins a large part of the vertical pressure is taken by the walls of the bin, which must, therefore, be designed to withstand the resulting compression. Either of two methods of solution is commonly used; both accord well with experimental results.

Janssen's method arrives at the equations:

$$V = \frac{wR}{k\mu'}\left(1 - e^{\frac{-k\mu'h}{R}}\right)$$

$$L = \frac{wR}{\mu'}\left(1 - e^{\frac{-k\mu'h}{R}}\right)$$

where V = vertical pressure in lb. per sq. ft. and L = lateral pressure in lb. per sq. ft. at any point on the bin walls; w = weight of filling material in lb. per cu. ft.; R = hydraulic radius of bin = area in sq. ft. ÷ perimeter in ft.; k = an experimental constant that can be approximated by the formula $k = \dfrac{1 - \sin\phi}{1 + \sin\phi}$ where ϕ = the angle of repose of the bin filling; $\mu' = \tan\theta$ = coefficient of friction of filling against bin wall (Table 3); h = depth in feet of the point investigated below the surface of the filling; e is the Napierian base.

Airy's method (*Proc. Inst. Civil Engrs.*, Vol. 131 [1897]) gives

$$P = \frac{wd(2h - d\tan x)(\tan x - \mu)}{2(1 - \mu\mu' + (\mu + \mu')\tan x)}$$

where P = total pressure on bin wall, d = breadth of bin, $\mu = \tan\phi$ = coefficient of internal friction of filling material, μ' = coefficient of friction of filling material on the bin wall, and x = angle that plane of rupture makes with horizontal = $45 - \phi/2$. P is a maximum when

$$\tan x = \sqrt{\left(\frac{2h}{d} + \frac{1 - \mu\mu'}{\mu + \mu'}\right)\left(\frac{1 + \mu^2}{\mu + \mu'}\right)} - \frac{1 - \mu\mu'}{\mu + \mu'}$$

hence the equation for $P_{max.}$ is

$$P_{max.} = \frac{wd^2}{2}\left[\frac{\sqrt{\frac{2h}{d}(\mu + \mu') + 1 - \mu\mu'} - \sqrt{1 + \mu^2}}{\mu + \mu'}\right]^2$$

and

$$L \text{ at any depth} = \frac{wd}{\mu + \mu'}\left[1 - \frac{\sqrt{1 + \mu^2}}{\sqrt{\frac{2h}{d}(\mu + \mu') + 1 - \mu\mu'}}\right]$$

V at any point $= L/k$.

Compression in bin walls at any depth y is given by *Ketchum* as

$$F = wR\left[y - \frac{R}{k\mu'}\left(1 - e^{\frac{-k\mu'y}{R}}\right)\right]$$

where F is the total compressive load in the plane of the wall per foot of length of bin and other factors are as defined above. When the height of the bin is more than twice the diameter (or breadth), this equation may be written without serious error,

$$F = wR\left(y - \frac{R}{k\mu'}\right)$$

Bins with conical bottom. In Fig. 7 to determine unit stresses T parallel to an element of the conical bottom across any section such as X–X, determine first the total vertical load W' acting at this section. In a shallow bin W' = entire weight of right cylinder of material whose base is the section X–X, plus the weight of the part of the bin below X–X and the contained material. In a deep bin $W' = \pi r^2 V$ plus the weight of bin and material below X–X. In either case $T = W' \csc s/2\pi r'$. In the deep bin the weight of bin material and filling below X–X may be so small in relation to the total pressure that $T = Vr' \csc s/2$ is a satisfactory approximation. Unit stress T' in the ring X–X in a shallow bin is $T' = r'V\left\{\dfrac{\sin^2(s/\phi)}{\sin^4 s\left(1 + \dfrac{\sin\phi}{\sin s}\right)^2}\right\}$; in a deep bin $T' = Lr'$. (*Ketchum.*)

Bins with spherical bottom. Stresses in the bottom are calculated as in conical-bottom bins. Referring to bin in Fig. 8, unit stress T tangent to the bin bottom at X and in a plane through the bin axis is $T = W'/2\pi r' \sin^2 s$ and for a deep bin this may be approximated as $T = \frac{1}{2}Vr'$. Tension in the ring cut by section X–X is $T' = \frac{1}{2}Vr'$. (*Ketchum.*)

Suspension bunkers. In Fig. 9 let S = sag in feet, l = $^1/_2$ of span in feet, C = capacity in cu. ft. per ft. of length, P = maximum pressure, located at B, w = weight of filling in lb. per cu. ft., V = vertical component of force exerted by the bunker on supports at

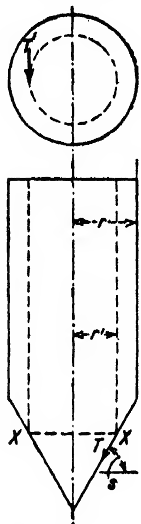

Fig. 7. Conical-bottom bin.

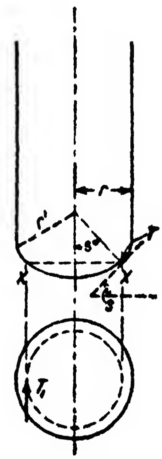

FIG. 8. Spherical-bottom bin.

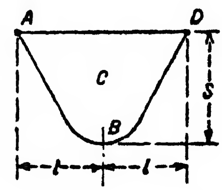

FIG. 9. Suspension bunker.

A and D, H = horizontal component of the same force, T = lb. maximum tension in plate per ft. of length of bin, L = length of curve AB. When the bin is level full, P = $1.25Sw$; $H = Cwl/3S$; $V = 5Slw/8$; $T = Cw\sqrt{^1/_4 + l^2/9S^2}$;

$$L = \frac{1}{60l^2}[y_0 + y_{10} + 4(y_1 + y_3 + y_5 + y_7 + y_9) + 2(y_2 + y_4 + y_6 + y_8)]$$

where $y = 4l^6 + 9S^2(2xl - x^2)^2$. Substitute for x values 0, $l/10$, $2l/10$, $3l/10$, etc., to obtain values for y_0, y_1, y_2, y_3, etc., respectively. Table 5 gives values of L for values of the ratio s/l ranging from $^1/_3$ to $^3/_2$.

Notes on design. With loads known, the design and spacing of members to carry them is done by the usual methods. LINING must be provided wherever moving ore comes in contact with the bin structure. Walls and slanting bottoms are lined with hard pine or hardwood planking set usually with the length parallel to the run of the ore, or with steel plate or old rails, discarded crusher plates, roll shells, ball-mill liners, and the like. Walls of the 4,000-ton, rectangular, steel bin at INSPIRATION main shaft (*119 J 477*) were protected by a curtain composed of discarded 1 $^3/_4$-in. steel rope. Hardest wear comes just around the gates; special, easily removable wearing surfaces should be provided at these points. Steel-plate linings often tend to work loose and curl up at corners and edges; this can be prevented by cover straps (battens) bolted or riveted through both lining and outside plates or floor boards; only vertical seams should be thus treated. TENSION RODS running through timber bins should be placed just above or just below a timber. Timbers directly under loading points may be protected by iron straps bent over the top and spiked on with a space of 1 to 2 in. between straps. Steel members may be protected by riveting to their upper surfaces steel plates 1 to 3 ft. wide on which ore will collect and form a cushion. When ore is allowed to form the bottom in flat-bottom bins, the discharge-chute liner plate should be projected 2 to 3 ft. into the bin to make discharge easier. It is well to make the dimensions of a bin such that stock lengths of planking will not have to be cut on the ground. A change of a few inches one way or another in dimensions will ordinarily accomplish this. Where possible lay end and partition PLANKING so that it forms a tie between front and rear posts of bent, in order to gain added stiffness.

Table 5. Length of one-half curve of suspension bunkers = L. (*From Ketchum; Walls, Bins and Grain Elevators*)

$\frac{S}{l}$	L
$^1/_3$	$1.06378l$

1	$1.45722l$
$^6/_5$	$1.61131l$
$^4/_3$	$1.71906l$
$^3/_2$	$1.85815l$

Timber connectors have been employed for many years on notable wooden structures (towers, bridges, roof trusses, etc.) in Europe; they deserve consideration as a means of economy in construction of bins since they (*a*) permit substitution of two or more planks for a single, massive timber, (*b*) utilize

the longitudinal strength of timber to better advantage, (*c*) require smaller allowance for loss of compressive and shearing strength at joints, (*d*) reduce amount of framing at joints, although most of the connectors require special appliances during construction. The connectors are various-shaped pieces of metal (Fig. 10) inserted between contacting faces at a joint, which is then held together by one or more bolts. Some connectors have outward projecting corrugations or teeth on both sides, requiring a hydraulic or mechanical press for assembly; others serve simply as short dowels, requiring only a special tool to cut an annular groove on each face concentric with the bolt hole. In ring connectors, of the latter type, a narrow dove-tailed gap on one side of the ring permits the metal to yield enough to distribute the compressive and shearing stresses uniformly to the wood inside and outside of the ring. For safe working loads applicable to American woods, see *Modern Connectors for Timber Construction* (*Rept. 24, Nat. Comm. on Wood Utilization, 1933*); also publications of Timber Engineering Co., Washington, D. C.

Fig. 10. Timber connectors (*Timber Engineering Co.*).

Framed *vs.* connected-timber construction. Staley (*140 #9 J 45*) compared (see Table 6) the estimated costs of two bins, one framed as in Fig. 11, the other, of the same size and type but assembled with 4-in. split-ring connectors, 3/4-in. bolts (a few 1 1/8- and 1 1/4-in.), and 3 1/4-in. ogee washers. Fig. 12 gives details of the more important joints for the latter method of construction.

Examples of timber bins. In flat-bottom timber bins the bents are spaced 3-ft. to 6-ft. centers, depending upon the height of the bin and weight of filling; 2-in. and 3-in. plank are usual for front and back; 6-in. plank or 2 × 6 laid on edge are usual on the bottom. The flat-bottom bin lends itself to CRIBBED CONSTRUCTION, similar to that shown in Sec. 11, Fig. 7, which is much cheaper than the framed type since framing and expensive carpenter labor are eliminated, and the smaller sizes of lumber are cheaper per MBM than big sticks. Fig. 13 represents a 220-ton bin built of 8-in. round timbers notched at the corners, with the crevices chinked with 3-in. and 4-in. round poles. This particular bin had no gates but was unloaded by moving the 3-in. bottom planks along with a pick. With a full bin, ore piles up in the chute; a car is run under the platform at this point and planks are moved along toward the end of the platform until the edge of the pile is reached when, upon moving the next plank, ore will fall into the car. With the bin only part full, a man enters the bin through the chute and proceeds as before, first removing the plank nearest the pile of ore. Figs. 11 and 14 are typical slanting-bottom timber bins. The wide spacing of bents in Fig. 14 is made possible by the small height of the bin. Vertical timbers are carried through to the sills. This is the cheapest form of small wooden bin, but if adopted for a large bin it would require excessively large and expensive posts. In some cases, as at DOME, it is convenient to splice a small post to the upper end of a larger one, using a through tie-

Table 6. Framed *vs.* connected-timber bins

Framed bin (Fig. 11)		Bd. ft.	Connected-timber bin	Bd. ft.	% Saved

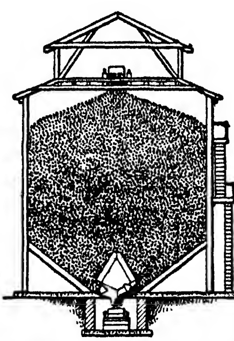

Fig. 19. Hopper-bottom bin with conveyor tunnel.

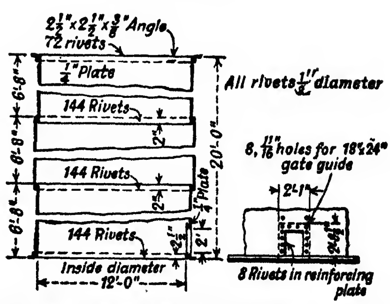

Fig. 20. Flat-bottom 100-ton circular steel bin.

Examples of steel bins. Fig. 20 shows a small circular steel bin with flat bottom and side discharge. It can be shipped knocked-down, punched, rolled, and nested. Central bottom discharge is more usual, since it gives a higher live capacity. Flat bottom circular steel bins in the Lake Superior copper-mine rock houses are 40 ft. diameter by 45 to 50 ft. high, built of 5/16- and 3/8-in. plates. Fig. 21 is a small rectangular bin with flat bottom. Such bins are uneconomical in use of steel as compared with round bins. At Timber Butte (*116 J 549*) steel bins 25 ft. diameter and 32 ft. high were set on a V-shaped concrete bottom of two slabs sloping 40°.

At Wright-Hargreaves (*140 #3 J 34*) two adjoining 32-ft. circular steel bins hold 2,000 tons of <1/4-in. ore. To reduce idle volume, the bottoms of the bins are arranged in parallel steps, 3 ft. high,

the lowest bench being 30 ft., and the highest 24 ft. below top of the bin. Chutes, 14×16-in., are spaced along the center line of each bench, four chutes on the middle bench, three on each of the others. The chutes of both bins discharge onto three parallel belt conveyors which deliver to a cross-conveyor at one end.

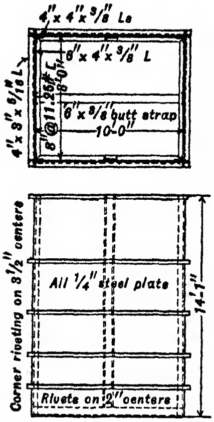

Fig. 21. Flat-bottom 50-ton rectangular steel bin.

Fig. 22 illustrates the 4,000-ton bin at the main shaft of the Inspiration Consol. Copper Co. (*119 J 484*) receiving ore by standard-gage RR. cars and delivering by pan conveyors to the mill. It is essentially a flat-bottom bin, although sides, ends, and bottom are all composed of cylindrical segments.

Suspension bunkers. Fig. 23 (*118 J 566*) shows two typical steel suspension bunkers for ore. The Inspiration bin is 330 ft. long with a nominal capacity of 40 tons per running foot. Columns are spaced 16 ft. 8 in. longitudinally and draw gates are at the halfway points between columns. The New Cornelia bin is 330 ft. long; nominal capacity is 33 tons per running foot, columns are spaced 20 ft. longitudinally and gates on 10-ft. centers. The dotted lines in the drawings show the positions assumed by the loaded bins. At New Cornelia the distortion strained the hopper fastenings badly. A similar bin 448 ft. long, 32 ft. wide, and 34 ft. deep with a capacity of 35 tons per running foot was built at Morenci (Sec. 2, Fig. 28). Supporting columns are on 18-ft. 8-in. centers longitudinally. Two intermediate expansion joints were provided. Design of suspension bunkers is largely indeterminate, and final designs should not be accepted without check against existing installations.

Baker suspended bins. Fig. 24 (*97 J 908*) shows several types of a modification of the ordinary suspension bunker, in which a rigid bottom is carried on a series of transverse triangular frames hung by suspension rods from the main supports; the walls are supported against these rods. The cut shows wood, reinforced-concrete and steel sides.

Design of large steel bins will usually be most economical if the bin is considered a unit of specified over-all dimensions, capacity, and receiving and delivery limitations, and the detailing is done by the steel company that is awarded the contract. Most large steel companies now have designers more experienced in ore-storage problems than the ordinary mill designer is experienced in steel construction.

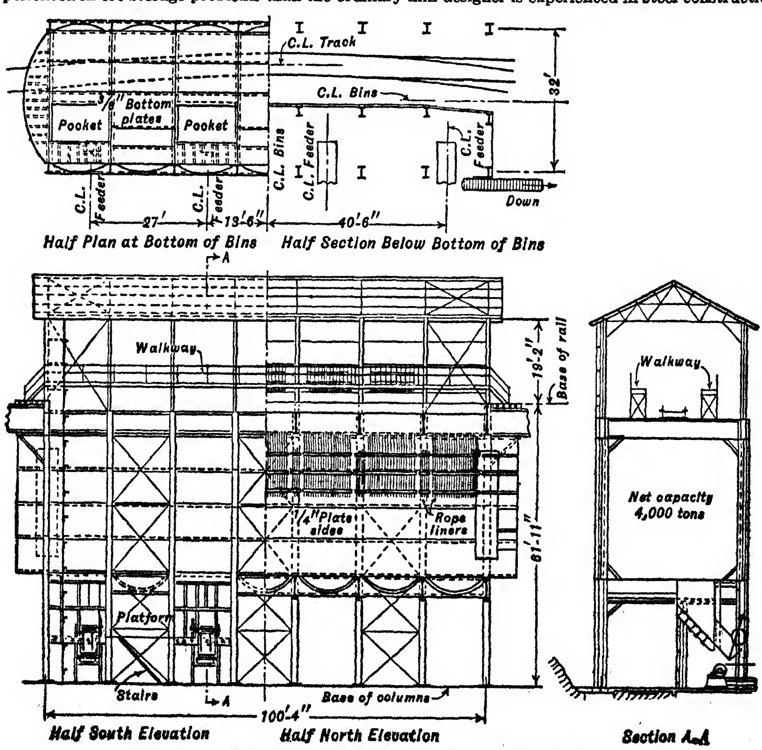

Fig. 22. Steel bin at main shaft, Inspiration Copper Co.

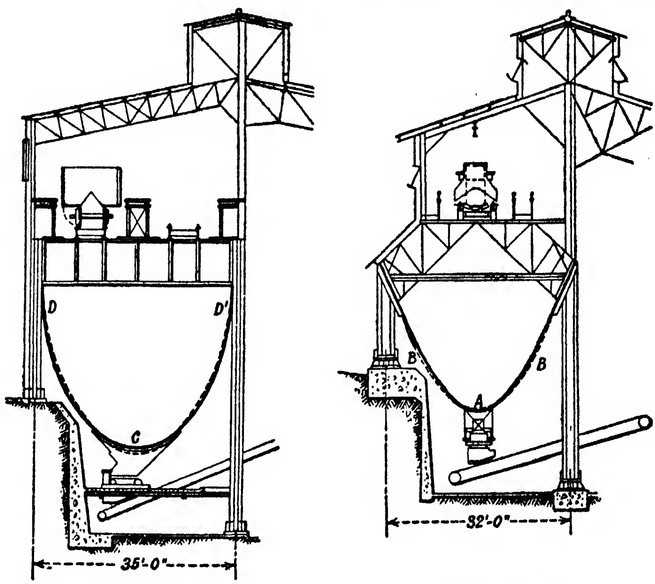
Examples of concrete bins. Fig. 25 shows a circular reinforced-concrete bin built by Witherbee, Sherman & Co. at Mineville, N. Y., for crude-ore storage. The live capacity was about 1,000 tons. The foundation block was of coarse stone bonded with a 1 : 10 mixture of cement and fine tailing; the wall mixture was 1 : 4 cement and fine tailing. Reinforcement, placed 4 in. from the outside of the walls, consisted of horizontal hoops of worn 1 1/8-in. hoisting cable, spaced as shown, with vertical



Inspiration New Cornelia

Fig. 23. Steel suspension bunkers.

cables at 4-ft. centers wired to the hoops. The bin was filled to the discharge point with barren rock before ore was run in. Fig. 26 (*71 EN 1234*) shows another bin of the same type but with central bottom discharge. Vertical reinforcement consisted of 1/2-in. round rods spaced 18 in.; horizontal, of worn 3/4-in. cable spaced 4 1/4 in. for the bottom 5 ft., 6 in. for the next 10 ft. and 9 in. to the top. Cables were lapped 3 ft. at the joints, raveled and clipped; vertical rods were lapped 2 ft. at the joints. The concrete mixture was 1 : 3 : 6 for foundation and 1 : 2 : 4 for walls; the maximum size of stone used was 2 1/2-in. Fig. 27 (*96 J 305*) shows a rectangular hopper-bottom bin reinforced with corrugated

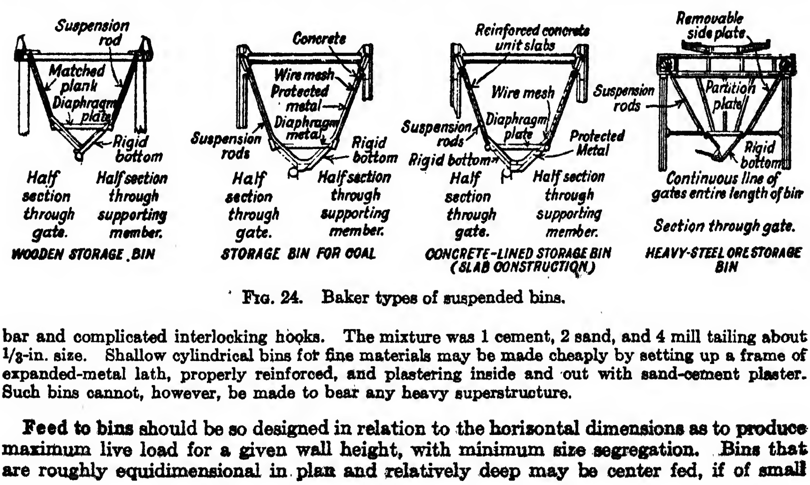


Fig. 24. Baker types of suspended bins.

bar and complicated interlocking hooks. The mixture was 1 cement, 2 sand, and 4 mill tailing about 1/8-in. size. Shallow cylindrical bins for fine materials may be made cheaply by setting up a frame of expanded-metal lath, properly reinforced, and plastering inside and out with sand-cement plaster. Such bins cannot, however, be made to bear any heavy superstructure.

Feed to bins should be so designed in relation to the horizontal dimensions as to produce maximum live load for a given wall height, with minimum size segregation. Bins that are roughly equidimensional in plan and relatively deep may be center fed, if of small

diameter, and supercharged, if headroom is available and design is suitable. Long bins are usually fed by a conveyor along the longitudinal center line with a traveling tripper having a 2-way spout. Large, relatively shallow and relatively equidimensional bins

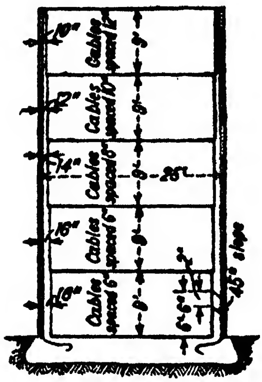

Fig. 25. Circular reinforced-concrete bin (*91 J 704*).

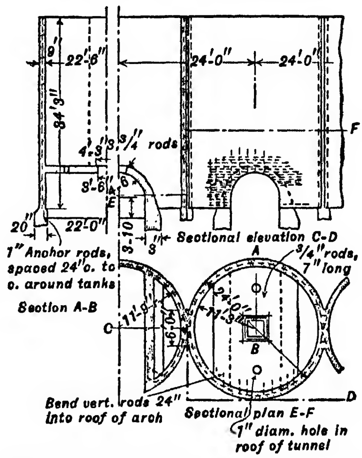

Fig. 26. Concrete bins at Croton Iron Mines.

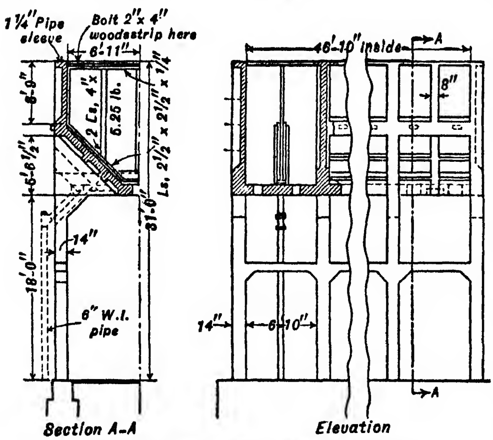
require sufficient superelevation of initial feed point to permit splitting of the feed stream and spouting toward the walls, or feeding by parallel conveyors with trippers, or the use of throw distributors, if marked loss in live capacity is to be avoided.

Control of feed to bins. At the Iron Knob mine of the Broken Hill Proprietary Co., where a comparatively small (300-ton) surge bin receives the direct discharge of 9-in. material from a 60×84-in. jaw crusher, the possibly disastrous effect of choking the crusher by supercharging of the bin was guarded against by hanging a pendulum in such position that it would be laterally displaced by the pressure of ore rolling down the pile when the latter reached a predetermined height. In this case, visual inspection was impracticable. Displacement of the pendulum was transmitted through rods and levers to a switch (protected by dash-pot delay mechanism against momentary or accidental motion) in the power line supplying the car-dump motor ahead of the crushers. The same principle was also applied to other bins at subsequent points in the crushing scheme (*31 CEMR 128*).

At Wright-Hargreaves (*140 #3 J 34*) an 8-ton surge bin, feeding three ball-mill circuits, receives ore via belt conveyors from two 1,000-ton mill bins. An electric eye is installed to catch a beam of light thrown across the top of the bin, interruption of which stops the conveyors when the bin is full. Details of the electric relay system, by which feeding is automatically resumed, are given in the reference.



All concrete heavily reinforced with high-carbon steel corrugated round rods.

Fig. 27. Reinforced-concrete tailing bin, St. Joseph Lead Co.

4. DISCHARGE FROM BINS

Bins are discharged through openings in the bottom or at the bottom of the side walls. The size of opening is made adjustable by means of gates. Rate of discharge in mill work is normally regulated by a feeder. The minimum size of discharge opening should be not less than three times the maximum dimension of particles passing through, if the

material is sized; nor less than twice the maximum dimension when material is a mixture of coarse and fine. These minimum dimensions will usually be greatly exceeded in fine-ore bins; with run-of-mine rock special provisions must be made to control the flow of material through such large openings, and the subsequent chutes and conveyors must be correspondingly large, so that there is always a tendency to cut down dimensions, with resultant clogging and lost time.

Gates. The type used depends on the size of material, destination, and regularity of discharge. When material contains large lumps, a gate that readily cuts completely

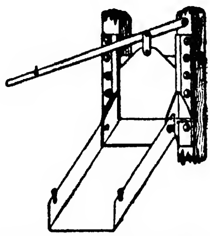


Fig. 28. Lever slide gate.

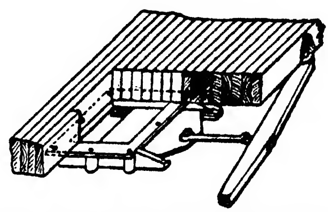

Fig. 29. Standard bottom-draught bin gate.

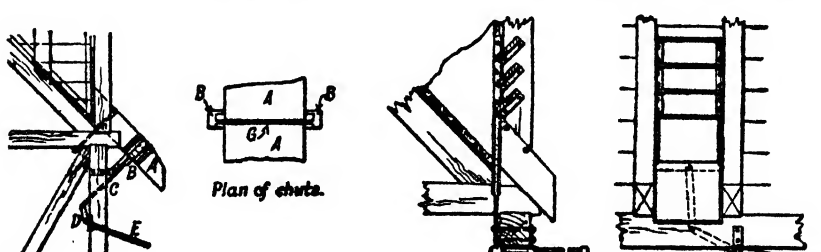
across the stream is wanted; if the destination of the discharged material is a car, a quick, wide-opening gate is desirable; if discharge is highly intermittent, a gate that opens and closes readily and quickly is necessary, while for regular discharge a slow-opening gate may be used and it is not so important that it be easily moved. Usual types are: (*a*) Sliding gates that move in grooves set into bin walls or bottom; these gates are hard to open when the pressure of the filling against them is great, and under such conditions must be geared down so much that they are slow (*b*) Cutoff gates, that present a portion of a cylindrical surface to the stream of ore, usually in a chute. Either the convex or the concave surface may be presented. (*c*) Finger and hammer gates, for coarse ores. (*d*) Chain or curtain gate for coarse and mixed ore. (*e*) Lifting chute or apron gates.

Slide gates. The LEVER SLIDE GATE, Fig. 28, is the simplest of this type. Ordinary sizes are 12×15- and 12×18-in. It is not suitable for heavy pressure and is difficult to close tightly when the ore contains both coarse lumps and fine material, as a lump caught under one side will stop the gate and hold it open, allowing fine material to run until larger pieces bridge the opening. For heavier service, up to 36×36-in. size, the slides are made with rollers against which the gate works. Fig. 29 shows a



(*a*) (*b*)

Fig. 30. Upward-closing slide gates.

similar gate for bottom draught. Usual sizes are 12×12- and 12×18-in. A bottom-draw valve for fine concentrate may be made of ordinary 6-in. pipe and fittings and strap iron (*90 J 704*). Fig. 30 shows two forms of upward-closing slide gates. These have the advantage over the downward-closing gate that they will not jam against lumps in closing. They have the disadvantage, however, that fine material causes wedging in the slot through which they work and that wear on this slot is excessive. RACK-AND-PINION gate, Fig. 31, is perhaps the most widely used of all types on small bins. While slow and sometimes difficult to move, it is easy to regulate closely and a pawl on the pinion will hold it in any position desired. The usual size range is 18×18- to 30×36-in.; corresponding weights are 250 to 450 lb. A double rack is used for very heavy service; some have roller slides and chain-controlled hand wheel; some also have a worm gear on the pinion shaft for exertion of additional force. Fig. 32 illustrates the use of air for operating sliding gates; these gates are quick-opening even under heavy

At WITHERBEE, SHERMAN & Co. the gate for a lump-ore (6-in. to 2-ft.) bin was 4 ft. 8 in.

square, made of 2-in. plank faced both sides with 1/2-in. plate, weighed 1,300 lb., operated under 60-lb. pressure, and was capable of crushing large lumps that wedged under it. It was run on rollers (*89 J 809*).

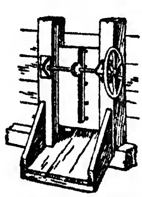


FIG. 31. Rack-and-pinion gate.

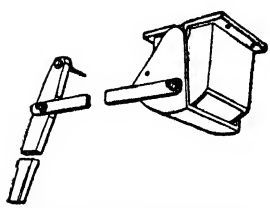

FIG. 33. Standard bottom-draught arc cutoff gate.

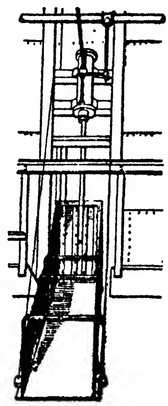

FIG. 32. Air-operated slide gate.

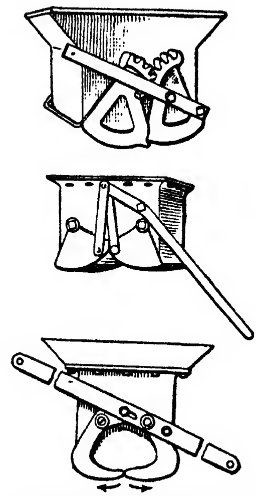

FIG. 33A. Duplex bottom-draught arc cutoff gates.

Arc cutoff gates are used both for bottom draught and side draught. Fig. 33 shows a standard bottom-draught type made in 10×10-, 15×15-, and 20×20-in. sizes. This gate is not hard to open, and is easy to close, but may catch against a large lump and therefore not cut off quickly. This same gate is made for side draught. Fig. 33A shows three types of duplex bottom-draught arc gates. These are made in sizes from 12×12- to 26×26-in. The gear type is the least rugged of the three.

Fig. 34 shows details of a particularly rugged type of arc gate for side draught, used at CANANEA CONS. COPPER Co. (*92 J 933*). These gates should be so set as not to back into the ore when opening yet to run with the stream to some extent in closing. When so arranged, they are readily and quickly opened and closed and are the best kind for intermittent service such as loading cars from a bin front.

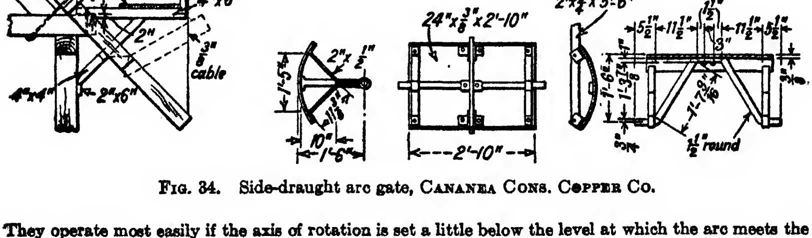

FIG. 34. Side-draught arc gate, CANANEA CONS. COPPER CO.

They operate most easily if the axis of rotation is set a little below the level at which the arc meets the chute bottom. Fig. 35 shows one of these gates arranged at the lower end of the bin chute, instead of at the bin wall. There is less pressure against the gate in this position, and hence it will be more readily opened. When open, one side of the sector forms part of the chute bottom. This type of gate cannot jam in closing, but is likely to cause material to jump out of the chute when it begins to close. The gate may be air-operated. Fig. 36 (*94 J 64*) is a geared concave form for coarse ore, designed to open

downward. It does not jam in closing but will cause fast-running lumps to jump as it begins to close. As it fails to open fully, a layer of ore is kept in the bottom of the chute, thus protecting the latter from wear.

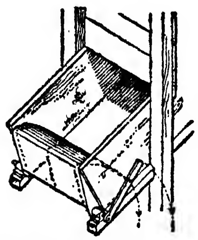

Fig. 35. Convex arc gate in chute (*92 J 740*).

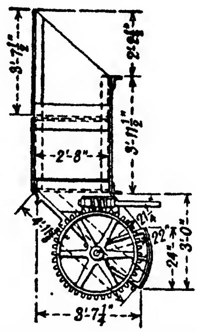

Fig. 36. Geared undercut concave cutoff valve, side-draught type.

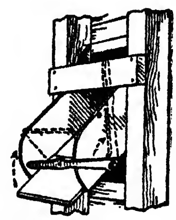

Fig. 37. Flap-valve bin gate.

Flap-valve gates. Fig. 37 shows the simplest form; it opens and closes readily and quickly, but is subject to wear by discharging material, particularly at the crack in the chute bottom. An air-operated form was used at Quincy Mining Co. (*98 J 827*).

Finger gates are particularly useful in discharging coarse ore. Fig. 38 (*97 J 856*) shows an air-operated form with all fingers operated together. Fingers are sometimes arranged for independent operation; this allows closer regulation of coarse material than is possible with any other type of gate.

Swing-hammer gate is similar in principle to the finger gate, and may be used with or without an automatic feeder; Fig. 39 shows its application to a mill bin (Fig. 15) at the Magma mine.

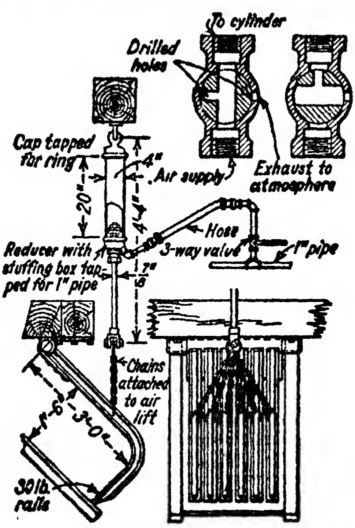

Fig. 38. Air-operated finger gate.

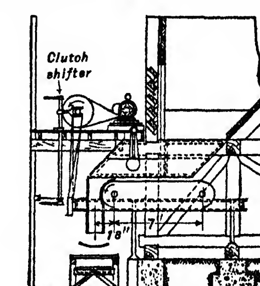

Fig. 39. Swing-hammer gate at Magma.

Ross chain or curtain gate consists of short sections of extra heavy chain, each with a cast-iron ball attached to its lower end, closely spaced in a row across the chute opening, and suspended in such position that they rest upon a bank of ore standing only slightly steeper than its angle of repose. Flow of ore under the chains is regulated by adjusting the height of the balls by means of light bridle chains also attached to them. This is one of the most satisfactory gates for discharging ore varying widely in size, since it is possible to bar through a large lump without causing a rush of fines. For further modifications of this device to act as a feeder, see Art. 22.

Jamming at bin discharge occurs either by reason of bridging of large lumps or by compacting of moist material under the pressure of the overlying filling; fine, dry material, if de-aerated by long standing under pressure, is equally troublesome. The usual cures are barring through the open gate,

sledging the outside face of the bin around the gate opening, and dynamite. Electromagnetic vibrators of the general electrical types used on electrical vibrating screens (Sec. 7, Fig. 36) are available in sizes weighing from 20 to 150 lb. or more, with proportionately powerful impacts. These are attached to the wall or bottom of the bin in the position which trial shows most effective. They are reported to maintain flow under difficult conditions. Power consumption of the largest size is less than 1 kw.

Louvres. Much trouble due to bridging can be saved by means of openings in the bin walls that give access to the material immediately around the gates. Fig. 40 (*122 P 593*) shows the method applied to a hopper bottom; it may be similarly applied to a vertical wall, as in Fig. 39. In either case the angle θ should be less than the angle of repose of the filing. A further development of the louvre

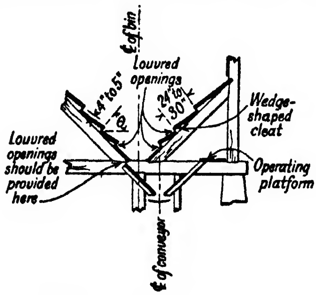

FIG. 40. Louvres in hopper-bottom bin.

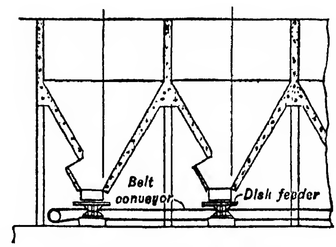

FIG. 41. Louvre-type gate.

principle is shown in Fig. 41, a construction popular in Europe, and not necessarily limited to concrete construction. The old idea illustrated in Fig. 42, using an auxiliary hopper to receive the otherwise unrestricted outflow of a bin, has proved well adapted to the handling of flotation concentrates. Another expedient, sometimes helpful, is to place the gate in a chute some 3 or 4 ft. down from the bin instead of at the top; when the gate is opened, ore held in the chute will usually start freely; if ore from the bin fails to follow at once, it is easily accessible for barring; stop boards are advisable with this arrangement. At some Lake Superior rock houses bins for coarse ore have two gates in the same chute, the lower one so placed that it will stop flow through the upper; this permits opening the other wide in case it clogs; the arrangement also allows stopping the stream for picking.

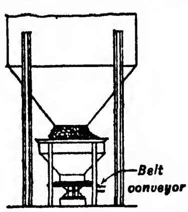

FIG. 42. Hopper-type bin gate.

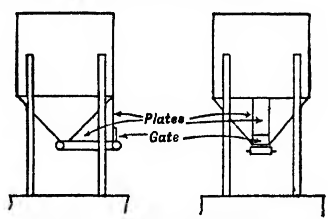

FIG. 43. Cone-bottom bin for fine heavy concentrate.

Moist material, especially when fine, may have an angle of repose of 90° or more and a sliding angle against wood or steel almost as great. The most difficulty is met in storage bins following intermediate crushing and those for mixed granular and flotation concentrate. Compressed air is most effective for starting such material. In bins a series of perforated compressed-air pipes set vertically and extending nearly to the bottom will, when blown, break up most hang-ups. Elsing (*89 J 203*) describes the use of a pointed 9-ft. length of 1 1/4-in. pipe supplied with air at 80 to 90 lb. per sq. in. pressure for unloading fine gravity concentrate from cars. Prior to its use it required 60 to 90 min. to bar material out of a 6-car train; with it, 15 to 20 min. was sufficient. Fig. 43 shows the manner in which a conical-bottom bin for fine, heavy concentrates, found troublesome to discharge from a central opening, was reconstructed by cutting a vertical slot the full height of the cone and supplying side and end walls to confine the outgoing ore to a rectangular space, of which the whole bottom was occupied by a belt or apron feeder; results were satisfactory.

For feeders applied to the discharge of bins, see Arts. 22 and 23.

5. GROUND STORAGE (STOCKPILING)

Applicability. Ground storage, or stockpiling in the open air, may be advantageous under one or more of the following conditions: (*a*) Cheap, bulky materials—crushed stone, sand, gravel, oyster shells, etc.—not warranting cost of bins. (*b*) Large volume of material—anthracite, wet phosphate concentrates, etc.—entailing prohibitive cost for adequate bins. (*c*) When advisable to insure uninterrupted supply to a treatment plant

working at large daily capacity—cement works, phosphate driers, chemical and metallurgical plants. (*d*) When receipt or delivery of material is seasonal or widely fluctuating —raw or washed Lake Superior iron ores, anthracite, crushed rock and gravel. (*e*) When several bulky ingredients are to be mixed before treatment or delivery—copper, lead, and iron ores, concrete aggregates blended to specifications; mixing may occur during the making or the reclaiming of the stockpile. (*f*) Certain metallurgical products (including some of high value) not damaged by weather and occurring in large heavy lumps unsuited for bin storage. (*g*) Medium- or low-grade mill products reserved for possible retreatment. In general, stockpiling is seldom employed at ore concentrators except at some of the iron-ore washers on the Mesabi Range where climatic and shipping conditions make it advisable to stockpile concentrates. If size segregation (Art. 2) must be avoided, material going into the same stockpile (by whatever method) should have a size ratio preferably not exceeding 2 : 1.

Building stockpiles is done by: (*a*) Direct fall from screen or washer—stone, sand, gravel. (*b*) Dumping cars or trucks from a trestle. (*c*) Unloading cars or barges by clamshell crane. (*d*) Transferring from temporary open-bin storage by crane. (*e*) Belt conveyor, with or without tripper, mounted in fixed position, on a swinging boom, or on a laterally traveling bridge. (*f*) Cable or drag scraper, or bulldozer, usually auxiliary to other equipment and helping to extend the available area of storage.

Reclaiming from stockpiles is accomplished by: (*a*) Power shovel or clamshell crane, delivering to cars, trucks, or hoppers; some of these devices serve as both excavator and carrier. (*b*) Belt conveyor traversing a tunnel beneath the pile, fed through overhead chutes, and usually transferring to another conveyor or an elevator for final disposal. (*c*) Portable loaders, usually of flight-elevator type, delivering to cars or trucks. (*d*) Scraper or bulldozer for bringing outlying material to within reach. (*e*) Special and elaborate mechanical systems of scrapers, elevators, and conveyors designed primarily for chemical and metallurgical plants; parts of such a system may serve for both stocking and reclaiming.

Relative merits of the five common methods applied to stockpiling and reclaiming of gravel and crushed stone are evaluated by N. Severinghaus (*44 #4 RP 49*) as follows, lower numbers being the more favorable:

	Belt conveyor	Cable and drag scrapers	Clamshell crane	Cars or trucks	Bulldozer
First cost	5	1	4	3	2
Operating cost	1	3	2	4	5
Breakage of stone	1	4	2	3	5
Flexibility in amount of storage	5	3	4	1	2
Flexibility in hourly capacity	1	3	3	2	3
Operating labor required	1	2	3	5	4
Ease of changing location	5	3	4	2	1

Examples. The following cases illustrate a variety of methods.

Iron ores. Mesabi Chief mine, Keewatin, Minn. (*16 MMt 334*), stocks a maximum of 100,000 tons of washed ore in a circular pile 55 ft. high and of 165-ft. radius by a Link-Belt system including the following series of belt conveyors: (1) A self-contained shuttle receiving all or none of the washed product (in the latter case, the product goes direct to shipping bin): width, 30 in.; speed, 350 f.p.m.; driven by 10-hp. motor through herringbone reduction and roller chain. (2) Main conveyor, 30-in. × 258-ft., on a steel trestle with one center support; inclination, 5° (20 1/2 ft. total rise); 370 f.p.m.; driven by 20-hp. motor through herringbone reduction; gravity take-up for belt tension. (3) Distributing conveyor (24-in.) receiving ore from the preceding through a circular hopper; 470 f.p.m.; driven by 10-hp. motor through worm gear and tandem pulleys. This conveyor is mounted on a boom 93 1/4 ft. long, sloping 12° upward, and capable of swinging a horizontal arc of 240°; it is anchored at the desired position by guy ropes. Auxiliary head pulleys on the conveyor permit shortening its run, in order to fill space within the outer circle of ore. Reclamation is by a revolving traction shovel.

For reclaiming from a stockpile of iron-ore concentrate at the Harrison washery, Mesabi Range, the Athey Mobiloader has been employed (*142 #1 J 39*). Model D8 machine is a caterpillar-mounted mechanical shovel, resembling some underground ore loaders in that it discharges its load by lifting and throwing overhead to the rear, but differing in that the whole machine traverses the space between loading and discharge points. Two tests with a 3 1/2-cyd. dipper, loading 75-ton RR. cars on tracks parallel with the toe of the stockpile and at distances, respectively, of 90 and 80 ft., gave the following results: (*a*) 61 trips to load 4 cars averaging 69.5 long tons; average load per trip, 4.41 tons; average time for round trip, 0.96 min.; best time, 0.85 min. (loading, 15 sec.; moving load, 18 sec.; dumping, 6 sec.; returning, 12 sec.); rate, 277 long tons per hr. (*b*) 107 trips to load 7 cars averaging 73.1 long tons; average load per trip, 4.78 tons; average time, 51 sec.; best time, 46 sec. (loading, 10 sec.; moving load, 18 sec.; dumping, 5 sec.; returning, 13 sec.); rate, 337 long tons per hr.

Florida pebble phosphate. Ground storage of wet concentrates, received in RR. cars from the washers, is customary at the drying plants. At Mulberry (*141 #9 J 55*) the International Agricultural Corp. dumps 50-ton cars of pebble from a trestle; surplus beyond the capacity of this pile is moved by clamshell crane to a parallel pile. Reclamation at 400 t.p.h. is by 36-in. belt conveyor in a tunnel beneath the trestle, delivering by cross-conveyor and elevator to a 400-ton silo feeding a drier. Flotation concentrates are first dumped into bins, but thereafter are handled in the same manner as the pebble by a parallel and duplicate conveyor-elevator system. At the Ridgewood drier (*141 #10 J 40*) the Southern Phosphate Corp. unloads wet pebble (no flotation concentrate) from cars standing on a trestle by clamshell crane moving on a parallel track on the trestle. Reclaiming tunnel, of concrete, is 10(high)×9-ft., 440 ft. long. At 10-ft. intervals, three 10×10-in. chutes, on center and both sides, discharge into two traveling hoppers which feed a 24-in. belt conveyor at 150 t.p.h. A cross-conveyor then delivers to hoppers feeding the driers. At Pierce (*141 #11 J 57*) the American Agricultural Chemical Co. has combined wet-storage capacity of 50,000 tons at three places, all near the drier, two for pebble, one for flotation concentrate. Pebble is dumped from a low trestle, and reloaded by Brownhoist clamshell crane into cars standing on the same trestle track, which crosses the six 200-ton drier hoppers. Flotation concentrates are reclaimed by a 3-cyd. (2 1/2-ton) Crescent scraper, operated from a Sauerman tower, which discharges to the first of two conveyors leading to the driers. At Coronet (*141 #12 J 57*) the Coronet Phosphate Co. has stored as much as 300,000 tons of wet pebble (none finer than 20-m). Cars are dumped from a single-track trestle and reloaded at the same level, for transfer to drier hoppers, by Brownhoist or Browning clamshell crane.

Crushed stone. Permanente Corp., Calif., consuming 4,170 tons of limestone to make 16,000 bbl. of Portland cement per day, provides ground storage for 560,000 tons of limestone between quarry and grinding-mill bins, in three conical piles at consecutively lower elevations: (*a*) 5,000 tons of unsized shovel output, at about 1,000 t.p.h.; (*b*) 550,000 tons of crushed rock, <6-in.; (*c*) 5,000 tons <1/2-in. An additional 100,000-ton pile of 3~6-in. rock provides for seasonal sales to the sugar industry. In each case, the pile is formed by discharge from the end of a stationary belt conveyor and is reclaimed through pan or vibrating feeder by a belt conveyor inside a tunnel beneath the pile. The rugged topography (plant being about 1 mi. from and 1,150 ft. lower than the quarry) favors this method of storage and transport (*148 A 374*).

The rock quarry on Santa Catalina Island, Calif. (*IC 6609*), crushes and screens into four sizes, each caught in a separate pocket. Between this point and the barge-loading dock, each size is stockpiled twice, involving the use of three conveyors in sequence, the first two being equipped with trippers (also with screens to eliminate dust), depositing each size in a separate pile, four piles in a row. The loading ends of the second and third conveyors are in tunnels provided with a tipping-chute gate under each pile. The third conveyor (36-in.×400-ft., driven at 200 f.p.m. by 60-hp. motor) passes over a scale and thence to a loading boom on the dock.

Weston & Brooker Co., Cayce, S. C. (*IC 6744*), produces five market sizes of crushed granite. Screens deliver their oversizes into eight pockets, with 1,000-ton combined capacity, open at top. For direct shipment, the pockets deliver to cars by conveyor and loader. For stockpiling of 40,000 tons, a revolving electric crane with 90-ft. boom and 2 1/2-yd. clamshell bucket excavates from the pockets and deposits each size on a separate pile in a ring formation with outside diameter of 257 ft. Reclaiming follows the reverse operation. When additional storage is needed, some of the stone is moved outward by a caterpillar crane with 1/2-yd. clamshell and 60-hp. gasoline motor.

Palmetto Quarries Co., Columbia, S. C. (*34 #10 PQ 27*), stores eight sizes of crushed granite in the manner shown in Fig. 44. Only the coarsest size, 3~2-in. and relatively small in tonnage, is entirely

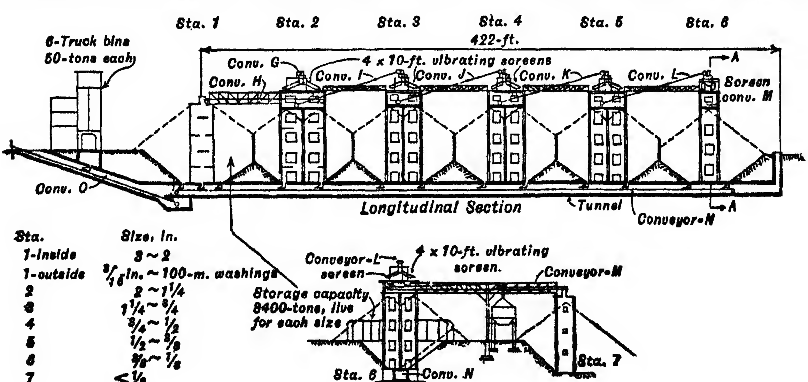

Fig. 44. Screening and storage system, Palmetto granite quarry.

enclosed (in the 500-ton silo, Station 1); other sizes fall from their respective screens directly into rectangular concrete towers, which are 64 ft. high from top of the reclaiming tunnel to the screen floor. The baffle floors in Stations 1 and 2 are to reduce breakage of the coarse stone there handled. Openings on all four sides of a tower allow material to roll out into a conical pile, separated from adjoining ones by plank fences about 25 ft. high. Each pile holds 4,000 tons, 85% of which is recoverable by gravity

discharge to the conveyor *N;* a crane or bulldozer increases available storage to 10,000 tons of each size. The <1/8-in. screenings, of which 50,000 tons can be stored, arrive via conveyor *M* from the top of Station 6 and are dropped into a circular tower (Station 7) of which the side openings are fitted with

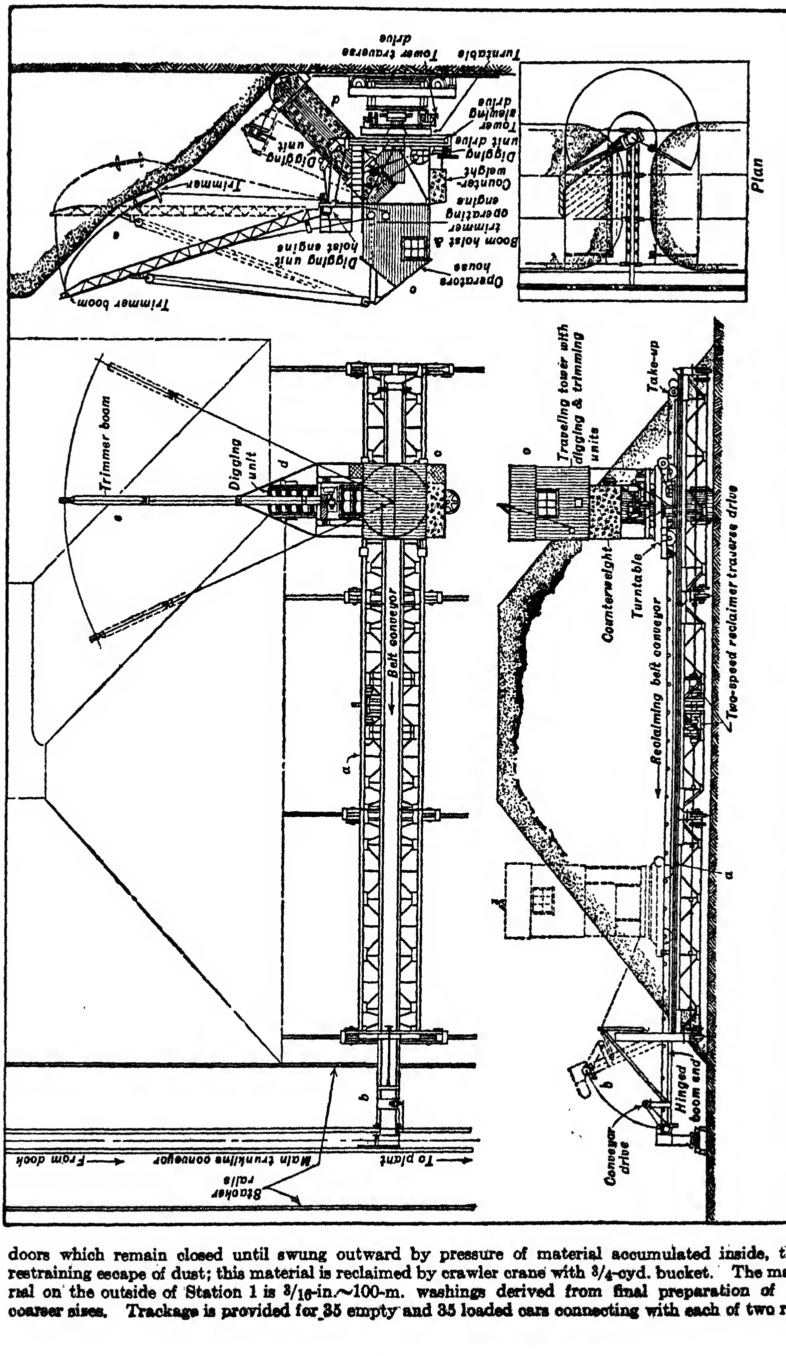

Fig. 45. Reclaiming system, Mathieson Alkali Works, Lake Charles, La. (*Robins Conveying Belt Co.*)

doors which remain closed until swung outward by pressure of material accumulated inside, thus restraining escape of dust; this material is reclaimed by crawler crane with 3/4-cyd. bucket. The material on the outside of Station 1 is 3/16-in.~100-m. washings derived from final preparation of the coarser sizes. Trackage is provided for 35 empty and 35 loaded cars connecting with each of two rail-

roads; loading-out capacity of the system is 450 t.p.h. For details of the elaborate system of belt conveyors installed at this plant (including those, correspondingly lettered, shown in Fig. 44) see Table 20.

At MATHIESON ALKALI Co., Saltville, Va., 6-in. limestone feed for shaft furnaces is stockpiled by a boom conveyor from the washing plant on an open stockpile behind a retaining wall near the bottom of a steep hillside. Gates in the wall feed aerial-tram buckets.

Sand and gravel. At a FORT WORTH (Tex.) gravel pit (*IC 6652*), after a washing to remove fines, the material (250 t.p.h.) passes consecutively over five vibrating screens, undersize of each being delivered to the next screen by a belt conveyor about 60 ft. long. The resulting six sizes fall directly onto conical piles, without separating partitions, with combined capacity of 30,000 cyd. About an equal volume of additional storage is gained by use of a slack-line cableway transferring excess material to one side and later reclaiming it by reversing the 1/2-cyd. bottomless scraper. Beneath the row of piles is a 7×7-ft. tunnel with three or four 16×16-in. clamshell gates under each pile; a 24-in.×475-ft. belt conveyor @ 250 f.p.m. receives the gate discharges and delivers them to another 24-in. belt (+15°) to a railroad loading pocket. Shipments are blended to specifications by adjusting the flow from the several gates.

At DURBIN, Calif. (*IC 6607*), washed and sized gravel is first distributed among 18 @ 200-ton bunkers in two rows on opposite sides of double-track RR. which extends (for storage of empty cars) 2,000 ft. beyond the bunkers. Storage yard includes two parallel tracks spaced 60 and 120 ft. on each side of the central tracks, making space for six longitudinal piles with total capacity of 60,000 tons. Gravel for stockpiling is drawn from the bunkers into 60-ton cars which are moved by the same clamshell steam crane that unloads them (50-ft. boom, 1 1/2-cyd. bucket, burning 7 bbl. oil in 10 hr.). The crane can unload 3 cars per hr., but it loads slightly faster.

At ELIOT, Calif. (*IC 6705*), PACIFIC COAST AGGREGATES stocks 250,000 tons of sized gravel in parallel rows on both sides of RR. track; bottoms of the piles are depressed below ground level. Cars are unloaded and reloaded by Diesel locomotive cranes with 1 1/4- and 1 1/2-cyd. clamshell buckets; cars are spotted by 20-ton gasoline locomotive. Of the several storage methods employed by this company at its numerous plants, this one has proved most flexible; it can ship 100 carloads a day.

See also Sec. 3, Arts. 24, 38, 41.

Automatic mechanical system. At Lake Charles, La., the MATHIESON ALKALI WORKS has a plant designed for storage and reclamation of oyster shell, dolomite, and coal or coke, all by the same system. Materials arrive by barges and by RR. cars on a track parallel with edge of the dock; the cars dump into a track hopper. A stiff-leg derrick with clamshell bucket transfers material from barges or track pocket to an elevated conical hopper discharging to an inclined pan conveyor and thence to the head end of a belt conveyor running inshore at right angles to the edge of the dock; this main or trunk-line conveyor reaches to the plant and serves for both stockpiling and reclaiming. Stockpiles triangular in section are formed on both sides of this belt conveyor by an inclined swinging-boom conveyor mounted, together with a tripper and hopper for transferring from the horizontal to the inclined conveyor, on a truck which moves on two rails between the two piles; the boom is adjustable as to height. The reclaiming system, Fig. 45, comprises the following units: (1) A traveling bridge *a* running on four rails parallel with the stacker rails and trunk-line conveyor and normally buried under the pile; this bridge can move in either direction, at 6 f.p.m. when reclaiming, or at 60 f.p.m. when disengaged; it carries a belt conveyor of which the outer end is supported on a hinged boom *b* so that it can pass the stacker, if necessary. (2) A tower *c*, rotatable on its base and also movable lengthwise of the bridge *a*; a 10-hp. motor supplies the longitudinal, and a 5-hp. motor the rotating movement. The next two items are both attached to this tower and move with it. (3) An excavating elevator *d* delivering through a hopper to the belt conveyor on the bridge; alternate close-connected pans of this elevator are deeper than the others and are equipped with teeth; all are carried between two steel-bushed roller chains. (4) A trimmer *e*, consisting of two disks centrally attached to a rope which is operated from a 5-hp. reversible drum hoist and passes over a sheave on the outer end of an adjustable boom; this device has proved particularly useful in reclaiming oyster shells. See also Sec. 3, Fig. 31.

Robins-Messiter bedding and reclaiming system, long in use at some copper and lead smelters and more recently adopted at a few iron blast furnaces, aims to produce a mixture

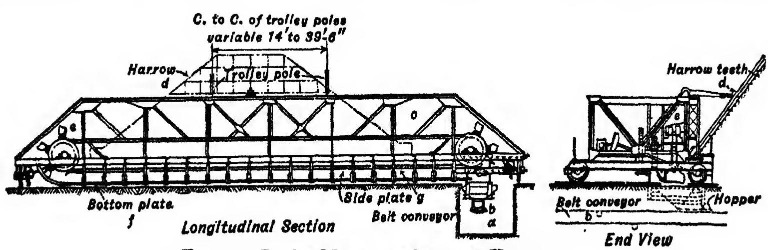

FIG. 46. Robins-Messiter reclaimer at KATANGA.

uniform in assay and size analysis, while also permitting adjustment of both factors to meet predetermined specifications. The beds are formed in rectangular piles, triangular in cross-section, by discharge from automatic traveling trippers on overhead belt conveyers, the latter receiving from a main trunk conveyor which brings materials from some central

source. In general, each pass of a tripper may deposit about 200 lb. of ore per lin. ft. of pile, making a total (for perhaps 350 passes) of 32 to 36 tons per ft. of completed pile. Adjustment as to grade of reclaimed mixture may be made at this time on the basis of assays of the several components. RECLAIMING. Along one side of each pile is a trench *a*, Fig. 46, 6 ft. deep by about 7 ft. wide, in which is installed a belt conveyor *b*, discharging to a trunk conveyor for delivery to the final destination. One end of a traveling bridge *c*, about 10 ft. longer than the base width of the pile, spans this trench. The bridge carries two essential mechanisms besides its own travel drive: (1) The harrow *d*, which is a trapezoidal skeleton framework equipped with downward pointing teeth, adjustable as to inclination and slowly oscillated lengthwise, *i.e.*, across the end of the pile, by eccentric and connecting rod. (2) An excavating conveyor *e*, which consists of an endless chain of open-connected scrapers traveling along a continuous bottom plate *f*; the forward edge of this plate is held close to the toe of the pile, while a vertical side plate *g* closes its rear edge. The well-mixed material is thus collected and transported to the trench conveyor. The whole reclaiming outfit can be moved from one pile to another by a car running on rails in a wide trench at one end of the bedding floor. Power to operate the bridge and its equipment is drawn from trolley wires.

TRANSPORT OF MATERIALS

By

Henry A. Behre, Formerly Assistant Professor of Mining,
Sheffield Scientific School, Yale University

Revised by

E. J. Tournier, Robins Conveying Belt Co.; and E. K. Judd, Mining Engineer,
New York, N. Y.

Handling, as related to mineral dressing, involves transport over considerable distances, both vertical and horizontal, as well as through relatively short distances into and out of storage containers. The specific problems ordinarily encountered require the handling of: (a) run-of-mine from mine delivery point to the primary breaker; (b) coarsely broken dry mineral between primary and secondary crushers and into and away from storage bins; (c) relatively coarse wet products, such as jig feed, jig products, and the like, in the mill; (d) wet sand and slime pulps; (e) the same material dry; (f) froth-flotation concentrates. The apparatus described in this section includes conveyors and elevators, chutes and launders, feeders, weighers and distributors, pumps and air lifts. Transport by wagon, truck, railroad, rope haulage, tramways, etc., is treated in Sec. 20.

Conveyors are applicable when the horizontal distance is relatively short. There is no arbitrary limit beyond which a conveyor system cannot be used, but batch transport, as by cars, is usually more economical when the distance exceeds, say, 2,000 ft. Travel may be horizontal or inclined either up or (more rarely) down, the maximum practicable inclinations varying with the type of conveyor and the nature of material. Any conveyor can be arranged to receive (also to discharge) its load at one or at more than one point.

Types of conveyors. Belt conveyor, the most widely used type, consists of a continuous belt, which is supported at intervals along both its upper and return runs by various kinds of idlers. Pan conveyors are similar to belt conveyors in method of drive and support, but differ in that the carrying surface consists of a series of articulated plates or shallow pans supported on rollers and tied together by pins. Bucket conveyors differ from pan conveyors in that buckets of rectangular horizontal cross-section are substituted for the shallow pans or plates of the latter. The buckets may be continuous, *i.e.*, with overlapping edges, or spaced at definite intervals. Flight conveyor is essentially a trough through which a series of scrapers attached to links or rope is drawn. Screw conveyor pushes material along the bottom of a semicylindrical trough by means of a spiral screw revolving therein.

6. BELT CONVEYOR

Arrangement. The carrying element is a continuous belt passing around a head pulley and a tail pulley, supported on its carrying run by troughing idlers (Fig. 47, *A*), properly spaced, and on the return run by return idlers (Fig. 47, *B*). The simplest form of conveyor is loaded near the tail pulley through a chute and delivers over the head pulley. It is driven through the head pulley by various methods of speed reduction; for other forms of drive, see Fig. 57. This type of conveyor may be run at an inclination (Table 7) which, for ordinary service, is best limited to 18° or 20° (3 7/8 to 4 3/8 in. per ft.). For actual examples, see Table 14. Fig. 48 represents various types of belt-conveyor installations. Minimum radius of curvature to maintain the belt on the troughing idlers when running empty in the fourth arrangement is 125 ft. If this is structurally impossible, the third arrangement

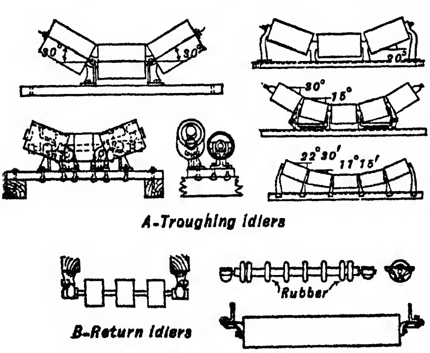

Fig. 47. Belt-conveyor idlers.

is frequently employed, or tandem conveyors may be installed, the horizontal delivering to the inclined.

Table 7. Maximum recommended slopes for belt conveyors (*Robins*)

Material	Slope		Material	Slope	
	Deg.	In. per ft.		Deg.	In. per ft.

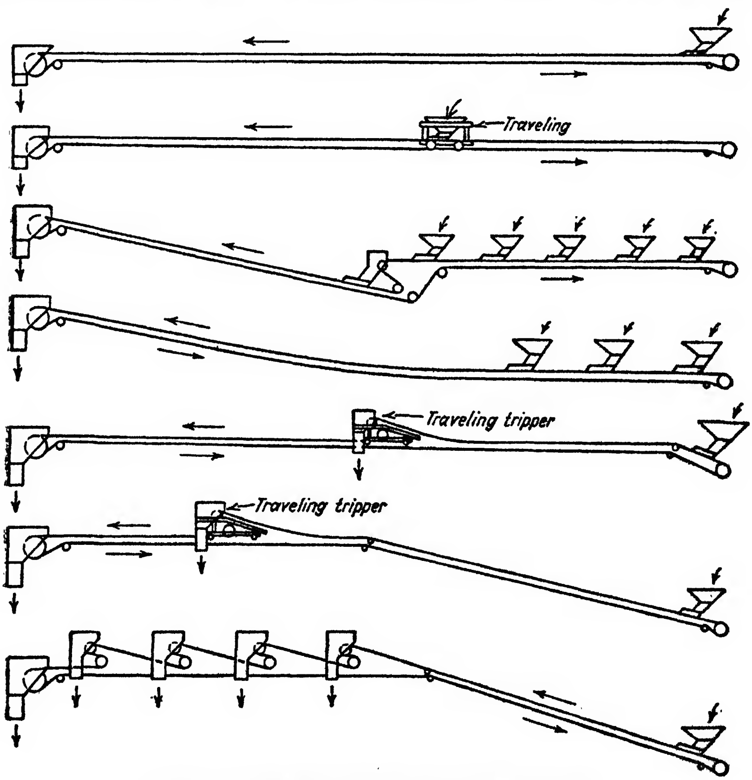

FIG. 48. Arrangements of belt conveyors and trippers.

Conveyor belting is made of several layers or plies of heavy cotton duck most commonly bound together with rubber "friction" and covered completely with a layer of best-grade vulcanized rubber. The strength of the belt depends upon the weight and strength of the duck and the number of plies; also upon the way in which the joints in the plies are spaced. Belt duck is made with the lengthwise or warp threads heavier, stronger and closer together than the transverse or filler threads. The strength of the duck depends upon the weight, which is stated as the number of ounces per piece 36 in. long in the direction of the warp threads and 42 in. wide. The ordinary weights are 28, 32, 36, and 42 oz. The number of plies ranges from 3 for short, narrow belts to 15 for long, wide belts. Table 8 gives recommended limits as to number of plies in rubber belts of various widths. Minimum number depends upon the required belt tension (see p. 39) and the weight (or strength) of the duck (tensile strength of rubber is not considered as adding to ultimate strength of a belt); maximum number of

plies is governed by the number, size, and arrangement of the pulleys in the driving system and by the lateral curvature imposed by the troughing idlers. For safe working tensions on rubber belts composed of various weights of duck, see Table 17. Stepped-ply belts have one or two more plies along both edges than along the middle, the additional plies being continuous across the bottom of the belt, turned upward over the edges, and gaping along the top side; this permits an additional top thickness of rubber cover along the center line, where abrasion is most severe, and promotes lateral flexibility for troughing, without loss of the longitudinal stiffness necessary to avoid sagging and spilling over the edges between idlers. The strength of such a belt is figured on the average number of plies as between middle and edges. One American manufacturer adds a breaker strip of tough, open-weave fabric (not counted as a ply) between uppermost ply and the top cover, turned down and under along the edges, and imbedded in the same friction as the rest of the belt.

Table 8. Recommended number of plies in rubber belts of various widths (*Robins*)

Width, in.	Min.	Max.	Width, in.	Min.	Max.
14	3	5	36	5	9
16	3	5	42	6	10
18	4	5	48	7	11
20	4	6	54	7	13
24	4	6	60	8	15
30	5	7			

The life of belt under a given service depends upon the character of the bond between plies, *i.e.*, FRICTION, and the thickness and quality of the rubber cover. The friction should be of such strength that plies will not separate under the tension of the power pull or in passing around the pulleys. The character of the rubber cover depends upon service demanded. The quality should be of best-grade pure vulcanized rubber in order to resist abrasion and keep out moisture. The minimum economical thickness is about $1/32$ in.; although this is too thin for any but the lightest service as a top cover, it is a common thickness for the bottom. On heavy service the pulley side of the belt usually has a cover $1/16$ in. (sometimes $1/8$ in.) thick and the carrying side up to a usual maximum of $1/4$ in.; belts with $3/8$-in. top covers are installed at CHINO and CHUQUICAMATA (*Q*), and elsewhere for particularly severe service. The friction between cover and belt should be the same as between plies, or greater. The edges of conveyor belts may be subjected to hard wear by rubbing against guide rollers, or the inside of discharge boxes, trippers, and the like. They should, therefore, be protected with extra thicknesses of rubber, firmly bonded to the rest of the belt.

Age, light, and heat are all destructive to rubber belts. Age causes hairline cracking of the cover and this deterioration goes forward most rapidly in sunlight. Aging lessens both the tensile strength and stretch of rubber compounds, deterioration in both qualities being most rapid in the first year and amounting to as much as 50% of the tensile strength and 63% of the stretch (ultimate elongation) in samples tested by the U. S. Bureau of Standards. When the cover breaks down, dirt and moisture get into the belt fabric, the friction is destroyed, plies pull apart, and the belt is ruined. Heat causes a similar deterioration of the rubber cover and also causes breakdown of the friction rubber with consequent loosening of plies and cover. Ordinary rubber belts are not recommended for handling materials hotter than 140° to 150° F. Special belts with under-vulcanized rubber for friction and cover are made for handling hot materials, but even such belts deteriorate rapidly. Other special types for hot materials introduce a layer of woven asbestos between cover and body, or entirely replace the rubber top cover by asbestos fabric.

Life of rubber belt. Table 9 gives examples (*Q*) of belt life, together with the factors by which the life is chiefly determined. Owing to the multiplicity of variables, no consistent trends are evident. The common supposition that a short belt is less durable than a long one, at the same speed and tonnage (owing to the greater frequency of loading impact at a given spot on the belt) is not clearly supported by the available data. In general, coarse ore is seen to be more destructive than fine, as would be expected.

Duplex belt is designed to avoid discarding an entire belt with still serviceable carcass when only the top cover has deteriorated. It consists of a friction-duck belt of suitable thickness, upon which a renewable rubber cover is superimposed. The lower belt, which receives its tension from the drive unit, is the POWER BELT; the upper, or WEAR SHEET, carries the load but is not under tension. The latter is not driven, but moves by frictional contact with the upper run of the power belt and travels slack on the return run. When the wear sheet is worn out, it is replaced by a new one. The power belt remains in service and may outlast several successive wear sheets. The power belt is designed according to power requirements (see p. 37). The wear sheet is usually 4 to 6 in. wider than the power belt, as protection for the latter. It is made of rubber compound reinforced with sufficient duck to overcome any elasticity of the rubber, and to provide body to hold the belt fasteners. The thickness of rubber depends upon the nature of service; for coke, trap rock, ore, etc., a $3/8$-in. rubber wear sheet is customary. Duplex belt cannot be used with a tripper.

Balata belt is multiple-ply canvas belt without covering but impregnated with a solution of balata gum. This belt is said to be somewhat stronger than rubber belt with the same number of plies because the strength of the duck has not been impaired by the heat of vulcanizing. It cannot be used in hot locations because the gum softens at 120° F. It has been used extensively in South Africa but not much in the United States. Robertson and Johnston (*102 J 10*) report lives ranging in days from 414 to 672 and in tons handled from 400,000 to 800,000 for balata belts carrying crusher product (<3-in.) in RAND gold mills, as compared with 345 to 1,700 days and 200,000 to 850,000 tons for rubber belt in similar or harder service.

Steel conveyor belts (*14 CE 109, 182; 16 ibid. 279*). Swedish belts 0.035 in. thick, made of hardened and tempered steel with tensile strength of 80 to 85 tons per sq. in., come in single widths up to 32 in.; greater widths are obtained by joining two or more belts along their edges; one installation near London has a belt 12 ft. 10 in. wide. A German belt 23 $1/2 \times 0.04$-in. has a tensile strength of about 47 tons, or

$2\frac{1}{2}$ times that of a 5-ply reinforced rubber belt of same width. Steel belt 0.04 in. thick requires head pulleys of about 40-in. diameter, against 16 to 20 in. for $\frac{5}{16}$- to $\frac{7}{16}$-in. rubber. Lateral stiffness of a steel belt is sufficient to prevent sagging of its edges between idlers, but the lack of stretch may cause even a loaded belt to lift off the idlers at an upward curve. Steel belts are most commonly operated flat, and usually with skirt boards; capacity of a $23\frac{1}{2}$-in. belt, thus equipped, is about 10% less than that of a $31\frac{1}{2}$-in. troughed rubber belt, or 60 to 80 tons of coal per hr. at a speed of 236 f.p.m. Some steel belts have been troughed by passing over idlers made in the form of helical springs and carried on a self-aligning bearing at each end; such idlers were spaced $5\frac{1}{4}$ ft.; flat return idlers, at $16\frac{1}{2}$ ft. Up to distances of 1,650 ft., and a load of 120 t.p.h., level, a steel belt requires about the same power as a rubber belt. During its life, a rubber belt may carry about twice the tonnage of a steel belt, but on the basis of total tons moved, replacement of a rubber belt costs 60% more, synthetic rubber 120% more than steel.

Idlers are required on both carrying and return runs. Carrying idlers are usually TROUGHED, *i.e.*, set so as to bend the belt up at the sides, and thus increase carrying capacity. Return idlers are straight-faced. The carrying capacity of a belt loaded so that the upper surface of the load comes within a given distance of the edge increases with steepness of troughing up to 45°. The disturbance of the load in passing over the troughing idlers increases, likewise, with increase of side slope, and there is a corresponding increase in belt wear and power consumption. As a result, standard troughing rarely exceeds 30° and some manufacturers recommend a maximum of 20°. At such angles it is easier to keep the belt straight and there is less failure of belts by longitudinal cracking.

Troughing idlers (Fig. 47, *A*) are commonly made with 3 or 5 rollers. In the 3-roll type, used with narrow belts, the usual slopes of the inclined rollers are $22\frac{1}{2}$° and 30°; in the 5-roll type, commonly used for wide belts, the inner rollers may be sloped 15° and the outer, 30°. In some types, the slope of the outer rollers is adjustable. Rollers faced with rubber 1 in. thick are designed for installation under a loading point, to reduce wear from impact on the belt. The cheap grades of rollers are made of cast iron with babbitted hubs running on cast-iron shafts bored for grease-cup lubrication. Ball-bearing and roller-bearing idlers of pressed steel or cast iron show savings in power losses due to idler friction alone of as high as 60%. In general, plain-bearing, grease-lubricated idlers are falling into disuse, since antifriction bearings, of both roller and ball types, can now be applied to belt-conveyor idlers nearly as cheaply as plain bearings; in most cases, the difference in price is approximately 10%. Since the antifriction idlers require lubrication only at infrequent intervals, the saving in maintenance cost more than offsets the difference in price of the idlers. Among 120 conveyors reported in 1939 (*Q*), 90 had antifriction idlers, although plain bearings were still to be found in some large mills.

Troughing idlers are spaced according to width and stiffness of the belt and the load carried. With light loading and ordinary belt a spacing of 5 ft. is allowable, but this should be the limit under any conditions; with heavy loading and wide belts, spacing should be reduced to 3 or $3\frac{1}{2}$ ft., or even less for 54- or 60-in. belts.

Return idlers (Fig. 47, *B*) are made of the same materials and provided with the same types of bearings as troughing idlers, but ordinarily with one pulley only. They are 1 to 2 in. wider than the belt and are spaced 6 to 12 ft., commonly 10 ft. apart. Since it is the carrying and dirty face of the belt that rides the return idlers, these are subject to excessive wear. Corrective measures (aside from cleaning of the belt by sprays, wipers, etc.) include (*a*) chilled cast-iron pulleys with unfinished (therefore hard) faces; (*b*) rubber-faced pulleys; (*c*) rubber-disk rollers (Fig. 47, *B*); the latter may be so adjusted as to stagger the tracks of the disks and thus to distribute the wear; the slight tendency to sag between disks also helps to dislodge adhering material.

Side or guide idlers are set to bear at right angles to the edges of the belt at places where the latter tends to run off the troughing idlers. They are hard on the edges, both wearing the belt and tending to fold it back, causing a crack 1 or 2 in. in from the edge. They should not, therefore, be used unless unavoidable. Belts can sometimes be straightened and side idlers avoided by canting troughing idlers slightly toward head pulley, thus giving the horizontal idler pulley more bearing and more effect on the belt, or they may be skewed.

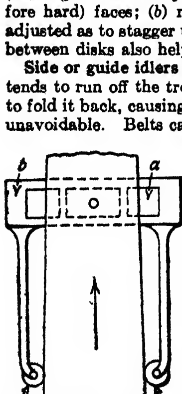

FIG. 49. Automatic guide idler.

Automatic training idlers. The device shown in Fig. 49 has been successful at several of the large copper mills. It consists of an ordinary troughing idler *a* mounted on a pivoted plate *b* with guide idlers *c* carried on projecting arms. If the belt rides, *e.g.*, to the left, the troughing idler is swung backward on the right, which causes the belt to shift toward that side. Other types are now available for both carrying and return runs. The Robins troughing trainer (Fig. 50, *A*) consists essentially of a 3-pulley antifriction idler mounted on a flat steel base. The latter is fitted with a swivel center pin fastened at the center of a sub-base, which is supported at both ends on the conveyor stringers; this permits the troughing idler to pivot on the pin. At the outer edges of the idler end pulleys two ball-bearing guide rollers are mounted on hinged trunnion shafts set per-

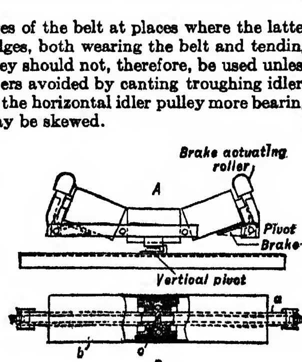

FIG. 50. Automatic training idler (*Robins*).

pendicular to the outside idler pulleys. Each trunnion is hinged at a point below the guide roller and has a short arm extending below the hinge and furnished at its end with a small friction block curved to fit the outside diameter of the idler pulley. Normally, these brake blocks hang free of the pulleys, but they make contact when a slight touch of the belt presses against the guide pulley. This causes a slight drag on one side and swings the idler on its axis, thus steering the belt back to its central position. The return-belt trainer (Fig. 50, *B*) consists of three principal parts: a hollow stationary shaft *a* supported by brackets on the conveyor stringers, a tubular roller, and an antifriction bearing *c* centrally located inside the roller and fastened to the shaft. The antifriction bearing is pivoted on a fixed swivel pin located at the center of the roller and inclined forward about 30°. The roller not only rotates on its bearing but also is free to rock about the inclined pivot. If the weight of the belt falls more on one side than on the other, the heavy side forces the roller downward and forward, skewing the roller, whereupon the belt climbs to the high side and moves toward the center of the conveyor.

Pulleys should be crown-faced, 1 or 2 in. wider than the belt, mounted on sufficiently heavy shafts to insure against bending, and the driving pulley (usually the head pulley) should be securely keyed and clamped to the drive shaft. The diameter in inches should be at least 5 times the number of plies; on 114 conveyors reported (*Q*), diameters of head pulleys ranged from 3 to 9 in. per ply (6 to 7 in. most frequently). Robertson and Johnston (*102 J 15*) tell of an 8-ply belt on a 20-in. pulley that separated along the plies in 4 mo. The pulley at the other end of the conveyor is fitted with a TAKE-UP MECHANISM to compensate for small changes in belt length and hold belt tension constant. The usual allowance is 12 to 18 in. for belts under 100-ft. centers; 18 to 24 in. from 100 to 200 ft., and 30 to 36 in. for longer belts. Fig. 51, *a*, shows a common type of screw-adjusted take-up. On conveyors longer than about 400 ft., general practice is to use a counterweighed take-up, of which two types are shown in Fig. 51, *b* and *c*. Such automatic take-ups are also necessary on conveyors of any length equipped with automatic weighing or feed-regulating devices (Arts. 22, 23).

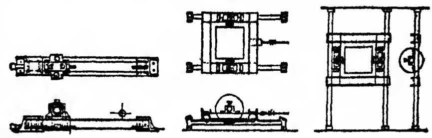

FIG. 51. Take-ups for belt conveyors.

Table 10. Widths of troughed belts recommended for materials of various maximum size (*Robins*)

Width, in.	Maximum size, in. Sized	Unsized	Width, in.	Maximum size, in. Sized	Unsized
14	2	2 1/2	36	9	18
16	2 1/2	3	42	11	20
18	3	4	48	14	24
20	3 1/2	5	54	15	28
24	4 1/2	8	60	16	30
30	7	14			

Capacity depends upon width of belt, degree of troughing, speed, slope, size and specific gravity of the material carried, and its angle of repose.

Width of belt is determined primarily by the size of material to be carried, after that by the capacity desired at suitable speed (see below). A given width will carry coarser material if accompanied by a considerable proportion of fines (Table 10 and Fig. 52). Minimum width is preferably 14 in., as a narrower belt will not conform to the troughing idlers when empty unless of very light weight; 60 in. is the present maximum width available. The loading chute should not exceed two-thirds the projected width of the troughed belt, if material is to be prevented from falling off, and the chute should be more than three times the size of the particles, if they are of uniform size, and more than twice as large as the largest where mixed sizes are handled. Troughing allows the load to be carried nearer the edge of the belt than is safe on a flat belt.

Table 11. Capacities of belt conveyors in American mills (*Q*)

[Tons per hour at uniform speed of 100 ft. per min.]

Width, in.	Extreme range	Approx. aver.
12	3 to 17	10
14	3 to 29	13
16	16 to 53	32
18	22 to 92	50
20	3 to 78	50
22	27 to 75	45
24	14 to 145	70
28	75 to 100	87
30	17 to 200	110
36	80 to 290	190
42	29 to 440	160
48	157 to 450	250
54	266 to 405	330
60	240 to 293	270

Capacity formulas. Manufacturers give formulas for capacity in terms of belt width in the form $V = KW^2$, in which V = cu. ft. per hr. at 100 ft. per min. belt speed, W = width of belt, in., and K is a factor having a constant value of 3.5 (*Jeffrey*) or a value ranging from 3.14 for 14-in. to 4.11 for 60-in. belts (*Robins*); *i.e.*, capacity (at constant speed) increases slightly faster than square of width. Fig. 52 coordinates capacities in tons and in cubic feet per hour with width and speed of belt and with maximum advisable size of material. In practice, wide deviations from recommended best conditions are often compelled by local circumstances, of which probably the most important is the necessary provision for peak loads.

Table 11, based on about 150 belt conveyors in American mills (*Q*), with capacities reduced to a uniform speed of 100 f.p.m., shows the variations that occur. So far as can be judged by plotting such

discordant data, installations show a tendency to relate capacity more nearly to width than to square of width. Capacity (at given speed) is but slightly affected by size of material, since conveyors of the same width are frequently reported to carry almost identical tonnages of coarse, medium, and fine ores.

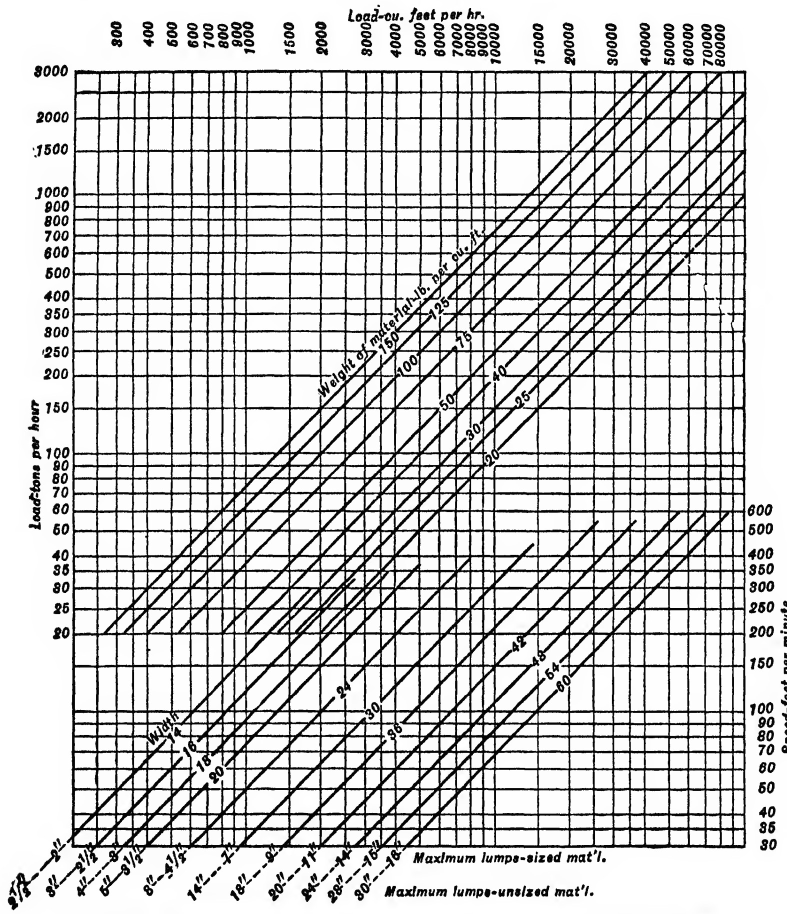

Fig. 52. Width, speed, and capacity of troughed belt conveyors (*after Robins*).

Speed depends upon the size of particles carried, character of material, width and slope of belt, and capacity of the loading device. The limiting speed in every case is that at which material is blown off the belt by air resistance. With small material that flows easily and steadily in a loading spout so that the belt is evenly loaded, belts may be run fast, but with coarse material the feed is necessarily irregular and bare spots will be left on a belt run too fast. With large lumps there is danger of throwing material off the belt in passing idlers when the belt is run too fast. If material is friable and breakage undesirable, as, for instance with coke and coal conveyors, belts must be run slowly if excessive breakage at the discharge end is to be avoided. Ordinary idlers are not carefully turned and balanced as is necessary for high speeds and will rattle and vibrate at speeds much over 400 f.p.m. This limitation does not apply with well-made ball- or roller-bearing idlers. Minimum speed is limited to the necessity for throwing material clear of the head pulley, if headroom is an important consideration. The minimum speed to effect clean discharge is about 150 f.p.m. Lower speed is necessary on inclined runs than on horizontal owing to the greater difficulty in bringing the loading material up to speed.

Table 12 gives maximum advisable speeds for troughed belts carrying various materials; in general practice, a reduction of 25% from these maxima is recommended.

Table 12. Maximum advisable speeds (f.p.m.) for troughed belt conveyors

Apart from the physical limitations stated, a good rule is to run the belt at as low a speed as will carry the required load. In this way the percentage of the total load that comes into contact with the belt surface is least, the number of times that any given spot on the belt is subject to the abrasive action of the oncoming stream is a minimum, and power consumption and internal belt strain are least. Table 13 gives a few examples of notably high speeds.

Slope. The maximum allowable slope varies with the size and shape of material, method of loading, speed of belt, and moisture content. (See Table 7.) Coarse, rounded material requires a flatter slope than fine material or flat slabs; mixed sizes can be raised on a steeper slope than sized material, and uniform feed permits steeper slope than intermittent feed. At normal speeds a slope of 18° is safe for <3- or <4-in. material; <$^1/_4$-in. dry material can be run at 22°, and at 25 or 26° if the conveyor is speeded to 350 or 400 f.p.m.; sand tailing with considerable moisture (15 to 20%) may run backward at 15°, but <2-mm. tailing containing 28 to 30% water was readily carried at a slope of 13° 10′ at the Bonne Terre mill.

Table 14 gives data on conveyors operating at close to maximum inclination (*Q*).

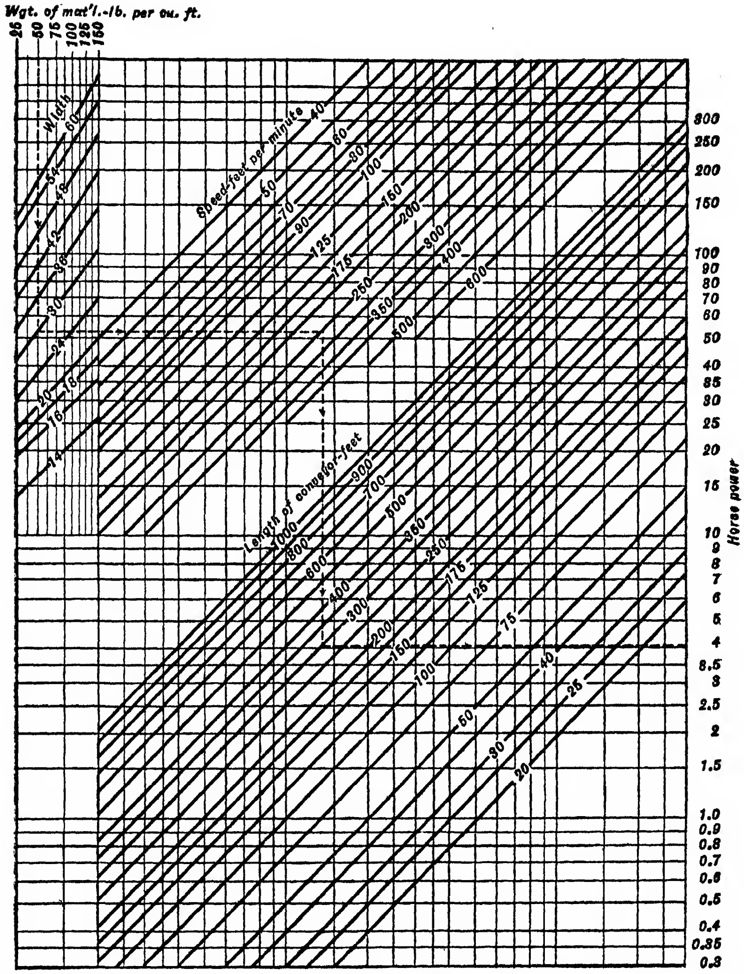
8	0.270	0.291
9	0.291	0.315
10	0.312	0.340

Vertical transition curve. The inclined portion of the belt may lift off its idlers in installations like the fourth in Fig. 48. The worst condition arises on starting, and at the instant when the whole horizontal portion is fully loaded, while the curved and inclined portions are still entirely empty. The minimum curvature necessary to avoid lift of the belt can be calculated from the weight of the belt per ft. and its momentary tension at the point of curvature (see p. 39). Jeffrey Manufacturing Co. gives the formula for a fully loaded belt, $R = 1.1P/w$, in which R = minimum radius, ft.; P = total belt tension at point of curvature, lb.; w = weight of empty belt, lb. per lin. ft. For full but intermittent loading, the numerical factor should be increased to 1.3 to 1.5. Weight of belt is best ascertained from manufacturers' catalogues. Table 15 gives approximate weights of one standard brand, having $^1/_8$-in. top and $^1/_{32}$-in. bottom cover, in lb. per lin. ft. and per in. of width; for other thicknesses of cover, add or subtract 0.01733 lb. per lin. ft. per in. width for each $^1/_{32}$ in. of rubber.

Power consumption depends upon the load carried, the inclination and speed of the belt, the spacing and kind of idlers and size of pulleys. The general formula is Hp. = $PS/33{,}000$, where P = pull on belt in lb. and S = speed in ft. per min. P is made up, in horizontal conveyors, of idler friction due to the empty belt plus that due to the load and may be written as $P = Lfd(X + Y + Z)/D$ where L = length in ft. c-c. of tail and head pulleys; d and D are the diameters, respectively, of the idler bearings and the idler pulleys; f = coefficient of idler-bearing friction; X = weight of revolving part of idlers per ft. of length including troughing and return, Y = weight of 2 ft. of empty belt (carrying plus return) and Z = weight of material on 1 ft. of belt. By experiment, $f = 0.35$ for ordinary grease-lubricated idlers. $Z = 2000T/60S = 33.3T/S$, where T = tons per hour. Clearing and substituting, Hp. $= \dfrac{LSd}{100{,}000D}\left(X + Y + \dfrac{33.3T}{S}\right)$ (approximately). Fig. 53 correlates length, width, speed, and power for fully loaded horizontal conveyors equipped with roller-bearing idlers; for plain bearings, add 80% to power. For an inclined conveyor the weight of the down-going belt balances that of the rising belt, so that the added power consumption is only that due to the load of material. This may be written Hp. $= 2000TH/60(33{,}000) = TH/990$ (or, more conveniently, $TH \times 0.00101$), where H = lift in ft. The additional friction losses at the end pulleys require allowance. Fig. 54 plots the percentages by which the total driving-shaft power (for horizontal travel plus lift, if any), ascertained as above, should be increased to cover pulley losses, assuming a single-pulley head drive; the data assume the pulleys to be mounted on roller-bearing pillow blocks; for plain bearings, double the allowances. Tandem or center drives require a further addition of 4% for plain, or 2% for roller-bearing pillow blocks on the extra pulleys. If a tripper is employed, pulley friction has to be overcome in both fixed and automatic types, the latter also drawing its motive power from the conveyor belt; Fig. 55 shows the power requirements for both types, excluding that involved in lifting the material an additional distance which may be taken as averaging 5 ft. (corresponding to Hp. $= 5T/990$). Transmission and speed reduction incur a power loss of about 5% for each belt or open gear reduction; the same allowance will cover the loss in a modern oil-enclosed reducer regardless of the number of reductions. An approximate rule, frequently used for horsepower of the conveyor alone, is: Hp. = 2% *of the tons per hr. for every 100 ft. of length plus 1% of the tons per hr. for each 10 ft. vertical lift,* or Hp. $= (0.02L/100 + 0.01H/10)T$.



Enter at "w'g't of mat'l" and follow parallel to broken line.

Fig. 53. Power required at drive shaft of fully loaded horizontal belt conveyor with roller-bearing idlers; excluding terminal and tripper losses (*after Robins*).

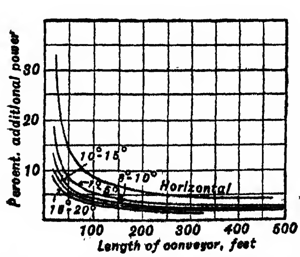


Fig. 54. Corrections applied to Fig. 53 for power losses at head and tail pulley.

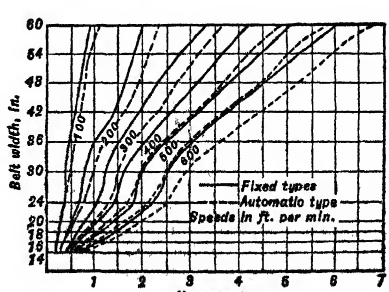

Fig. 55. Power for trippers (see text reference).

Laboratory tests indicate that the coefficient of friction for oil-lubricated idlers is about 60%, and for roller-bearing idlers 25% of that for grease-lubricated idlers. This does not mean, however, that 0.21 and 0.09 respectively can be substituted for 0.35 (= f above), on account of the fact the 0.35 takes into account many things besides actual idler friction. *Hetzel* gives the following empirical formula for long conveyors with ball-bearing idlers: Hp. = $(0.0087L/100 + 0.01H/10)T$. Table 16 gives power consumed by horizontal conveyors in a few American mills; Table 14 gives corresponding data on some conveyors operating at notably steep inclinations.

Maximum belt tension. Having ascertained the power to be applied to the driving pulley, by summing all of the factors enumerated above except transmission and reduction losses, the effective or power pull is $P_p = \dfrac{\text{Hp.} \times 33{,}000}{S} = P_t - P_s$, where S = ft. per min., P_t = maximum tension on the belt, which occurs on the tight side of the pulley, and P_s = tension on the slack side, taking P_p, P_t, and P_s in lb. To induce motion without slip-

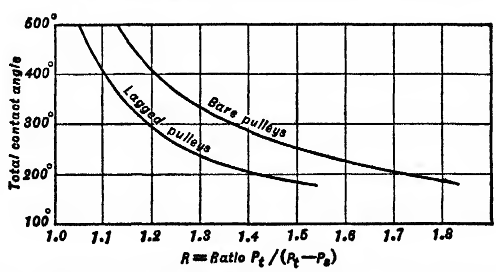

FIG. 56. Factors for converting effective pull to maximum belt tension.

ping requires a certain ratio R between maximum and effective pulls, or $R = P_t/(P_t - P_s)$; whence $P_t = RP_p$. The value of R depends upon the arc of contact and the coefficient of friction between belt and pulley, the latter usually accepted as 0.25 for bare cast-iron pulleys and 0.35 for rubber-lagged pulleys. Fig. 56 gives values for R adopted by the principal manufacturers. If a 180° turn over a single pulley will not develop the required pull, one of the driving methods illustrated in Fig. 57 may be adopted; tandem drive is often installed at or near the mid-length of a conveyor. Tandem pulleys should

be geared together; where great power is required, each of the pulleys may be driven by a separate motor.

Some additional tension is introduced by the weight of the belt when it is inclined at more than a very small angle. In Fig. 58, if B = weight of each run of the belt and i is the angle of inclination, the tension at the head pulley due to each run of the belt = $B \sin i$. The load on the idlers is $B \cos i$, and their resistance to turning under this load, *i.e.*, their resistance to a down hill run, is $(fdB \cos i)/D$. The added tension on each run is, therefore,

$$P_i = B\left(\sin i - f\frac{d}{D}\cos i\right).$$

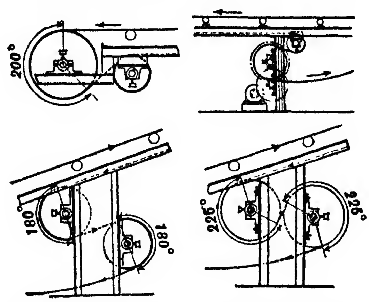

FIG. 57. Driving arrangements for conveyor belts.

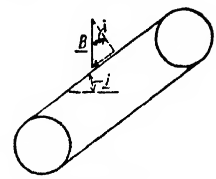

FIG. 58.

Selection of belt. Table 17 gives recommended safe working tensions, in pounds per inch of width per ply, for rubber belts operating under two sets of conditions: (A) Fed mechanically, overloading prevented, take-up device to avoid over-stressing; also applies to temporary and other conveyors the life of which is not important. (B) Not fed mechanically, overloading and overstressing possible, maximum life desirable; also applies to any conveyor having a vertical lift of 100 ft. or more, due to additional tension caused by weight of descending run of the belt. The maximum belt tension P_t having been computed, as above, select a safe working tension t from Table 17; then the required number of plies = $P_t/(t \times \text{width, in.})$. Fig. 59 correlates the data applicable to a belt composed of 28-oz. duck, given the driving power.

Table 17. Safe working tensions in rubber conveyor belts (*Robins*)

[Pounds per inch width per ply]

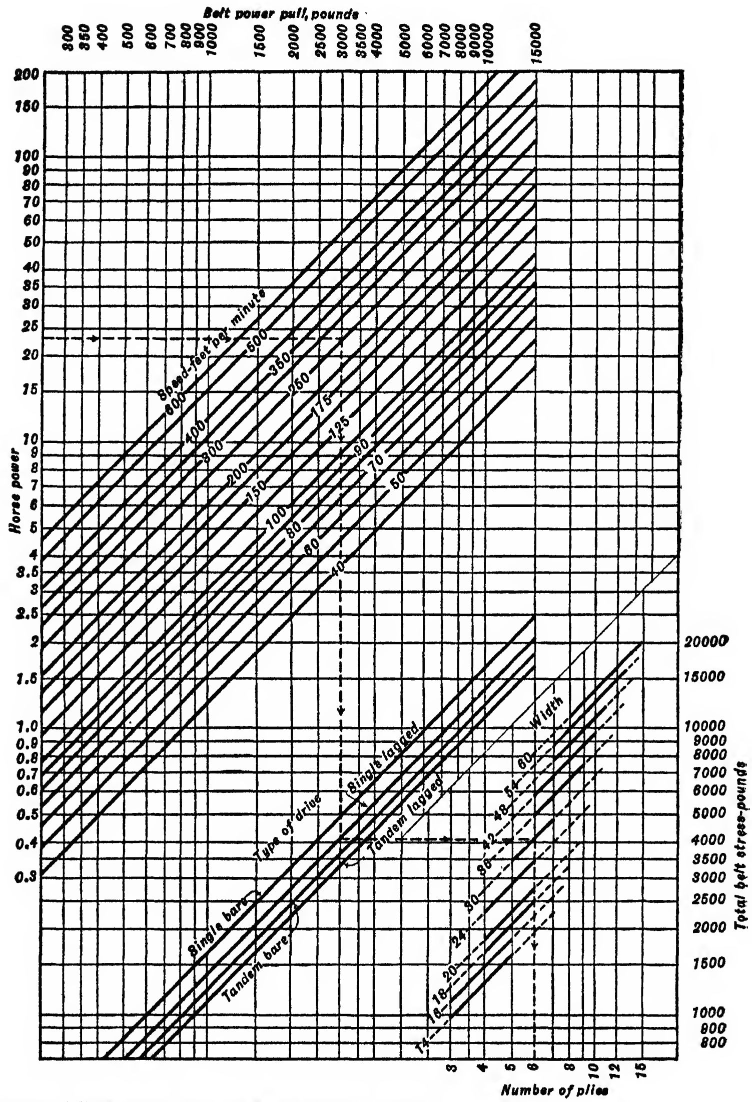
Weight of duck, oz.	Condition A	Condition B
28	23	20
32	27	23
36	30	25
42	40	35

Feed to conveyors should be so delivered that when it reaches the belt it will be moving in the same direction as the belt, and as nearly as possible at the same velocity. This can be accomplished by inclining the feed chute at such an angle that the horizontal component of velocity of the rock leaving will be about the same as the speed of the belt, but as this may develop an undesirably high falling velocity, injurious to the belt, the slope is generally a compromise, or special arrangements are provided to relieve the belt of vertical shocks. Large pieces falling directly on the belt are liable to cut it.

Special feed chutes may have a screen or grate in the bottom so that finer material falls on the belt first and acts as a cushion for larger pieces which will not pass the grate; clogging of the grate makes this device ineffective and it will not be satisfactory for all materials. A chute with sides converging toward the end, or a V-notch in the chute bottom, acts similarly and does not clog. The end of the chute may be made in a long curve ending at a tangent parallel to the belt and may thus present the feed with little vertical force. This requires giving the feed sufficient velocity to pass along the curved part; considerable wear will take place on the chute. Other specially shaped chutes designed to keep the finer material near the bottom are also used.

The feed should be so delivered that it makes first contact with the belt just beyond an idler pulley; the belt then yields sufficiently to take up impact gradually and to avoid cutting; rubber-cushioned idlers are available to serve the same purpose. To bring the material up to speed, especially if the belt is traveling fast, results in considerable slipping and tumbling with corresponding wear; this is more pronounced with inclined belts.

Skirt boards should always be provided to keep material from running off the belt before it has become settled on it. They are made of wood or steel and have a strip of belting nailed or bolted onto their lower edges, to close the space between the boards and the belt. On level conveyors skirt boards need be only 3 or 4 ft. long, but on rapid or inclined conveyors they should be longer; on steep inclined conveyors carrying coarse material they are sometimes provided the entire length to prevent spill of any pieces that slide or roll back.



Enter on "Horsepower" and proceed parallel to dotted line.

Fig. 59. Plies of 28-oz. duck required in conveyor belts of standard widths.

Discharge of conveyors may be by fall at the head pulley or by some device which removes the load before the head pulley is reached. The most satisfactory device of this sort is a TRIPPER (Fig. 60). This is usually mounted on wheels running on tracks so that the load can be delivered at several points, as over a long bin or into several bins; the discharge chute delivers to one or both sides of the belt. Trippers may be moved by hand, by head and tail ropes from a reversible hoisting drum, or by individual motor mounted on the tripper, or they may be

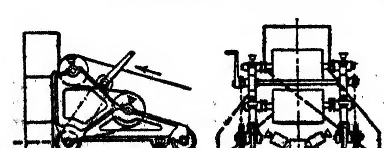


Fig. 60. Tripper for belt conveyor.

automatic, traveling backward and forward under power derived from the belt. Plows or scrapers to remove the load cause extra wear on the belt and when scraping only to one side they cause the belt to run out of line. The length of additional belt for travel around tripper pulleys ranges from 10 ft. for small to 14 ft. for larger trippers. For additional power required by trippers, see Fig. 55.

Trajectory of end discharge. In some cases, as in design of a receiving chute, it becomes important to calculate the trajectory of the falling stream; this, as well as the point of departure from the belt, depends upon belt speed, pulley diameter, and coefficient of friction of the material against the belt, the latter being affected by the nature of the material and its moisture content. Computations fail with sticky materials.

Gates (*141 #1 J 55*) gives the diagram in Fig. 61 for ascertaining the point of departure of dry materials, assumed to be moving at belt velocity and in a direction tangent to the pulley at that point. Thus A and B indicate, respectively, the points of departure from a 46-in. pulley at 34 r.p.m. (veloc., 409 f.p.m.), and from an 18-in. pulley at 40 r.p.m. (veloc., 188.5 ft. per min.). Angles may be scaled from the chart. If the r.p.m. curve touches or falls inside the diameter curve, the material merely drops vertically.

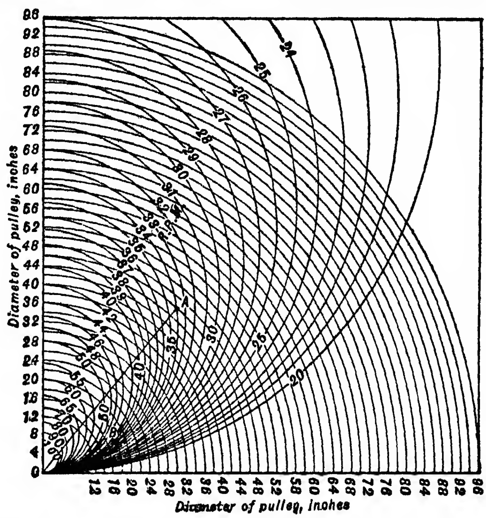

Fig. 61. Gates diagram for locating point of discharge from a belt conveyor.

Booth (*135 J 552*), at the N'Kana mine, observed that actual trajectories invariably fell outside those calculated on the assumption that ore starts its fall at belt speed. In one case with a speed of 383 f.p.m., and pulley diam. plus belt thickness, 42 1/2 in., the stream was 8 1/2 in. outside its theoretical position when it had fallen 53 in. below center of pulley. The discrepancy was traced (with mathematical support) to downward sliding of the ore on the belt after passing the angle corresponding to its coefficient of friction; as its motion was still constrained to circular, this added velocity increased its centrifugal momentum at the point of departure, with the effect noted. Booth gives the graph in Fig. 62. Enter the bottom of the rectangular diagram at the belt velocity in ft. per min. Move up to the radial line corresponding to pulley diameter, and thence horizontally to extreme left. From this point draw a line tangent to the curved line at lower right, and from corner A draw a line parallel with this tangent to cut the vertical line B; at intersection, read the angular displacement (from vertical) at the point of departure. With this angle, re-enter the left side of the rectangular chart; move horizontally to intersect the pulley-diameter line, and thence vertically downward to read actual ore velocity at point of departure. For illustration, the dotted lines give the procedure for a belt moving at 358 f.p.m. over a 30-in. pulley, showing that the ore leaves the belt with a velocity of 372 f.p.m. (or 14 f.p.m. faster than belt travel) at a point 19° beyond the vertical. Both of these factors having been ascertained, the trajectory may then be plotted by the conventional method shown in Fig. 63. Draw a circle at any convenient scale representing pulley diameter plus belt thickness and locate the point of departure. At this point, P, construct a tangent, on which lay off equal distances L to the scale: 0.01 in. = 1 f.p.m. of ore velocity at P. Number the dividing points consecutively, and from each one drop an ordinate as scheduled in Table 18; lower ends of the ordinates trace the trajectory.

If, in Fig. 63, the velocity and diameter lines intersect above the top of the diagram, start the trajectory horizontally from the top of the pulley or (with an inclined belt) in the projected direction of the belt (whichever throws farther), using belt speed in the determination of L.

Table 18. Ordinates for tracing trajectories (see Fig. 63)

No.	In.	No.	In.	No.	In.
1	0.50	6	17.375	11	58.375
2	1.875	7	23.375	12	69.50
3	4.875	8	30.875	13	81.875
4	7.75	9	39.125	14	94.50
5	12.125	10	48.25	15	108.50

Cleaning the belt of material that sticks is done by scrapers or revolving brushes placed under the head pulley or under the first pulley of a tripper; water sprays are used in some instances. Some types of revolving brushes are made of heavy fiber bristles mounted on a wooden core supported on a shaft which receives power from the conveyor drive shaft. Another type consists of spirally molded rubber mounted on a steel tube carried by a driving shaft. This receives power through a spur-gear transmission totally enclosed in an oil-tight case and driven either from the conveyor drive shaft by chain

and sprocket, or individually by a small electric motor. Bristle brushes wear out rapidly and are suitable only for nonabrasive materials; neither are they applicable to belts handling sticky material, for which the rubber brush is preferable.

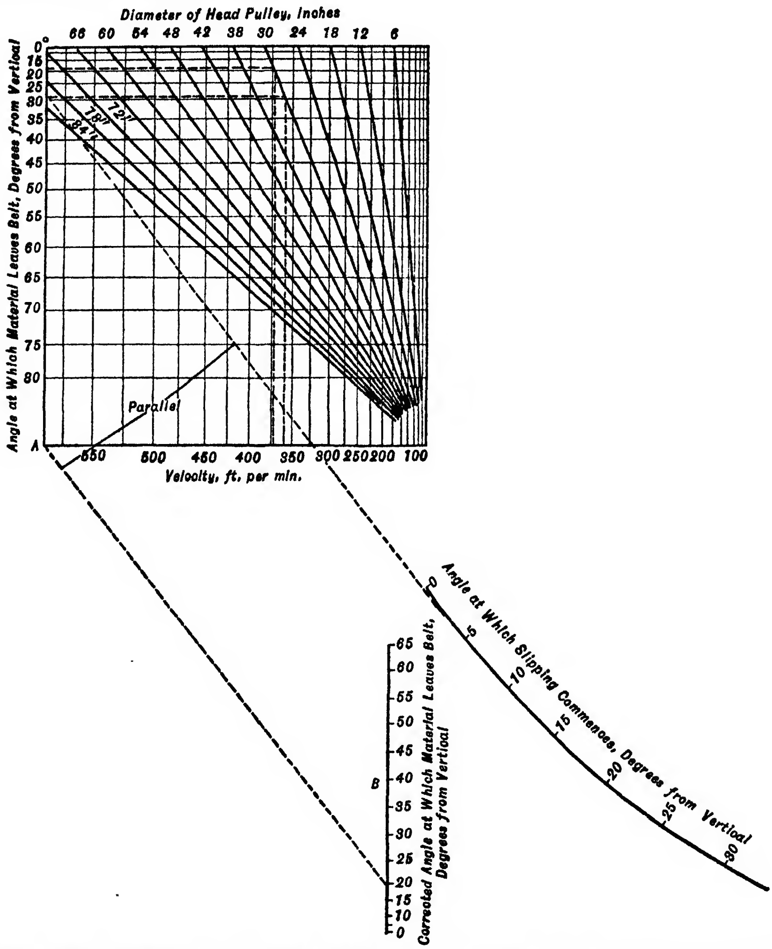

Fig. 62. Booth diagram for ore velocity and discharge point on leaving belt conveyor (see text for use).

Support for a conveyor usually consists of wood or steel bents with longitudinal stringers across the caps on which the idlers are mounted; short conveyors are readily supported on the stringers alone. A light flooring ($^7/_8$-in. boards or thin steel sheet) is generally placed across the stringers between the upper and lower run of the belt to prevent material from falling onto the return side and possibly cutting the belt as it passes around the tail pulley.

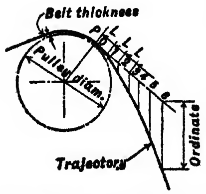

Fig. 63. Method of tracing trajectory of belt-conveyor discharge (see Table 18).

Performance of a very large installation at H. C. Frick Coke Co. Colonial mine, East Roscoe, Pa. (*71 A 1123*), is shown in Table 19. All of the conveyors were 48-in. except No. 20, which was 60-in. The duty was transportation of run-of-mine bituminous coal from underground loading chutes to barges 4.3 mi. distant.

Table 20 gives details of an elaborate system of belt conveyors installed by Palmetto Quarries Co., Columbia, S. C., for handling crushed granite from quarry floor, through crushing, screening, and washing plants, to RR. cars (*84 #10 PQ 27*). Conveyors *B*, *C*, and *D*, all inclined at 18°, were substituted for derrick and cableway previously used for hoisting from the bottom of the quarry, about 230 ft. below ground level.

Downhill belt conveying. At PERMANENTE cement plant, Calif. (*148 A 374*), part of an 1,150-ft. fall for <6-in. rock from quarry to plant is obtained on three successive 36-in. belts (with two transfer stations): No. 1, 1,630 ft. long @ − 4° 30′; No. 2, 2,225 ft. @ − 6°; No. 3, 1,300 ft. @ − 10° 30′; total fall, 600 ft. Each belt moves at 500 f.p.m. and is controlled by a 200-hp. motor; when loaded to capacity, the three conveyors return about 260 kw.

Cost of belt conveying. Table 21 gives examples of cost, together with the factors on which cost chiefly depends; all but a few of the conveyors are equipped with antifriction bearings.

7. PAN AND APRON CONVEYORS

Pan conveyors are used for lump material that would cut a belt, or for finer material when loading pressures would be excessive for belts, or when, on account of low speed imposed by other conditions, belt tension is excessive. They consist of articulated steel pans carried on chains; the chains run over head and tail sprockets and are supported on the run by wheels or rollers running on tracks on the supporting frame. Different types of pans are shown in Fig. 64.

The shallow V-shaped pan *a* has the advantage that it discharges higher at the head sprocket than the other types, but the stiffness is not so great on wide conveyors as that of the deeper pans and it

Table 22. Capacity of pan and apron conveyors at 20 ft. per minute (*a*) (*After Stephens-Adamson*)

a Based on material weighing 100 lb. per cu. ft. For other specific weights and for other speeds capacities are in direct proportion.

cannot be used on as steep slopes (15 to 20° max.). Pan *b* can be used up to 25° slope; it is stiff and well suited for hardwood lining, as shown. With such lining the conveyor becomes substantially of the apron type and should not be used on slopes greater than 15°. Pan *c* can be used on slopes up to 30°.

Pans are made of 1/4- to 3/8-in. steel; they are replaceable on the chain links, but if wear is great they should be lined with metal or hardwood.

Chains are subject to great tension on account of the slow speeds at which the conveyors are usually run; working loads may run as high as 25,000 lb., but it is better to keep down to 8,000 to 10,000 lb. per sq. in. pin pressures, if possible. For light service, malleable roller chain is used (Fig. 72, *D*); for heavy service, steel-bushed roller chain; and for heavy feeder service, heavy all-steel roller chain.

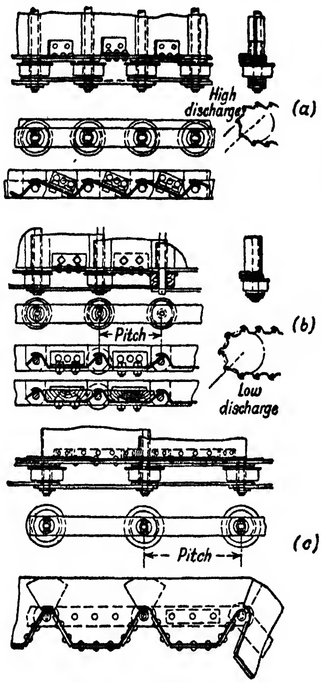

Fig. 64. Pan conveyors.

Apron conveyors (Fig. 65) are essentially very shallow pan conveyors; in some cases the pans have no ends and spill is prevented by skirt boards. They are used for horizontal transport or inclinations up to 10° or 12°. Their principal application is in heavy feeder service. The lighter type (*a*) has the rollers at the side of the pans; in the heavy type (*b*) the rollers are underneath in order to cut down the unsupported span.

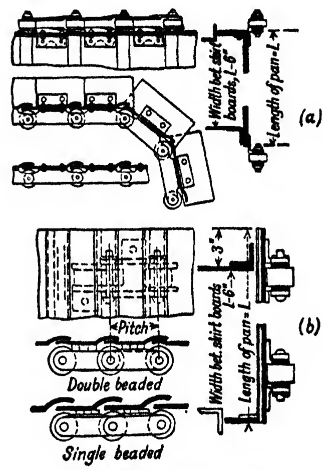

Fig. 65. Apron conveyors.

Speed of pan and apron conveyors in metal-concentration plants rarely exceeds 50 f.p.m. and when they are used as feeders, speed usually ranges between 2.5 and 10 f.p.m. In the latter service they should be driven by some variable-speed device capable of ready speed change and convenient stopping and starting. In coal handling, the usual speeds are from 50 to 100 f.p.m.

Capacity may be estimated from Table 22. Ordinarily actual capacities will be below the tabular figures on account of irregularities in feeding; these irregularities are greater the higher the speed of the conveyor.

Power consumption. Stephens-Adamson Co. states that the chain pull at the head sprocket with machined bushed-roller chain, well lubricated, is 12% of the combined weight of load and conveyor for level conveyors; with rough, malleable roller chain, the corresponding figure is 24%; inclination lessens the frictional resistance in proportion to the cosine of the angle with the horizontal. The following formulas give chain pull P and horsepower.

For steel-bushed roller chain:

$$P = (4L + 33.3H)T/S + 0.24LW,$$
$$\text{Hp.} = (TL/8250 + SLW/137{,}500 + HT/990)(1 + 0.1N).$$

For rough malleable chain:

$$P = (8L + 33.3H)T/S + 0.48LW,$$
$$\text{Hp.} = (TL/4125 + SLW/68{,}750 + HT/990)(1 + 0.1N).$$

where L = horizontal projection of conveyor, ft.; H = total vertical lift, ft.; W = weight per ft. of conveyor, lb.; T = tons of material carried per hr.; S = speed, ft. per min.; N = number of gear-speed reductions. Weights of a standard make of apron conveyor (excluding terminals) with malleable-iron links, per ft. of length c-c. and per in. of width, range from 2 to 1.55 lb. for light, 3 to 2.11 lb. for medium, and 4.44 to 2.75 lb. for heavy duty; with steel links, thimbles, and pins, weights range from 4.25 to 3.0 lb. for light, 4.67 to 3.83 lb. for medium, and 6.33 to 4.55 lb. for heavy duty; in each case, the smaller unit weight applies to the wider apron.

Table 23 gives data on a few installations of this type in American mills.

e Variable, 4 to 20.

Skirt boards for apron conveyors should be placed about 3 in. inside the edge of the pans (Fig. 65) and should clear the pans just enough to insure against rubbing; this excludes entry of any material underneath the boards that cannot be broken without stalling the conveyor. Heavy angles lined with plate or heavy timbers lined with longitudinal steel straps are the usual skirt-board material; they must be stiff enough, as above indicated, to crush small particles between them and the pans, if necessary, without any noticeable deformation.

8. BUCKET CONVEYOR

Bucket conveyor (Fig. 66) consists of a continuous line of buckets attached by pivots to two endless roller chains running on tracks and driven by sprockets. The buckets are

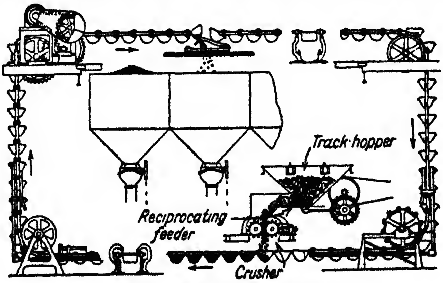

Fig. 66. Bucket conveyors.

so pivoted that they always remain in an upright position. The carrier can transport either horizontally or vertically and thus is both a conveyor and an elevator. The path

need not be rectangular but may be made almost any desired polygonal shape. Buckets are dumped by means of a cam placed to engage a shoe on the bucket, thus turning it into dumping position; the device can be placed anywhere on a horizontal or slightly inclined run. The buckets have overlapping edges to avoid spilling when fed from a continuous stream; a special tripper reverses the overlap on the return trip so that it will not interfere as the buckets start rising. The carrier has been used most in coal handling but it is a very satisfactory device for use at custom mills and smelters where several varieties of material must be moved in and out of separate bins; thus mixed charges can be made up with one carrier fed simultaneously from a number of chutes.

Sizes and usual speeds of Peck carriers (Link-Belt Co.) are shown in Table 24.

Table 24. Size, capacity and speed of Peck carriers (*Link-Belt Co.*)

9. FLIGHT CONVEYOR

Flight conveyors (Fig. 67) consist of chain-drawn scrapers or flights running in a trough through which they drag the material to be transported. The trough may be placed on either the upper or lower or on both runs of the chain. Flights are usually made of malleable iron or steel, and the troughs of steel lined with steel or cast-iron wearing plates. Troughs may be placed at any angle from the horizontal to about 30°, but capacity is very much lowered as inclination increases.

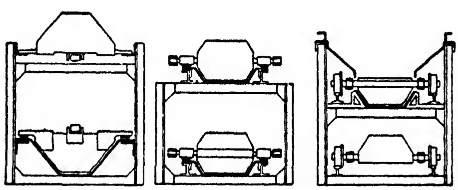

FIG. 67. Flight conveyors.

Speed. The usual range is from 50 to 100 f.p.m.
Capacity may be estimated from Table 25.

Table 25. Capacity of flight conveyors (*After Stephens-Adamson*)

8×24	....	....	135	90	120	96	72
10×24	....	....	172	115	150	120	90

Power consumption. L. D. Moss (*Peele*) states that for level conveyors anthracite requires about 3 hp-hr. per ton-mile; bituminous coal, 3.5 to 4; and ashes, 4 to 6. Additional horsepower required for elevation may be obtained from the formula: Hp. = *tons per hr.* × *ft. lifted* ÷ 990. Add 10% for each gear speed reduction at the head sprocket to the total for horizontal transport plus elevation.

Applicability. Flight conveyors are rarely used in metal-concentrating mills on account of excessive wear but are frequently used in coal washeries, where the material handled is less abrasive than ores. They are sometimes very useful for transporting short distances in confined spaces where no elevation may be lost or even slight elevation must be gained. Table 26 gives data on several flight conveyors in mills of the New Jersey Zinc Co.

Table 26. Flight conveyors in mills of New Jersey Zinc Co.

10. SCREW CONVEYOR

Screw conveyor is a continuous spiral flight encircling and fastened to a shaft lying within a horizontal or inclined trough; rotation of the flight pushes material forward. The shaft is supported on a bearing at each end and, if necessary to maintain alignment, may also be carried on hangers at one or more intermediate points; such bearings are variously equipped, as stated in Table 27. The shaft is rotated at one end by pulley and belt, sprocket and chain, or bevel gear; recommended maximum speeds are given in Table 28. Horizontal or slightly inclined troughs are commonly open on top, or covered by an easily removable lid; at slopes above, say, 30°, a pipe may be substituted for the trough. Clearance between flight and trough should be about equal to the average size of lumps in the feed when these lumps consist of material not readily broken during transit. The maximum permissible feed size (Table 29) depends upon the diameter of the flight, the percentages of coarse and fine sizes in the feed, and the resistance of lump material to crushing; if the feed is all coarse, permissible maximum size is smaller than if lumps constitute only 20 to 25% of the feed. Feed may be introduced through chute or spout at an end or other points; one advantageous arrangement, avoiding accidental flooding of the conveyor, is to equip the feed end of the shaft with a flight of smaller diameter and enclosed in a pipe issuing from the bottom of a hopper, this short flight thus acting as a feeder to the conveyor proper. The following data, and the accompanying tables, are from R. F. Bergmann (*41 CME 470*).

Capacity, cu. ft. per hr., for standard sizes and pitch and at different speeds is shown in Fig. 68; to convert to pounds, multiply by the factor W in Table 27; the comparatively wide range of weight in certain cases is due to differences in quality or moisture content. On inclined conveyors with standard pitch, capacity is diminished, owing to backslip, by the following percentages: at 10°, 15%; at 15°, 20%; at 20°, 40%.

Power for a horizontal conveyor may be computed by the formula: Hp. $= 1 + (ALN + CWLF) \cdot 10^{-6}$ in which A is related to diameter of flight and character of bearings, as in Table 30; L is length, ft.; N is speed, r.p.m.; C is cu. ft. per hr. (Fig. 68); W is lb. per cu. ft. (Table 27); and F is a factor Table 27) varying with character of the material. On a conveyor inclined upward at not over 20°, the additional power is approximately that theoretically corresponding to the vertical lift; direct calculation is inapplicable to steeper inclinations owing to the variations introduced by necessary modifications in design.

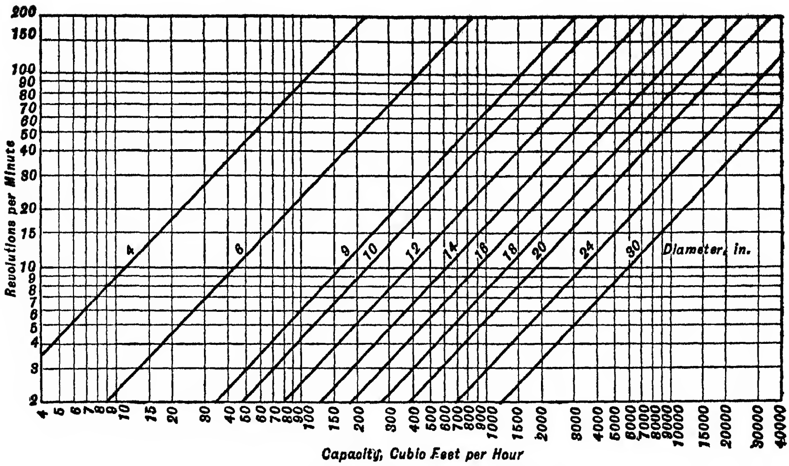

FIG. 68. Capacity of screw conveyors (*after Bergmann*).

Table 27. Factors affecting operation of screw conveyors (*After Bergmann*)

11. MISCELLANEOUS CONVEYORS

Johns conveyor (*138 #1 J 47*) transports wet or dry material in a continuous stream and in any direction, including the vertical, without transfer at points where direction changes. It consists of two parallel molded-rubber endless belts, semicircular in cross-section, normally facing each other and locked by tongue-and-groove joints along their edges, thus forming in effect an endless rubber pipe. At loading and discharging points, the two halves are unlocked and spread apart by passing over suitably designed rollers; other rollers restore the belts to their normal position. One of the halves carries inwardly projecting disks at short intervals, of such diameter as to form a succession of tightly closed

pockets when the two halves are interlocked. A steel chain is imbedded in a rubber fin along the outside back of each half; driving and guide rollers are so adjusted as to impart a twist to the intervening spans, whence the increased tension on the chains maintains tight contact between the two halves. Manufacturer's data on capacity are as in Table 32. Tonnages for other speeds and unit weights are in direct proportion.

Rotary tubular conveyor in the MT. LYELL mill transfers ball-mill product to a classifier at the rate of 169 tons of solid per hr., in a pulp containing 19.5% water (*PC*). The conveyor is a horizontal tube, 41 ft. long, 21 in. diam., having a double-lipped scoop at the feed end which revolves on a circle of 7-ft. diam. The tube is rotated at 29 r.p.m. by a 15-hp. motor delivering its full load. The interior of the tube has no spirals (flow being maintained by the hydrostatic head developed by the scoop) but was once provided with 3×3-in. angles, riveted longitudinally, merely to reduce wear on the shell. More recently, the tube has been lined with rubber, the life of which greatly exceeds the 18- to 24-mo. life of the earlier tubes.

Fuller-Kinyon pump transports fine, dry materials such as cement or cement ingredients, hydrated lime, fluedust, etc., through pipe lines; when just sufficiently aerated, such materials flow almost like liquids. If uniformly sized, the limiting coarseness is about 40% >200-m. (or all <48-m.), but grains as large as 20-m. can be pumped if accompanied by about 50% of <48-m. Maximum permissible moisture content depends upon the nature of the material; a granular sulphide concentrate, for example, must be practically bone-dry, whereas some materials retain their fluffiness with up to 2 or 3% free moisture. Fig. 69 shows essential features of the H-type pump. Material enters the hopper *1*, preferably through a closed chute provided with rotary feeder. It is then pushed forward by the screw *2*, on which the pitch diminishes toward the end, thus compacting the material by pressing it against the flap-valve *3*, of which the amount of opening is controlled by the counterweight *4* outside of the pump; this compacting seals the pump against back-pressure. Air at a pressure of 10 to 30 lb. per sq. in. is distributed through the manifold *5* to the jets *6*, of which the size (rarely over 1/4 in.) and number are adapted to the particular conditions. The conveying pipe is standard wrought-iron with screwed flanges, the faces of which (and the abutting ends of the pipes) are machined so that, with accurately sized gaskets, a joint will offer the least possible friction.

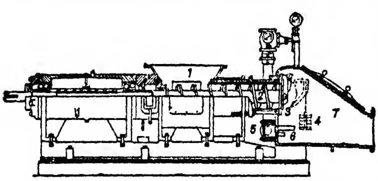

FIG. 69. Fuller-Kinyon pump, Type H.

Material thus aerated is propelled by the combined forces supplied by the screw and by the expansion of air in the chamber 7; its travel does not depend upon the velocity of a carrying current of air. In one case, cement was loaded on a ship about 4,000 ft. from the pump; in another, cement was elevated 302 ft. through a 730-ft. pipe. Table 33 gives data on a few typical installations. A mobile pump is also available, designed for unloading similar materials from box-cars, flat-bottom bins, etc., both air and delivery pipes being flexibly connected. The two rubber-tired wheels are independently motor-

driven, whence the movement of the pump can be controlled by an automatic switch in the hands of the operator at any distance within eye-shot.

12. BUCKET ELEVATOR

A bucket elevator (Fig. 70) consists of a number of buckets *d* fastened to an endless chain or belt *a* running respectively on two sprockets or pulleys *b*, *c* at different elevations. Material is fed at *e* directly into the buckets or is scooped up from the BOOT *f* and carried up and discharged into a receiving hopper *g* as the buckets pass over the upper (HEAD) wheel. The line joining the centers of the pulleys or sprockets may be inclined at any angle between 65 or 70° and the vertical. Bucket elevators are called CONTINUOUS if the buckets are spaced practically touching and CENTRIFUGAL-DISCHARGE if the buckets are spaced, say, one or more bucket-depths apart. The height of lift in concentrating mills is seldom over 75 ft. but there is no definite limit in the ordinary range of requirements.

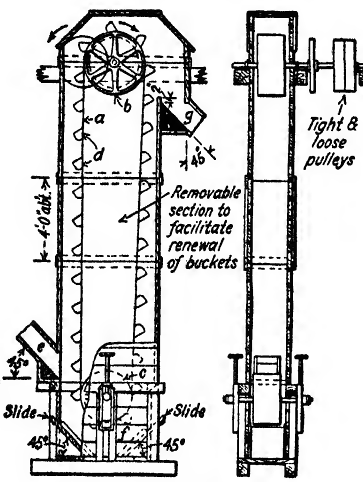

Fig. 70. Belt-bucket elevator.

Drive is usually by a spur gear on the head shaft and pinion on a jack shaft belt-driven from a motor or line shaft. Direct belt drive from a line shaft to the head shaft is sometimes used; also direct connection of a motor to the pinion shaft. Gear drive is better than belt drive because it permits higher drive-belt speed, and belt drive is better than direct connection because the belt will slip in case of a sudden jam and possibly save breakage of the bucket line.

Head shaft should be extra heavy and as short as possible. The greatest stress is due to the weight of the loaded bucket line and to sudden shocks arising from obstruction to the free motion of the line; a shaft strong enough to support this loading is more than large enough to transmit the necessary power and to come within safe limits for bearing pressures. A light shaft that bends under load causes uneven and excessive wear on bearings.

Size of head shaft. Let w = total load in lb. of shaft, pulley, bucket line, and ore; l = length in inches of the shaft between bearings; d = diameter of shaft in inches; z = section modulus = $\pi d^3/32$; s = permissible working stress in lb. per sq. in. = say, 5,000 lb. Then $wl/4 = sz = 5{,}000\ \pi d^3/32$ and $d^3 = wl/1963.5$.

Bearings may be of standard pattern but preferably ball-and-socket, grease-lubricated. Special COLLARS with an interlocking rim to cover the end of the bearing are sometimes used to exclude grit; closed ends aid exclusion. Shafting is frequently turned down on the ends to permit the use of smaller-sized bearings.

Rubber belt is the usual medium for carrying buckets in American concentrating-mill practice; BALATA BELTS have been used widely in South Africa. Rubber elevator belts are usually made with 32-oz. duck; for heavy work, 36- or 42-oz.; with a $^1/_{32}$- to $^1/_8$-in. rubber cover on the pulley side for protection against pulley slip and some cover on the bucket side also, to provide for the wear of entering feed; for wet materials the cover on the pulley side is usually twice as thick as on the bucket side and ranges up to $^1/_8$-in. The edges usually have extra heavy covering. The belt should be 2 to 4 in. wider than the bucket to prevent the buckets from catching on the housing or any other projection. Elevator belts are subject to heavy loads; surface wear is severe both on account of loading conditions and slip and creep at the head pulley; the perforations for bolts allow access of grit and water, and this in conjunction with acute bending around small boot pulleys, and frequent bending due to short length disintegrates the internal bond (FRICTION). (CREEP is change in belt length, due to difference in tension on the two sides of the head pulley, so that the belt shrinks in passing from the up side to the down side and this causes relative movement between the surface of the pulley and the belt.)

Belt replacement is the most important item of upkeep in elevator operation so that precautions to extend belt life pay for themselves in short periods. On elevators with buckets spaced some distance apart and run at low speeds, triangular strips of wood are sometimes fastened to the belt between buckets to prevent material from running along the belt and getting caught behind the buckets; this practice is reported to have greatly increased the life of belts (*59 A 225*). When deterioration occurs chiefly on the outside of a belt, owing to excessively abrasive nature of the material, the life of the belt can often be extended by shifting all buckets into the previously open spaces between them; buckets on tailing ele-

c Also drives an inclined belt conveyor.
d Thickened (galena) flotation concentrates, 96% <200-m. *B, sg* = belt and spur gear; *D, r* = direct, with speed reducer.

vators in the Tri-State field have been thus shifted as many as three times before the belt was discarded.

A mill of the St. Joseph Lead Co. at Flat River, Mo., contains 14 vertical bucket elevators, both wet and dry, with combined length of 1,585 ft. of rubber belt; all buckets are of malleable iron, AA type, with reinforced front edge and corners, those on the dry elevators being further protected by a welded deposit of hard metal (*IC 6658*). Life of a wet bucket is about 11 mo.; that of belts, wet or dry, is 3 yr. or more. On the 20- and 28-in. belts, buckets are attached by 2 rows of 3/8-in. bolts, with a cross-strip of belting to hold the bottoms away from the belt; on 16-in. belts, by a single row of bolts. All belts are covered with heavy burlap (cider cloth). Boot pulleys are solid, with shafts running in wooden or oil-packed steel bearings. Table 34 gives additional data on these elevators, and Table 35 includes several other installations in American concentrators.

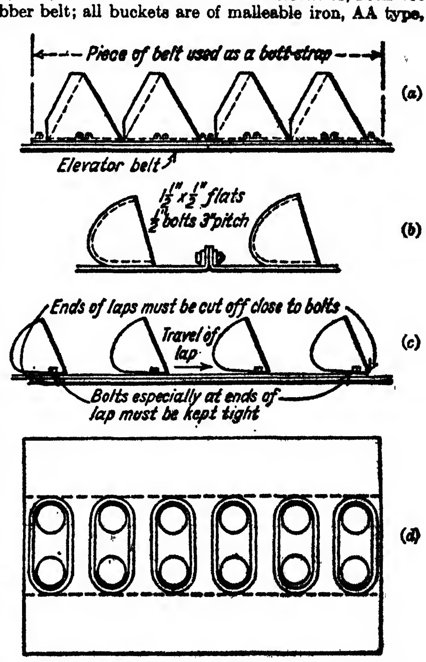

Fig. 71. Methods of splicing elevator belts (*after Hetzel*).

Splicing belts. Various methods are shown in Fig. 71. The Jackson fastener (*d*) consists of stamped steel plates each with two countersunk bolts, two oval cup washers with prongs, and two sleeve nuts. The bolts with cup washers are inserted into holes in the belt from the pulley side, the steel plate put on, and the sleeve nut tightened. The cup washers cause the belt to be drawn up into the concave parts of the steel plate and the sleeve nuts wedge the warp threads of the duck together and a tight joint is made. Butt-strap joint (*a*) is usually twice as long as the width of the belt or, with continuous buckets, the length of two buckets on each side of the joint. The lap-joint (*c*) is simple and easily made. With butt-strap and lap-joints on heavy belts (over 6-ply) the extra thickness caused by the double layer of belt at the joint causes movement between the belts when passing over the pulleys and tends to loosen the bolts and allow sand to enter between the layers. When a lap-joint is used the direction of motion of the belt should be as indicated by the arrow to prevent turning over the end when slipping occurs at the head pulley.

Head pulley should be large enough to prevent undue internal strain between the plies of the belt; a diameter in inches at least four, better five, times the number of plies in the belt is satisfactory. The diameter is also limited by the belt speed and discharge requirements. WIDTH OF FACE should be 2 to 4 in. greater than the width of the belt. The pulley face is usually crowned, but high crowns must be avoided unless the buckets are placed in two rows. A solid cast pulley with split hub and one or two keys and set screws is best; as a further precaution against loosening, a heavy band may be shrunk around the split hub or a keyed, solid-hub pulley pressed onto the shaft. Head pulleys are generally made extra heavy with two rows of arms on wide-face pulleys and long hubs extending almost the entire width of face.

Lagging increases traction between the pulley and belt and decreases wear on both. The most satisfactory lagging is 3- or 4-ply rubber belt or 2- or 3-ply belt with a $1/16$- or $1/8$-in. rubber cover, fastened by $1/4$-in. flat-head bolts; the bolt holes in the rim should be countersunk outside so that the heads of the bolts are drawn down below the outer edge of the lagging, and thus prevented from wearing the belt.

Chains or link-belts running on sprocket wheels are commonly used for elevating broken stone. They have the great advantage of positive drive, and are applicable to hot materials that might damage rubber belts. Their chief disadvantage is the great wear at the articulations, where lubrication is difficult or impossible; notwithstanding the use of special wear-resisting alloy steels, chain is unsatisfactory for wet pulps or dusty abrasive material.

The standard detachable chain, Fig. 72, *A*, is cheapest and is widely used; the links are easily replaced but no provision is made for lubrication or exclusion of grit; it can be obtained in alloy steel. Fig. 72, *B*, shows interlocking riveted pintle chain, usually made of malleable iron; most of the strain comes on the links rather than the pins, and grit is excluded to some extent. Ley bushed chains (Fig. 72, *C*) have malleable-iron links with case-hardened steel pins and bushings which are easily replaced. Special links (Fig. 73) carry the buckets.

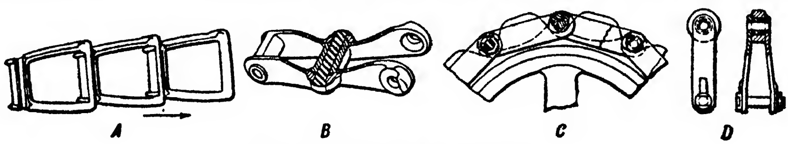

FIG. 72. Chain links for elevators.

An elevator may have one or two chains. Single chains are attached to the back of the buckets; double chains may be attached either to the back or sides. With elevators inclined at any considerable angles from the vertical, the chains are usually placed on the sides of the buckets and provided with rollers which run on a track, thus supporting the loaded side. Fig. 72, *D*, shows link for malleable-iron roller chain. For details of the numerous types of chains and link-belt see catalogues of Stephens-Adamson Co., Link-Belt Co., Jeffrey Mfg. Co , C. O. Bartlett & Snow, and others.

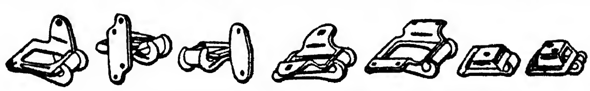

FIG. 73. Links with attachments for holding buckets.

Housings. No housing is needed with coarse and nearly dry material except to guard against possible spill of material on men or machines near the elevator. If wet pulps or fine dusty materials are being elevated, a housing should be provided to confine splash or dust. Wood or steel is commonly used; concrete less frequently. The front of the housing (upcoming side) is made in removable sections, and doors are provided to allow access to the boot.

The simplest WOOD HOUSING consists of 1- or 1 $1/2$-in. matched boards nailed vertically to the inside of an outer framework. Fig. 74 shows details of a wooden elevator housing made up of two layers of matched boards; the outside layer is placed horizontally and nailed to the framework and the inside layer is nailed vertically to the outside layer. Building paper painted both sides with asphalt paint laid in wet between the two layers of boards prevents leakage. CLEARANCE between the belt and buckets and the housing should be not less than 4 $1/2$ in. on the sides, better 6 to 8 in., and from 8 to 12 in. or more front and back. Boards running parallel to the belt are sometimes nailed on the inside of the housing to take any wear if the belt runs out of line. The joints on such boards should run in the direction of travel of the belt. The housing is usually light and is supported when possible on the floors of the mill building. SUPPORT FOR HEAD-PULLEY shaft and bearings is provided by special girders in the building frame. STEEL HOUSINGS are made in sections of light sheet steel with light angles riveted to the edges; sections are bolted together through the angles. REMOVABLE SECTIONS should be conveniently placed to allow access for observation and repair. A crane rail should be provided above the head pulley.

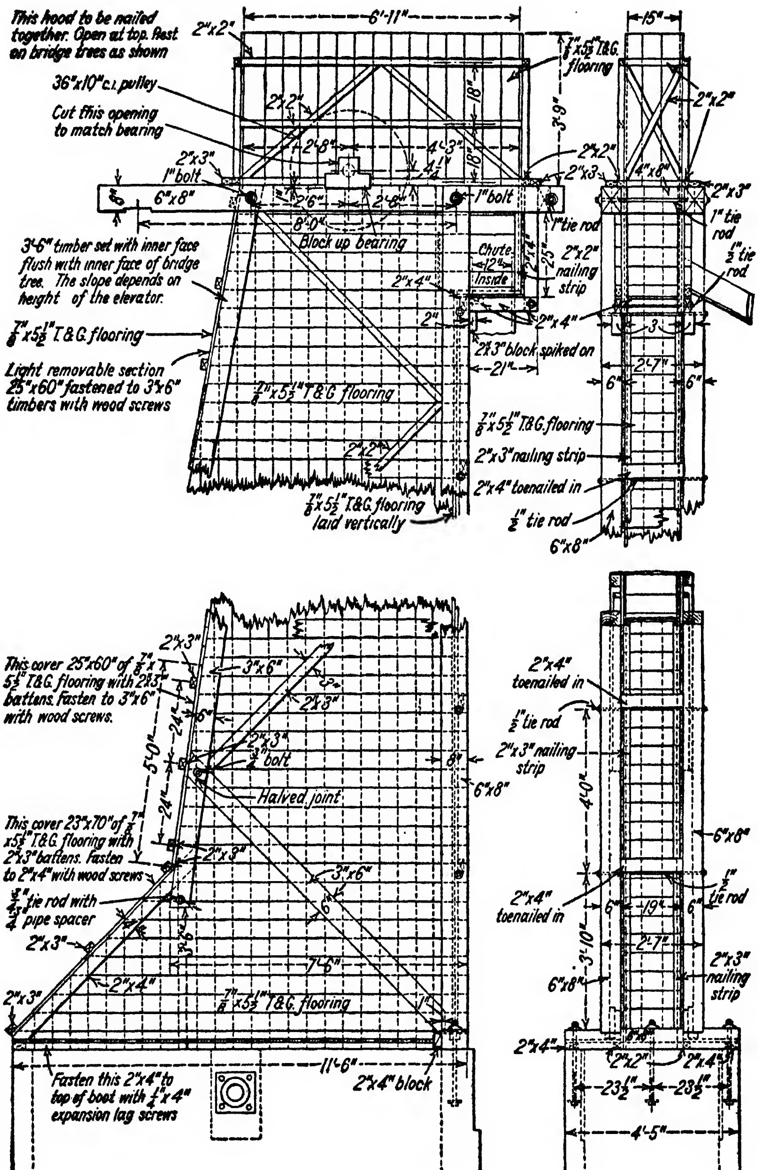

FIG. 74. Wooden elevator housing.

Boots for elevators may be small or large. Small boots are used for elevators lifting coarse material so that, if there is any spill, the material will be readily moved by the buckets.

Boots of cast iron or steel can be obtained from makers (Fig. 75). The bottoms are smooth and rounded to permit easy sliding of accumulated material in front of the buckets; removable liners are usually provided. Bearings for the boot-pulley shaft are sometimes supported on the boot with a take-up as shown in Fig. 75. CLEARANCE between the bucket tips and the bottom of the boot should be

sufficient at the lowest position of the boot pulley to prevent the buckets from jamming against accumulated material; at least 3 times the diameter of the largest pieces handled should be allowed. For fine wet pulps the boots should be large to reduce wear on the sides and bottom. Such material is frequently fed directly to the boot and is scooped up by the buckets. The boot then may be either a concrete sump or a large wooden box 2 or 3 times the width of the housing and of greater length (see Fig. 74).

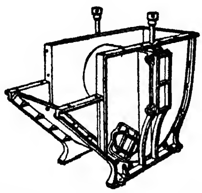

Fig. 75. Cast-iron elevator boot.

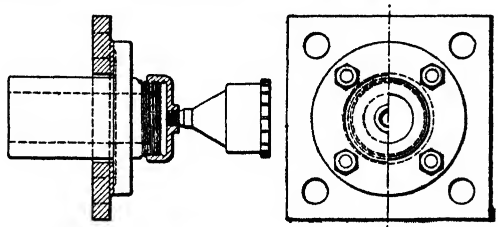

Fig. 76. Special bearing for boot-pulley shaft.

Boot pulley is usually smaller than the head pulley, ranging from 6 in. less to two-thirds the diameter of the head pulley, but never less than 24 in. diameter. Boot pulley shaft is usually lighter than the head shaft. Bearings are supported on the boot or, better, independently outside. Proper lubrication of boot bearings is difficult and is usually neglected. Fig. 76 shows a bearing with flange for bolting to the boot walls. Grease from cup at end moves in opposite direction from any entering grit and tends to keep the bearing clean. Take-ups are necessary on vertical elevators to compensate for belt stretching. The usual form is supported on the boot and consists of a screw moving the bearing in guides. Special weighted automatic take-ups can be procured. The amount of take-up is necessarily small and when the limit is reached the belt must be shortened. Take-ups can be omitted from inclined elevators; if the boot pulley shaft is placed behind the head pulley a horizontal distance equal to the diameter of the head pulley, the sag of the loaded belt is sufficient to allow as much stretch without loss of wrap on the boot pulley as would be provided by a take-up. With inclined elevators extra tension is put in the belt, if the hang of the loose side is within the line of the catenary between the head and boot pulleys.

Head housing. A removable housing should be provided around the head pulley, extending a distance above the head shaft equal at least to the diameter of the head pulley. It should make a tight joint with the receiving hopper and be provided with a light, easily removable cover.

Receiving hopper is provided with a receiving iron to catch material as it discharges from the buckets. The receiving iron is placed as close to the buckets as possible (rarely more than 1 in. away from the edges of the buckets) and at a point low enough so that all material will be discharged from any bucket before it passes the lip of the iron. The best position to avoid too great a loss of lift varies from a few inches below the center of the head shaft for high-speed centrifugal-discharge elevators carrying a freely flowing material to a point below a 45° line drawn tangent to the circumference of the head pulley for slow-speed elevators or those carrying sluggish material. The receiving hopper is usually made with rectangular bottom, and material is allowed to bank up to its own angle of repose, thus avoiding the use of liners. If discharging material strikes the sides of the hopper, liners are provided. The receiving iron in inclined elevators may be placed closer under the head pulley than in vertical, but the housing will be somewhat more complicated, greater floor space required, and if the inclination is great, rollers must be provided to support the loaded belt. Material discharges from the hopper through a chute or launder let into the side or end a few inches above the bottom.

13. CONTINUOUS-BUCKET ELEVATOR

This type is used for elevating coarse and comparatively dry material. It is usually run at low speeds so that the discharge takes place by dumping of the buckets as they pass over the head pulley, with little aid from centrifugal force. As a bucket dumps, its load slides over the bottom of the preceding bucket and is caught in the discharge chute. Speed should not be so great as to cause excessive spill at the feed chute, and with material containing a large percentage of freely running fine material it should be fast enough to give sufficient throw as the buckets pass over the head pulley to prevent the fine sand from running out the sides of the buckets and falling back into the boot. With continuous chain-bucket elevators the speed is seldom greater than 100 f.p.m.; continuous belt-bucket elevators run at higher speeds; Table 36 gives proper speeds for various head-pulley diameters.

Table 36. Speeds for continuous-bucket elevators (*After Hetzel*)

Head pulley		Belt speed, feet per minute

24	25	157
27	24	175
30	23	180
33	22	190
36	21	198

Buckets for continuous-bucket elevators are shown in Fig. 77, and their dimensions, capacities, and weights in Table 37. They are usually made of steel plates riveted together (*a*, *b*), with or without ears for lapping adjacent buckets. The transverse section depends upon the material carried and the slope of the elevator.

In Fig. 78, *AOB* represents a bucket in the position it occupies when the next following bucket is starting to dump. Angle *XOB* should be 40 to 50° so that material dumped from the following bucket onto *OB* will slide freely; angle *BOA* should be at least 50 to 60° to prevent lumps of rock from wedging and to minimize sticking of damp fine material. $BOA = 90 - XOB + YOA$. Setting $XOB = 50°$ and *BOA* at 60°, *YOA*, the inclination of the down-going belt, is 20°. The carrying capacity for any given inclination of elevator and length of bucket front depends upon angle *BOA*; for elevator slopes of 10° to 30° from the vertical, buckets with angle *BOA* between 60° and 70° have maximum carrying capacity.

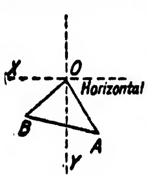

FIG. 78.

Fastening buckets to belts is done by means of bolts. Other methods have been proposed but have not worked out satisfactorily. One or two rows of bolts may be used, the latter for all but very small buckets; two rows are spaced 1 to 2 in., and pulley should be at least 30-in. diameter, if two rows are used. Buckets work loose readily, and an elevator should be inspected at short intervals so that buckets may be tightened before they fall into the boot and tear off others. Double rows of narrow buckets set staggered on a wide belt are better than wide buckets because they allow the belt to conform to the crowned head pulley without undue strain on belts and bucket bolts. The gap between bucket and belt in passing over a pulley depends upon the length of the back of the bucket, the place of attachment, and the diameter of the pulley. If the buckets are bolted along the upper edge of the back, the gap at the bottom is

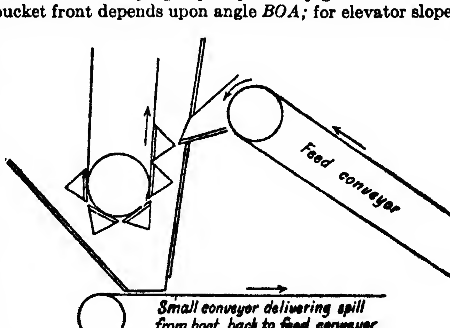

FIG. 79. Arrangement for removing spill from elevator boot.

large, and in passing over the head pulley material will be spilled into the gap unless extraordinary precautions are taken; if bolted near the bottom, the large gap picks up material in passing through the boot, and the buckets will probably be torn away. Center bolting is the compromise adopted. The gap $= g = \frac{(\sqrt{d^2 + l^2}) - d}{2}$, where d = diameter of head pulley and l = length of back of bucket; g should never exceed $l/8$.

Feed. A continuous-bucket elevator should be fed through a chute delivering to the rising side at a point such that the bottom of the feed chute is two bucket spaces above the foot shaft. This gives a chance to catch spill in a later bucket. CLEARANCE between the feed chute and the outer edge of the bucket should be great enough to prevent a large piece of material from jamming.

Spill that falls into the boot must be dug out by the buckets, with consequent increase in wear and power consumption. Small accumulations in large boots may be removed manually through doors; Fig. 79 shows an ingenious method of removing large amounts mechanically. (H. M. Roche, BEACH GLEN MINE, Dover, N. J. *PC.*)

Inclination is usually 10° to 30° from the vertical; this increases the chance of catching spill in succeeding buckets and also aids sliding discharge.

14. CENTRIFUGAL-DISCHARGE ELEVATOR

These elevators employ centrifugal force developed in passage over the head pulley to throw material clear of the buckets into the receiving hopper. As rising buckets reach the head pulley, centrifugal force becomes effective and tends to push the bucket contents toward the lip. The force acting on the bucket loads is the resultant of gravity and this centrifugal force. Centrifugal force, $C = 2Wv^2/gD$ where v = peripheral velocity in ft. per sec., D = diameter in ft. of the circle described by the center of gravity of the load, W = weight of the bucket load in lb., and g = acceleration due to gravity (32.2 ft. per sec. per sec.). Material should start to discharge from the bucket when the direction of the resultant of the forces becomes perpendicular to the front of the bucket; actually discharge begins somewhat later, the amount of lag varying with the fluidity of the load. Free-flowing material discharges close to the theoretical point; sluggish and sticky materials lag considerably.

Critical speed is that for which the centrifugal force is equal in magnitude and opposite in direction to gravity. At this speed the load is in equilibrium with respect to the bucket (see Fig. 80) and $C = W = 2Wv^2/gD$; $v^2 = gD/2$; $v = 4\sqrt{D}$ (approx.). To find the r.p.m. (N) for this condition: $v = \pi DN/60$; $\pi^2D^2N^2/3{,}600 = gD/2$; $N^2 = 1{,}800g/\pi^2D$, and $N = 76.6/\sqrt{D}$. d (diam. of head pulley) $= D - 2t - p$, where t = thickness of belt in feet and p = projection of the bucket in ft.

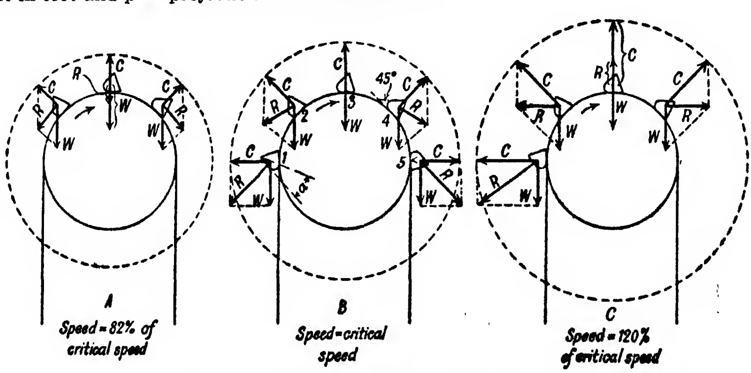

FIG. 80. Forces at the head pulley of centrifugal-discharge elevators.

As a bucket starts onto the head pulley the sudden application of centrigual force may, if the bucket is full of freely flowing pulp, cause some spill as the load shifts to bring its surface perpendicular to the resultant force. As the bucket passes around the head pulley the resultant force decreases but it always has a component pointing toward the bottom of the bucket until the bucket is vertically above the pulley center. In Fig. 80, *B*, the buckets have a 45° bottom angle, and the resultant force at position (1) is perpendicular

to the front of the bucket. The amount of material that the bucket will hold under this condition depends on the internal friction or fluidity of the mass; the load tends to take a position so that the angle a between the side of the bucket and the top surface of the load equals the angle of repose (Table 2); with mobile pulps the carrying capacity of the bucket is distinctly limited, but with sticky or coarse dry material and buckets not too heavily loaded, practically no spill will occur, because the initial condition is instantaneous and is followed by more favorable conditions.

Free discharge occurs on the discharge side of the pulley when the direction of the resultant is within the parallels to the front and back drawn through the center of gravity of the load; in such cases there is no friction between the load and walls of the bucket. For the 45° buckets shown in Fig. 80, free discharge at critical speed extends over the full quadrant from the top to the point at which the belt leaves the pulley. For a bucket with bottom angle of 30°, free discharge extends only to a point 60° from the vertical; a bucket with 15° bottom angle will discharge freely only to a point 30° beyond the vertical. The bucket may still discharge beyond the point at which free discharge ends but discharge will be retarded by friction due to the component of the resultant perpendicular to the front of the bucket. Thus while a bucket with a small bottom angle has the greater carrying capacity, its period of free discharge is so limited that net capacity is ordinarily less than that of buckets with more flare.

Belt speeds below the critical speed (Fig. 80, *A*). The bottom angle is unimportant except that material packs and holds back more with small angles. Under the conditions pictured in *A*, while the bucket is moving from the top position to a point about 45° beyond, the resultant lies inside the tangent to the circle of rotation of the center of gravity of the load and the load tends to run out onto the belt; free discharge occurs between 45° and 90° beyond the vertical.

Overspeeds. Fig. 80, *C*, shows the effect of overspeed; 20% is probably the limit for efficient work. With 45° bottom angle, the resultant on the rising quadrant is always in a direction tending to push the load out; it reaches a minimum at a point 45° up from the horizontal. With a bottom angle between 35° and 40° the tendency to discharge is delayed until the bucket reaches 15° to 25° from the vertical. On the discharge side the resultant favors discharge over the whole quadrant; with a 45° bottom angle free discharge takes place after the bucket passes the 45° point; with smaller bottom angles free discharge starts later and *vice versa.*

The usual bottom angle for buckets handling ores or mill pulps is about 40°; this gives good capacity with a good range of free or nearly free discharge. Overspeeding usually causes incipient discharge in the rising quadrant but if overspeed is not excessive, most of the load is thrown well over into the receiving hopper. Excessive overspeed causes excessive discharge on the rising side and much of the load falls back into the boot. Low speeds cause delayed discharge, and the load may not be thrown clear, causing a considerable spill back into the boot, but the wear on the receiving hopper is not so great and friable material is not broken up as much as with the more violent ejection of higher speeds.

Table 38. Belt speeds for centrifugal-discharge elevators

Loading conditions are affected by belt speed, if the elevator is boot fed. High speeds, especially with boot pulleys of small diameter, may produce such great centrifugal forces that material is prevented from entering the buckets in the lower portion of the run and it is then necessary to carry a deep bed of material in the boot to get proper loading; with heavy pulps and coarse material this causes excessive power consumption and damage to buckets. Table 38 gives speeds for various head-pulley diameters; critical speeds should be used for freely flowing materials, the lower speeds for coarse or dusty materials.

Material coarser than 1/4-in. should not be boot fed.

Buckets for centrifugal-discharge elevators are usually of malleable iron; various styles are shown in Fig. 81. Corresponding dimensions, capacities, and weights are shown in Table 39. Styles *A* and *AA* are most used; *AA* is heavily reinforced on the front edge and corners. Style *B* is used for elevators inclined over 30° to the vertical; the high back prevents spill. Wear is greatest at the corners, especially when the buckets dig material from the boot. Replaceable wearing edges are sometimes used. LIFE of buckets under varying conditions is shown in Table 35. Buckets are fastened to the belt by special flat-head bolts in one or two rows near upper edge of the back of the buckets; Table 40 gives standard spacing. Soft-rubber washers or narrow strips of belting placed between the buckets and the belt protect the belt from cutting by the upper edge of the buckets or by gritty material caught behind buckets.

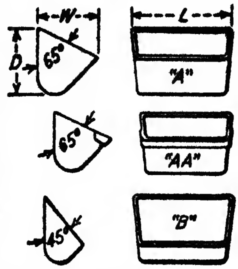

FIG. 81. Standard malleable-iron buckets.

Spacing of buckets should be such that discharging material from one bucket will clear the preceding bucket. *Hetzel's* recommendations for closest spacing are given in Table 41. Increase in speed causes discharge in a more nearly radial direction and therefore permits closer spacing. Sluggish material requires greater spacing to allow free pick-up in the boot. A rough rule is to space the buckets a distance equal to twice their projection; usual spacings are from 12 to 24 in.

Bolt holes 9/32-in. diameter for 1/4-in. bolts.

Load in buckets is rarely more than half the theoretical capacity. Buckets full of free-flowing pulps will spill on reaching the head pulley, causing waste of power. In design, buckets are calculated one-third full in determining capacity and full in estimating power requirements.

Discharge of packed or sticky material is aided by punching holes or slots in the bottom of the buckets; by attaching short lengths of bar iron or heavy chain loosely in the bottom; by a U-shaped wire with the ends bolted to the belt outside the bucket and the bottom of the U projecting to the bottom of the bucket so that as the belt bends around the head pulley, the wire moves and breaks up the packed mass in the bucket; or by high-pressure jets at the head pulley. Suspended boards or rods arranged to tap each bucket sharply as it comes over the head pulley are also used.

Power for elevators

Driving power for elevator belts is transmitted by friction between the face of the head pulley and the belt. This friction must be sufficient to overcome a force equal to the difference in tension between the tight and the loose side of the belt; if it is less, the belt will slip. Slip may be prevented by lagging the head pulley, or by decreasing the difference in tension between the two sides of the belt by light loading or tightening the belt. Excessive tightening overstrains the belt and brings an excessive load on the head-shaft bearings. The angle of wrap on the head pulley is about 180° for vertical elevators and slightly less for inclined elevators where the down side of the belt hangs loosely. The proper relation between the tensions on the tight and the slack side of the belt can be found from the formula $T_1/T_2 = 10^{0.00758fa}$ in which T_1 = tension on the tight side in lb., T_2 = tension on the slack side, f = coefficient of friction, a = angle of wrap in degrees. Table 42 gives safe values to use under various conditions. Dust or water between belt and pulley decreases the coefficient of friction.

Tension in the rising belt (T_1) is the sum of the weight of material in the buckets, the weight of the empty buckets and belt, the pull due to digging the load or filling the buckets, and friction losses in the boot shaft. Weights of malleable-iron buckets are given in Table 39. Weight of belting may be approximated as the product of the width in inches × number of plies × 0.03. (See also Table 15.) The pull due to loading and pick-up from the boot can be taken as equivalent to the pull of the load of material in the buckets for a length of belt in feet of from $2D$ to $12D$ where D is the diameter of the boot pulley in feet. The most favorable condition arises in a low-speed continuous-bucket elevator, which is front fed with practically no spill; for this a value of $2D$ may be used. For a continuous-bucket elevator for coarse material, picking up a large part of its load from the boot, $12D$ should be used; for front feeding of damp sand with little spill, $3D$; for thick pulps, 40 to 50% water, $3D$ to $4D$; ordinary dilute mill pulps, boot fed, which do not settle readily, $4D$ to $6D$; and for boot-fed pulps which pack, $10D$. Pull due to friction loss at the boot is covered by adding 1 or 2% of the total calculated pull from other causes.

Table 42. Coefficients of friction and values of T_1/T_2 for rubber belts on elevators with wrap angle = 180° (*After Hetzel*)

	Coefficient of friction	T_1/T_2
Clean iron pulley	0.25	2.19
Rubber-lagged pulley	0.35	3.00
Dusty work, iron pulleys	0.20	1.87
Dusty work, rubber-lagged pulleys	0.27	2.33
Wet work	0.20	1.87

Tension on the down side of the belt (T_2) is equal to the weight of the empty buckets and belt.

If the ratio T_1/T_2 thus found is greater than $10^{0.00758fa}$ the tension must be increased by take-up and allowance must be made for the added tension in determining the size of belt needed. Working stresses in elevator belts should be kept below 35 lb. per in. per ply for 32-oz. duck and 40 lb. for 36-oz. duck; in most cases the stress can be kept below 25 lb. Extra plies are usually allowed when external wear is great.

Horsepower to drive the belt = $(T_1 - T_2) \times$ *belt speed in ft. per min./33,000.*

To determine the horsepower to be delivered by the motor or line-shaft add 5% for each speed reduction through belts, chains, or cut gears and 10% for each reduction through cast gears.

Design of a continuous-bucket elevator

To raise 50 t.p.h. of 2-in. material weighing 100 lb. per cu. ft. 50 ft. vertically, the elevator to slope 10° from the vertical.

As the slope angle is small it may be disregarded in calculation. The volume to be delivered per min. $= \frac{50 \times 2{,}000}{100 \times 60} = 16.7$ cu. ft. Assume the buckets one-third full; then bucket capacity should be $16.7 \times 3 = 50$ cu. ft. per min. = 86,400 cu. in. per min. From Table 37 a 15×7 1/2×12-in. bucket has 450 cu. in. capacity. Number of buckets per min. = 86,400/450 = 192. As the length of the bucket along the belt is 12 in. a belt speed of 192 f.p.m. will be necessary, and from Table 36, a 36-in. pulley will be needed. Gap $= \frac{\sqrt{d^2 + l^2} - d}{2} = \frac{\sqrt{36^2 + 12^2} - 36}{2} = 1$ in., which is less than $l/8$ and therefore satisfactory. If lower speed is desired, a 16×8×13-in. bucket with capacity = 555 cu. in. gives 86,400/555 = 155 buckets per min. or a belt speed of $\frac{13 \times 155}{12} = 168$ f.p.m. and the gap will be 1.13 for a 36-in. pulley or within the limit $l/8$. Using the latter size of buckets, the number of buckets on the upcoming side = 50 × 12/13 = 48 (approx.). The load due to empty No. 10 steel buckets = 48 × 21 = 1,008 lb. The load in these buckets, assuming them full, = 48 × 555 × 100/1,728 = 1,541 lb. The belt width will be 18 in. Assuming 9-ply belt, the weight per ft. of length is approximately 18 × 9 × 0.03 = 4.86 lb. and the weight on the loaded side = 4.86 × 50 = 243 lb. Using a 30-in. boot pulley and assuming fair loading conditions, the pull due to digging in boot = the load carried on $6D$ ft. of belt $= \frac{6 \times 2.5}{50} \times 1{,}541 = 462$ lb. The total tension on the loaded side = 1,008 + 1,541 + 243 + 462 = 3,254 lb. Add for friction between 1 and 2%, say, 46 lb. and $T_1 = 3{,}300$ lb.

The tension per in. of width = 3,300/18 = 183 lb. and with a working tension of 25 lb. per in. per ply, 183/25 = 7.32 or 8-ply belt will be needed. The head-pulley diameter in inches is 4.5 times the number of plies, which is satisfactory. The exact weight of 18-in. 8-ply belt with 36-oz. duck is within the value assumed above.

Tension on the down side of the belt will be 1,008 + 243 = 1,251 lb., hence $T_1/T_2 = 3{,}300/1{,}251 = 2.64$ and the coefficient of friction should equal 0.309 (from the formula $T_1/T_2 = 10^{0.00758fa}$). A rubber-lagged head pulley should be used (see Table 42). Since a large allowance was made in estimating the tension on the rising side, by assuming full buckets, there should be no slip under normal working conditions.

Horsepower to drive the belt = (3,400 − 1,251) × 168/33,000 = 11 hp. Add 10% (= 1.1 hp.) for reduction by cut gears and 5% (= about 0.6 hp.) for belt drive from motor to pinion shaft; the motor power required will be 12.7 hp.; a 15-hp. motor that will operate at high efficiency over a wide range should be chosen.

Size of head shaft. The total weight to be supported = the load due to belt, buckets, and load on the loaded side, 3,400 lb., + belt and buckets on the empty side, 1,251 lb., + a 36×20-in. pulley, 660 lb., + the shaft (assumed), 200 lb., = 5,511 lb. Assuming 4-in. clearance on each side of the pulley, the thickness of the housing as 2 in., and placing 16-in. bearings just outside the housing, $l = 20 + 8 + 4 + 16 = 48$ in. $d^3 = 5{,}511 + 48/1{,}963.5 = 134.8$; d = about 5.12 in. The nearest standard size of shafting is 5 3/16 in.

Design of centrifugal-discharge elevators. Similar procedure should be followed except that in addition belt speed and bucket spacing must be such as to give satisfactory discharge.

Performances. See Table 35; also the various flowsheets in Sec. 2.

Cost of elevating fine wet pulps with belt-bucket elevators ranges from about 0.003 to 0.008¢ per ton per ft. of lift, of which cost power and repairs constitute substantially the whole, about equally divided. Cost for coarse dry materials will tend to be higher, if they are abrasive. In any case these costs are substantially negligible as compared with total milling costs. The important factor is, rather, the question of running time. Accurate data are not available for comparison of time loss in elevating fine pulps as between elevators and centrifugal pumps, but the almost universal adoption of the latter means of elevation over the past 20 yr. is eloquent evidence of the consensus of operators.

Automatic skip hoists, which are used to a considerable extent in feeding iron blast-furnaces and in raising water from shallow mines, were used at one concentrating plant, ALASKA-GASTINEAU (*Ed. 1, Sec. 2, Fig. 75*) for elevation in the roll-screen circuit. For performance see *Ed. 1, Sec. 23, Art. 6.*

15. CHUTES

CHUTES are steeply inclined troughs used for transportation of dry or nearly dry material by gravity; they may or may not be covered. Vertical chutes are usually equidimensional and are closed on all four sides. Round-bottom chutes are sometimes used for transportation of coal to lessen breakage. Chutes have most often been made of wood, lined with some wear-resisting material, but all-steel construction is becoming more common, especially for vertical or nearly vertical chutes.

Chutes must be well supported and rugged enough to stand the shock of material passing through; they must be large enough to pass the desired tonnage, and slope enough to keep the material moving. Covered and vertical chutes should have removable covers to allow access for replacing lining or relieving stoppages.

Liners are always placed on the bottom and frequently on the sides of inclined chutes; vertical chutes are lined on all four sides. Materials used for lining are sheet steel, cast iron, chilled cast iron, manganese steel, steel rails, old iron or steel, wood, rubber, or concrete. Some chutes are built in steps and material is allowed to build up; no lining is then needed. The same effect, *i.e.*, using the material itself as a liner, is obtained in mills of Andes Copper Co., New Jersey Zinc Co., and elsewhere, by inserting riffles of steel rail or angle-iron across the bottom of a chute. At the Franklin mill, wet chutes at uniform 45° slope are lined with cast iron on the bottom and steel plate on the sides, in addition to the cross-riffles. At the Ogdensburg mill, all chutes (at 45° slope) are constructed of 8- or 10-in. channels for sides and 1/4-in. plate for bottom, with a cover of 10-gage sheet; cross-riffles of 1/4×1 1/2×1 1/2-in. angle-iron are welded to the bottom, and discarded belting is often bolted to the sides (*PC*). At the Canisteo-Cliffs iron-ore washery (*135 J 341*) a semicircular chute of 32-in. diameter, 40 ft. long, made of 1/4-in. plate in butt-jointed sections, carries 500 t.p.h. of crude ore below 4 1/2-in. size. A 1/2-in. plate lining had to be renewed every 7 da. It was replaced by a chilled cast-iron lining 1 1/4 in. thick, made in segments 18 in. long and of such width and curvature that three segments filled the semicircle; edges and ends were square. Each segment was fastened by three 5/8-in. bolts with countersunk square heads, along its center line. By interchanging middle segments, which received the most wear, with side segments, life of the lining was extended to a whole season.

Chute linings in anthracite breakers have commonly been sheets of blue annealed iron (*66 A 422*), but these are rapidly corroded by acid water. Vitrified clay pipe makes excellent lining and wears indefinitely. Glass has been found too brittle. Hudson Coal Co. has used Corrosiron (cast iron with about 12% Si). It is made up in flanged U-shaped sections, 18 in. wide and 2 to 3 ft. long, both straight and spiral. At the Loree breaker this material had, in 1920, already outlasted 10 sheet-steel linings and bade fair to last indefinitely. When new, the surface is rough and requires a steeper slope than after the chute has worn smooth. This difficulty is overcome by setting the chutes on the final slopes, lining with sheet iron, and removing the lining a sheet at a time, beginning at the lower end.

Size. The width of a chute should never be less than three times the size of the largest piece which it is to carry, if free running is desired. No definite rule can be set for the cross-section of a chute to carry a given tonnage. The width is usually fixed by the size of opening from which the chute takes or to which it delivers its load; depth is usually made much greater than the depth of the stream both to prevent bounding out and for convenience in construction.

Minimum slope at which material will flow freely in a chute depends on the coefficient of friction between the chute lining and the material.

Holbrook & Fraser (*Bul 234 USBM 42*) found that sliding angles on smooth steel surfaces varied not only with hardness and specific gravity but also with the shape of the fragments. See Sec. 7, Table 20. Cubical or rounded pieces slide at smaller angles than flat or wedge-shaped pieces. The distribution of sizes in the material is important, especially if moisture is present; very fine material

Table 43. Data on chutes in American mills (*Q*)

Plant	Material size	Material	Width × depth, in.	Slope	Tons per 24 hr.	Lining: Material	Lining: Thickness, in.	Lining: Life, days

a Tapering to 16 1/2 in. wide at end.
b At or near minimum necessary slope.
c In semicircular segments, 5-in. radius, 27 in. long.
d Discarded plates, variable thickness.
e Has a grizzly bottom for feeding a belt conveyor.

tends to cake and retard motion; in general, sized material will flow on a flatter slope than unsized. At the IDAHO-MARYLAND mill, where all chutes slope 45°, are about 24 in. wide, and have steel-plate liners, the Brunswick ore (of ordinary consistency) flows freely, but the exceptionally sticky Idaho ore demands constant prodding to keep it in motion (*PC*). SAFE SLOPES are greater than the angle of repose of the material; if smooth liners are used, such slopes are steeper than necessary for sliding on the lining, but the chutes will not clog if the lining becomes rough and uneven. General practice is to make slopes for dry material at least 40 to 45°. Too great slope causes excessive bounding with resultant breakage of material and excessive wear on liners. Converging sides are undesirable; they should not be installed unless required, as for delivering to a conveyor or crusher.

Freda mill, of the COPPER RANGE Co., contains the following installations: (*a*) Six covered steel chutes, of 1/4-in. plate and lined with plate of same thickness; 4 1/2 ft. wide, 1 1/2 ft. deep, 3 ft. long, 27° slope; each delivers 100 to 125 tons (max. 175 tons) per hr. of run-of-mine rock 3×6×10-in. and smaller. (*b*) Other steel chutes deliver 100 to 125 tons per hr. (each) of mine-run rock from pan conveyor to impact crushers; width 18 in.; depth 16 in., length 6 ft., slope 42 1/2°, steel-plate lining 3/8-in. on the bottom, 1/4-in. on sides; removable cover. (*c*) Steel chutes receive <5/8-in. product from a screen and from a belt, delivering their united flow to a cone crusher; each is 16 in. wide, 10 in. deep, 8 ft. long, lined with 1/4-in. plate. (*d*) Five steel chutes, of 1/4-in. plate, 16 in. wide, 10 in. deep, 12 ft. long, sloping 42 1/2°, receive 340 tons per hr. (each) of <7/32-in. product drawn by drum feeders from a surge bin. (*e*) About 30 chutes, set at 45°, deliver to or receive from belt conveyors; most of these are of 1 3/4-in. tongue-and-groove pine, lined with 1/4-in. steel; wooden chutes are cheaper and more quickly erected than steel but occupy somewhat more space.

Table 43 gives data on chutes in several other American mills; except in the three cases noted, each slope is steeper than actually necessary for the particular material.

Automatic chute. Fig. 82 shows a chute installed in the Franklin mill of NEW JERSEY ZINC Co., designed to regulate the flow of dry, dusty ore and to deposit it on a belt conveyor with minimum disturbance. The chute *1*, 12 × 12 in. inside, formed of steel sheet reinforced with angle-iron, is rigidly connected to a vertical member *7* and a horizontal member *8*, the triangular structure thus formed being suspended and free to swing on the crossbar *6*. Counterweight *2* and helical spring *3* together act to hold the empty chute at a slope of 45°, in the position indicated by solid lines. In that position, the horizontal rectangular opening at the extreme bottom of the chute (the vertical end being permanently closed) rests upon and is closed by the plate *4*. When enough ore accumulates in the chute to overbalance the spring and counterweight, the bottom of the chute swings outward and allows ore to drop onto the belt. A flexible connection *9* between chute and hopper prevents escape of dust in that direction.

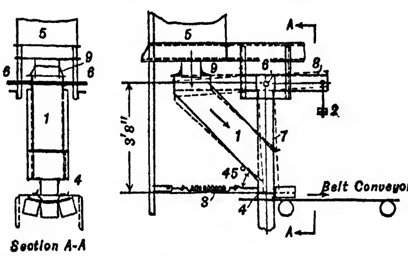

FIG. 82. Automatic chute.

16. LAUNDERS

A LAUNDER, as distinguished from a chute, is a trough for transport of solid material mixed with enough water to impart definite fluidity to the mixture. As a result of such fluidity, launder slopes may be, and usually are, much lower than chute slopes. Solid material is transported in launders either wholly in suspension or by rolling along the bottom under the impulse of the flowing water (BED-LOAD MOVEMENT) or by a combination of these two actions comprising a series of leaps and bounds with intervening rolling, called SALTATION.

Resistance to movement is caused by inertia of the solid and by friction both within the mass and between the mass and the wetted surface of the launder. Inertia varies with the size and density of the particles; friction varies with velocity, the shape of the launder, the nature of the wetted perimeter, the amount of material flowing, the percentage of solids, and the size, shape, and density of the particles.

Carrying force is the impulse of the stream, *i.e.*, a function of its mass, velocity, and direction. The more water flowing at a given velocity the higher the velocity of a given mass of water, and the more intense its turbulence the greater its transporting power.

Specific mathematical application of the foregoing generalizations to launder transport has proved impossible to date. Wilson (*A TP 1563*) made an ingenious attempt to apply modern turbulence theory, and evolved a general equation which, when fitted to the best experimental data for evaluation of constants, yielded an empirical equation usable in design (see Figs. 87 and 88, and the accompanying text). The method is not yet (1943) proved. Most designers today depend on records of proved minimum or working sizes and slopes for similar materials, and apply generous factors of safety, on the ground that regaining wasted headroom is much cheaper than loss of running time caused by clogged launders.

Performance. See Table 44.

At Calumet & Hecla, steel-lined wooden launders have the following grades, in. per ft.: 3/16 for 3/16-in. material; 1/8 for <28-m.; 1/16 for <100-m.; ratios of water to sand reach as high as 30 : 1 (*PC*). At Cons. Mining & Smelting Co. of Canada, launder grades vary between 3 3/4 in. per ft. for classifier sands (all <14-m., 5% <200-m.) and 1/4 in. per ft. for final mill tailing (11% >150-m., 80% <200-m.). All launders are generously proportioned to prevent spill, and usually run about one-third full; flow of bulky froths is accelerated by water sprays where needed. Several varieties of lining have been tested: (*a*) Rubber, 1/2 or 1/4 in. thick, with 1 or 2 plies of duck; this has been the most satisfactory material, when ordinary lumber was not sufficiently resistant; (*b*) wire-reinforced glass gave longer life and would be preferred even to rubber except for its liability to crack; (*c*) blocks cast from lead blast-furnace slag gave excellent service; (*d*) cement concrete wore rather rapidly, and involved delays while it was setting; (*e*) one specimen of wood from Australian "Ironbark" lasted 5 times as long as local lumber but only one-third as long as rubber (*PC*).

Slopes recommended by various designers are shown in Figs. 83, 84, and 85. In Fig. 83 curves *A* and *B* are the minimum slopes determined by Blue (*84 J 536*); curve *A* is

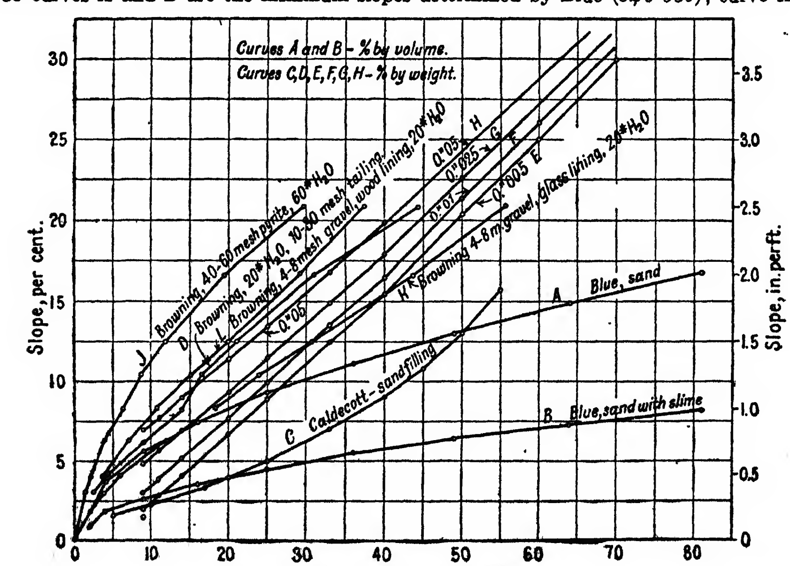

Fig. 83. Relation between percentage of solids and slope of launders.

for beach sand and curve B for angular mill tailing with some slime. Curve C gives slopes found suitable by Caldecott (*14 JCM 486*) for launders carrying sand containing about 4% pyrite, 10% of the sand being coarser than 48-m.; these values were calculated from the empirical formulas: $W = 12/(G - 1)$; $P = 100W/(W + 1)$ and $G = (W + 12)/W$, in which W = ratio by weight of water to solids, P = per cent. by weight of water, G = slope of launder, per cent. Curves D, J, K, and L were plotted from results obtained by Browning (*29 M&M 300*); D is for 10~30-m. limestone tailing (40% >20-m. and 60% 20~30-m.) in a rectangular wooden launder 2 1/2 in. wide; J is for 40~60-m. pyrite table concentrate in a wooden launder 2 1/2 in. wide; K and L are for 4~8-m. ordinary rounded pebbles, K with glass lining and L with wood. Curves E, F, G, and H were plotted from a table by Julian, Smart & Allen (*Cyaniding gold and silver ores*), for sand of predominating sizes 120-, 48-, 28-, and 14-m. respectively. Caldecott and Powell (*14 JCM 121*) state that sand pulp will flow slowly with 30% water on a 30% slope; with 40% water, on 20% slope; and with 60% water on a 10% slope.

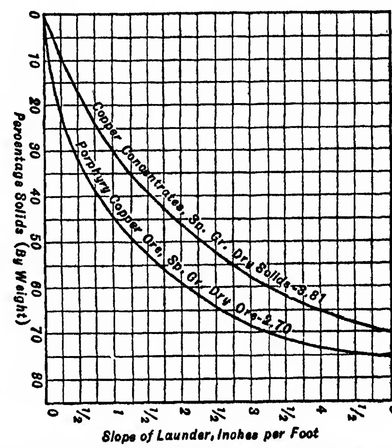

Fig. 84. Launder slope *vs.* percentage of solids (*after Linke*).

The wide divergence of the curves in Fig. 83 is due to the variety of materials and conditions. The largest size investigated was 4-m. rounded gravel. The slope is seen to vary approximately as the square root of the particle size. Velocities were 7 to 10 ft. per sec.

Fig. 84 (*153 A 655*) gives results of tests at Utah Copper Co. on raw monzonite ore (sp. gr., 2.7) and on (chiefly) chalcopyrite concentrate (sp. gr., 3.81) from the same; maximum grain size was not stated, but was probably <35-m. Fig. 85 (*153 A 655*) contains data based upon Rand siliceous ore (Schmitt, *2 RMP*) up to 1/2-in. size, and on Utah Copper porphyry ore for the coarser sizes; the whole curve proved applicable to the latter ore.

Use of curves. Bear in mind the characteristic of the particular material to be carried and err on the safe side; if insufficient slope is provided, water must be added, which may be wasteful or undesirable in subsequent treatment.

Gilbert (*PP 86 USGS*), summarizing experiments on the carrying capacity of water in flumes, stated that much of the movement is by rolling or sliding, especially when the current is slow and the solid coarse; that with a swift current or fine solid the particles travel by saltation and the finest material is suspended. When the principal movement is by rolling or sliding, the capacity of the current increases with coarseness of the solid material, up to the point at which the current is barely able to start the particles. When the principal movement is by saltation, the capacity increases with fineness of solid up to and probably beyond the critical fineness at which the solid goes into suspension.

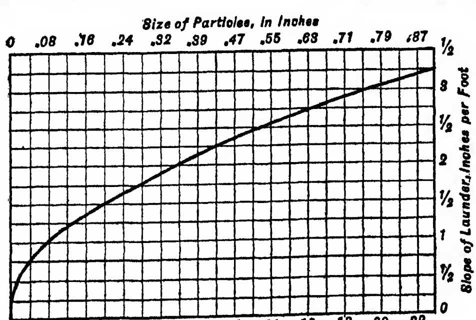

Fig. 85. Launder slope *vs.* particle size (*after Linke*).

Blue's experiments (*84 J 536*) were conducted in a U-shaped sheet-iron launder, 50 ft. long, 5 in. deep, with semicircular bottom of 2-in. radius. Two classes of solid material were used, (*a*) beach sand (77% 40~80-m.; 1% <100-m.; average size about 60-m.), (*b*) sharp quartz sand containing varying amounts of clayey slime, in the proportions of about 10% of slime and 90% of sand; the sand averaged about 80-m., 90% <40- and 10% <200-m. Various mixtures of each of these solids with water were fed and observations made at the slope when the "least perceptible quantity of sand just began to fall to the bottom." Depth was measured to 1/16 in.; rate of flow and the proportion of solids by

volume were determined by time samples taken at the discharge end and average velocities were calculated from these data. The results with beach sand indicated that the proportion by volume of wet solids in suspension, q, varied as the square of the slope S or, $S = k\sqrt{q}$. The sand-slime results were similar but less concordant; they indicated that with slime present more solid could be carried on a given slope with a given amount of water.

The value of k in the above equation was determined to be 0.186 for the beach sand and 0.091 for the sand-slime mixture. Blue also used his results to calculate values of the COEFFICIENT OF ROUGHNESS, n, in Kutter's formula by solving for values of the constant C in the Chezy formula (Sec. 20, Art. 2) and substituting in Kutter's formula (Sec. 20, Art. 2). The values of n obtained indicated the relation, $n = 0.0125q^{0.055}$ for beach sand and $n = 0.0105q^{0.02}$ for the sand-slime mixture. These values of n can be used only when the roughness of the launder is about the same as that of the sheet-steel channel used. In the case of beach sand, an ill-defined relation exists between v and q, *e.g.*, $v = 8.148\sqrt[4]{q}$. The experiments covered slopes ranging from 0.107 to 0.008, proportions of solids by volume from 0.0022 to 0.350; and depths from 5/8 in. up to 3 3/4 in. Calculated values of C varied from 72.2 to 135 and of n from 0.0080 to 0.0123. For the sand-slime mixture the slopes varied from 0.052 to 0.009, proportion of solids from 0.277 to 0.013, depths from 5/8 in. to 3 3/4 in., C from 70.0 to 128.0, and n from 0.0090 to 0.0118.

Table 45. Depth of water in a rectangular wooden trough (planed and painted) 12 in. wide

JULIAN AND SMART (*Cyaniding gold and silver ores*, J. B. Lippincott Co., 1921) calculate the size of launders by use of the Chezy formula ($v = C\sqrt{rs}$), assuming a relation between width and depth to obtain the minimum wetted perimeter (for rectangular launders, width = twice the depth), and making $C = 80$, which is an average value obtained from actual measurements of flow in launders carrying slime overflow and average stamp-battery pulp. Then if w = depth of the stream in ft., $2w$ = width, $2w^2$ = area of cross-section, $4w$ = wetted perimeter, $r = w/2$, and $v = C\sqrt{ws/2}$. If Q = cubic ft. per sec., $Q = 2vw^2 = 2Cw^2\sqrt{ws/2}$ or $Q^2 = 2C^2w^5s$, whence

$$w = \sqrt[5]{\frac{Q^2}{2C^2s}} = 0.151\sqrt[5]{\frac{Q^2}{s}}$$

Any relation between the width and depth of the stream may be assumed; various assumptions should be tested until the size determined is best for the conditions at hand. In the construction of small wooden launders the width is influenced by the widths of good lumber available without ripping or making a longitudinal seam down the center.

Table 45 (Gilbert, *PP 86 USGS*) is of value in determining dimensions, using Julian and Smart's method for calculating launder size.

RICHARDS (*S OD 1592*) gives Fig. 86 from Overstrom's data. The most economical water quantity is determined by following the ordinate for a given slope to its intersection with the inclined straight line on which weight of water is indicated. The weight of sand that 1 lb. of water will transport is then found by following the same ordinate to its intersection with the curve for that quantity of water and reading on the left-hand scale. To find the width of launder in inches divide the total weight of sand to be moved by the product: *lb. of water per in. of width* × *lb. of sand moved per lb. of water*. The diagram was plotted from experiments with quartz from 40- to 150-m. flowing in a wooden launder 2 1/2 in. wide. It indicates that the amount of solid carried is independent of the wetted perimeter. The curves indicate that there is a certain quantity of water for each slope that will carry a maximum amount of solids per lb.

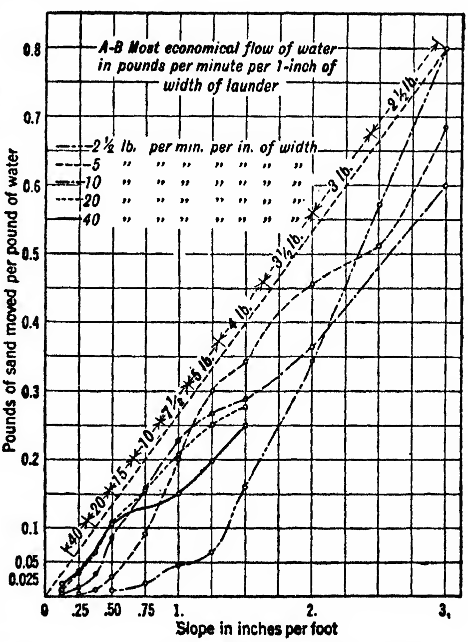

FIG. 86. Launder flow (*after Overstrom and Richards*).

LINKE (*153 A 655*) gives the following formulas as an aid to calculations involving flow of pulps, wherein: Q = g.p.m. of pulp; p = sp. gr. of pulp; a = dry tons ore per 24 hr.; b = sp. gr. of dry ore; c = % of solids in pulp; d = tons of pulp per 24 hr.; f = tons of water in pulp per 24 hr.; g = g.p.m. of water; h = lb. dry ore per min.

Given	Formulas
a, c	$d = \dfrac{100a}{c}$
a, c	$f = \dfrac{100a}{c} - a$
a, c	$g = \dfrac{\dfrac{100a}{c} - a}{6}$
a	$h = 1.3889a$
a, b, c	$Q = \dfrac{\dfrac{a}{b} + \dfrac{100a}{c} - a}{6}$
b, c	$p = \dfrac{100}{100 - \dfrac{c(b-1)}{b}}$
Q, b, c	$a = \dfrac{6Qbc}{c + 100b - bc}$
p, b	$c = \dfrac{100pb - 100b}{pb - p}$
p, c	$b = \dfrac{pc}{100 + pc - 100p}$

WILSON (*A TP 1563*) recommends design of launders according to Figs. 87 and 88. For use there must be known: Q = unit volumes of pulp per unit of time; d_g = equivalent sand roughness = diameter of grains which would, if packed, give the same roughness as that of the channel; w_s = unit weight of solids; w = unit weight of liquids; p = concentration of solids, *i.e.*, weight fraction of solids per unit weight of mixture; v_s = settling velocity of solids. Units must correspond, *e.g.*, ft., lb., sec. To use the charts, assume a value of b (= width of launder), compute the corresponding value of the abscissa in Fig. 87, and read d (= depth of stream). Then calculate $V = Q/bd$, compute the abscissa for Fig. 88, and read s (= decimal fraction slope). If proportions of stream are not as desired, reassume b. The curves have not been investigated beyond the limits shown, and their applicability to unusual pulps is not known. Slopes calculated will be minima, *i.e.*, equilibrium deposition of solid is contemplated; this is a condition for minimum wear.

Initial slopes. When material fed to a launder starts practically from rest, its velocity increases owing to the component of gravity acceleration parallel to the bottom of the launder, reduced by frictional resistance both within the mass of flowing material (viscosity) and between the flowing material and the sides and bottom of the launder. Velocity continues to increase until frictional resistance equals the gravitational force, thereafter remaining constant provided slope, shape, lining, etc., remain the same. Experimental evidence indicates that maximum velocity is reached quickly in launders on moderate slopes, and it is probable that in most cases launders are so fed that the initial velocity is close to or even greater than the velocity that would be reached starting from rest. If a launder at uniform slope is capable of holding solid material in suspension during the acceleration period, it is capable of carrying a larger load after constant velocity is reached. Practice recognizes this by increasing the slope for a short distance at the head end; velocity is thus quickly increased and full advantage may be taken of the carrying capacity of the stream at constant velocity.

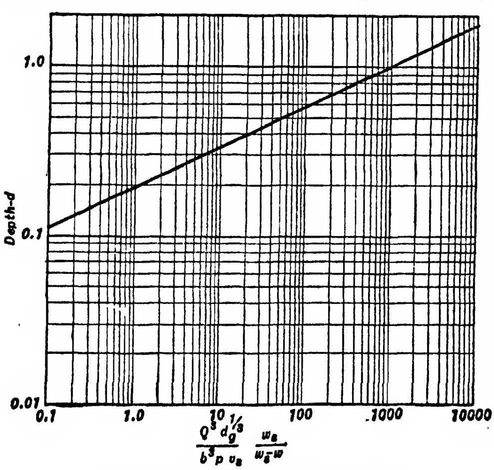

FIG. 87. Wilson chart for launder depth.

Shape of launder. Frictional resistance can be reduced in flumes or conduits for water by making the shape of the channel such that the wetted area is the smallest possible for the volume flowing. This is accomplished by making the bottom semicircular, which gives the smallest wetted perimeter for a given cross-section. The same principle applies to pulp in launders, when the solid material is practically all carried in suspension, but when this is carried wholly or largely by rolling, a semicircular bottom restricts the area available for free motion of the particles, and a rectangular cross-section is better. Gilbert found that rectangular or box flumes can carry more coarse solid than semicylindrical flumes of similar width and the same flow of water. Reduction of wetted perimeter likewise reduces the area exposed to abrasive action, and liner consumption is thus decreased. But the condition of least wetted perimeter may not always be most desirable. Where comparatively coarse material is transported, chiefly by rolling or sliding, it may be advisable to use a shallow stream, only slightly deeper than the size of the largest pieces

of solid; additional depth increases the amount of water used but only slightly increases the effective velocity in the lower zones of the stream. Gilbert, dealing with relatively coarse material in flumes, found that up to a certain limit, varying with conditions, the carrying capacity of the stream increased with increasing relative width of channel, and concluded that the ratio of depth to width for highest efficiency under such conditions would rarely be greater than 1 : 10 and often as small as 1 : 30, but that on large operations the width would usually represent a compromise between efficiency and cost of construction and maintenance.

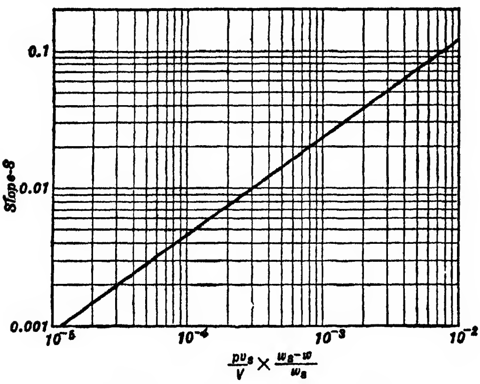

Fig. 88. Wilson chart for launder slope.

The use of wood for launders leads naturally to rectangular cross-section. Triangular-shaped cleats nailed into the corners of wooden launders make the shape of the bottom approach semicircular. V-SHAPED LAUNDERS of wood are used to a limited extent, having the advantage of simplicity. The shape may be made whatever is desired when sheet steel or cement is used.

Reinforced-concrete launder (Fig. 89) (*96 J 22*) was designed to carry overflow water 400 ft. It was cast in 16-ft. sections. The concrete mixture was 3 parts of 5/8-in. jig tailing, 3 parts ordinary mill tailing from 1/4-in. to 10-m., 1 part fine sand, and 1 part cement; the bottom was 2 1/2 in. thick; the sides 3 in. at the top, increasing to 5 1/2 in. at the bottom; a 4×1-in. ridge was carried along the bottom on each side; strands of worn hoisting rope were used for reinforcement. Single 1/2-in. strands were run along the top and two double 1/2-in. strands were placed along the bottom on each side. These were wrapped with wire about 5 ft. from the ends and two single strands, one from each pair, were taken up to the top of the side (*C* to *A*) while other two strands continued to the end of the section. Hooks *A* of 3/8-in. rod threaded at one end were used to draw the strands tight. Pieces of 1×1/8-in. strap *B* were put in at 18-in. intervals; at every other strap a piece *C* was run across the bottom with a slight turn-up at each end. The bottom was reinforced longitudinally by three 1/2-in. strands above the straps. Forms of 1-in. board were built up as shown; the bottom form *D* was supported on wedges *F*,

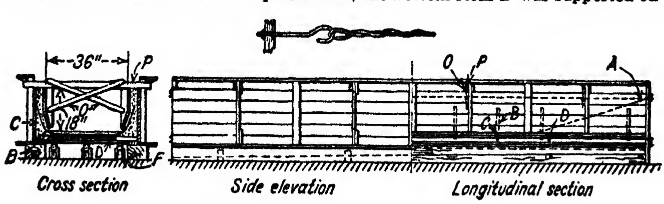

Fig. 89. Reinforced-concrete launder.

made by ripping 2×10-in. hardwood planks, 16 ft. long, diagonally; it was easily removed by knocking out these wedges. The inside forms were held in place by 1/4×1-in. iron braces *O*, so arranged that the forms could be swung in and held in place away from concrete when removing by use of extra holes in the braces. The COST was $0.75 per ft., compared with $2.40 per ft. for iron pipe of equivalent capacity.

Turns and bends should be avoided, if possible; sharp turns cause clogging on flat slopes and bends cause excessive wear of linings. The slope at turns is generally increased to avoid clogging. Schmitt (*2 RMP 88*) recommends bend radii not less than 10 times the width of the launder and increase of from 1 to 2% in slope. Linke (*loc. cit.*) uses the formulas

$S = (V/60)^2 \div 2.68R$, and $G = S(\sqrt{1 + R^2} - R)$, in which
V = velocity, ft. per min.; R = radius of curve, ft.;
S = crosswise slope, or banking, of bottom, in. per ft.;
G = additional grade to compensate for curve, in. per ft.

Junctions should be made so that the direction of flow in each launder is approximately the same. Boxes or small sumps are frequently used at junction points and sharp turns; the exit should be raised a few inches above the bottom so that the bottom may fill with settled solid and decrease wear and splashing.

Depth of launder should be sufficiently greater than the depth of the stream to take care of splashing and of any sudden surges. *Julian, Smart, and Allen* recommend making the launder 50% deeper than the stream for steady flow and 100% deeper where fluctuations are expected. Launders in practice show a much greater allowance in most cases. Of 95 launders reported, 71 had depths more than 3 times the wetted depth; the range was 1.3 times to 20 times and the average about 6.2 times (*Q*). In most cases, the launders with the smallest ratios were those conveying tailing to dump, where spilling was of slight importance. See also Figs. 87, 88.

Liners are selected with reference not only to their frictional resistance but also to their wearing quality and cost. WOOD is usually the most easily available material but its life is short, except where only fine solid in dilute suspension is flowing. Small wooden launders carrying material less than 1-mm. maximum size are generally left unlined; larger sizes are sometimes wood-lined. The life of wood in such service is long, it is easily replaced, and its lightness saves in the amount of support necessary. The life can be increased almost indefinitely by placing cleats of wood or angle-iron across the bottom at short intervals; solid material banks behind the cleats and makes a natural lining; frictional resistance is increased, however, and slope must be increased.

At the YMIR MINE, West Kootenay, B. C. (*34 A 602*), a 6×8-in. box-launder with 1-in. transverse riffles spaced 5 in. had a satisfactory life even when using soft hemlock or cedar lumber; the material was vanner tailing; the minimum slope was slightly under 5% (0.6 in. per ft.). At ALASKA-GASTINEAU a 2-in. fir lining in a 22×44-in. launder carrying 5,000 tons per 24 hr. of <1-mm. material, in a pulp containing 15% solids on a slope of 0.38 in. per ft., lasted 187 days. The general-tailing launder at the NACOZARI mill, carrying 2,295 tons solids per 24 hr. (2% > 35-, 58% < 200-m.) in a pulp containing 81% water, was 22 in. wide and 10 in. deep and usually flowed about half full at 9.2 ft. per sec. It was lined with 1-in. boards, those on the bottom being laid crosswise. Uniform and near minimum grade was 1.5%; indications were that on a straight stretch a grade of 1.2% would have been sufficient, but liable to choke if overloaded with coarser material (*IC 6358*). See also Table 44.

Rubber belting is a light and long-wearing lining, flexible and easily applied to wooden launders, but unless unfit for other service the cost is high. Special forms of rubber backed by fabric or metal (ARMORITE, LINATEX, VULCALOCK, etc.) are applicable to the lining of chutes, launders, and the like. At U.S.S.R. & M. Co. (Midvale) old 3/8-in. rubber belt used in 10×8-in. launder, sloped 3 3/4 in. per ft., carrying 25 tons per day of heavy <1.0-mm. concentrate in a 1 : 1 pulp lasted 2 yr. Similar belt in a 10×10-in. launder sloped 2 3/4 in. per ft. and carrying 85 t.p.d. of sand-table tailing of the same size in a pulp of 18% solids lasted over 3 yr. See also Table 44.

Slag lining was used at MORENCI (*102 J 644*). The slag castings were channel-shaped sections 12×12×2-in. weighing about 40 lb. each, reinforced with 1- or 1 1/2-in. hexagonal 26- or 28-gage poultry wire. The slag was poured into metal molds standing on end with two pieces of reinforcing wire placed in each side; when the slag had chilled slightly, the molds were removed and the hot castings buried in a sand bed to allow slow solidification of the center and thus avoid shrinkage strains. The cost was not over 12¢ per ft. as compared with $0.90 to $3.00 per ft. for white-iron castings. Their use in the 1,500-ton concentrator showed a saving in liner costs of $6,000 per year over a period of 2 1/2 yr. In a 2-mi. tailing flume the cost in 1912 for cast-iron lining was $7,015 or $0.01397 per ton. In 1914 cast-iron and slag were both used; the combined cost was $1,873.50 or $0.00407 per ton. From Jan. to July, 1915, slag lining cost $498.13 or $0.00197 per ton. In a launder taking roll product to an elevator, cast-iron liners lasted 90 da. compared with 180 da. for slag; cast-iron liners in launders carrying Wilfley-table feed lasted 60 da. while slag liners were still in use after 240 da. In the tailing flume the slag lining had an estimated life of 6 yr. compared with yearly relining with 2-in. plank. Slag lining in chutes running dry was satisfactory for material up to 5/8-in. Such utilization of slag is a useful outlet for a product ordinarily waste; its use, however, is limited to plants where slag is readily available. See also Table 44.

Sheet iron or steel, old boiler plate and discarded crusher steel and similar material are frequently used for launder linings. Table 46 shows the life of sheet-steel liners under various conditions. See also Table 44.

Table 46. Life of sheet-steel liners

Maximum size of material, mm.	Per cent. solids	Thickness of liners, inches	Life in days	Life in tons of solid transported per inch of width	Grade, inches per foot
13	Dry	1/4	120	3,840	4 1/4
7.0	33	1/4	700	26,600	2 1/2
7.0	40	3/8	350	33,250	5
6.0	0.4	3/8	450	22,500	1/4
5.0	....	1/4	180	5,220	2
5.0	10	12 gage (about 1/10 in.)	700	31,892	2
1.3	33	1/4	400	6,000	3
0.8	33	1/4	700	1,400	3 3/4
0.18	5	12 gage (about 1/10 in.)	1,050	17,850	5/16

Cast-iron liners are usually made in short channel-shaped sections. The useful life of such lining is shown in Tables 44 and 47.

The life of 5/8-in. cast-iron liners at Federal Lead Co., Flat River, Mo., in launders ranging from 6 in. to 13 in. in width and carrying different materials, was from 8 to 10 mo.

Table 47. Life of cast-iron liners

Maximum size of material, mm.	Per cent. solids	Thickness of liner, inches	Life in days	Life in tons of solid transported per inch of width	Grade of launder, inches per foot
15	50	1 3/4	90	5,130	2 3/4
12	25	5/8	180	10,800	2
7	20	1/2	360	16,000	4
2	42	1	365	9,125	1.67

Concrete lining is readily made in convenient lengths and sizes and makes a very satisfactory and cheap lining.

At Consolidated Main Reef mill (*19 JCM 77*) U-shaped sections of concrete lining were cast in 18-in. lengths, 9 in. deep and 11 1/2 or 13 1/2-in. outside widths. The thickness at the bottom was 2 to 2 1/4 in., tapering to 1 in. on the sides at the top. The average weight of an 18-in. length was 75 lb. Bend blocks for the turns were made of the same cross-section. Concrete slabs, 2 1/2 in. thick and of various lengths, were also used. The mixture was one part quartzite waste crushed to 1/2-in., one part of the <1/4-in. fine material from the above crushing, 1 part of washed drift sand, and 1 part of Portland cement. After concrete was poured into the molds it was allowed to set for 2 da., then submerged in water for 6 or 7 da., when it was ready for use. The joints between lengths were sealed with quick-setting magnesia cement or with mill blanketing. Cost for U-shaped blocks, including labor, material, and installation, was about $0.40 per running foot, which was little more than the cost of 1-in. pitch pine with 3×3-in. fillets and much less than the cost of lining with belting. Except at bends the concrete had a very long life (see Tables 48 and 49).

Table 48. Round-bottom concrete lining at Chino Copper Co.

Maximum size of material, mm.	Size of launder, width ×depth, inches	Solids, per cent.	Thickness of liner, inches	Life, in days	Life in tons of solid transported per inch of width	Grade, inches per foot
19	13 1/2×11 3/4	80	1 1/2	270 to 365	51,770	3 3/4
3	15 1/2×13 1/2	40	1	180 to 300	37,200	2

Steel bars set in concrete (*19 JCM 77*). Discarded Osborn-liner bars in 7-ft. lengths were set on edge and laid in cement on the bottom and sides of a 14×12-in. launder having triangular wooden fillets nailed in the corners. The lining was from 5/8 in. to 1 in. thick and could be placed and dried for use within 9 hr. Quick drying was accomplished by slowly burning old bags soaked in kerosene on top of the cement lining. Slope was 8.5%; pulp was 74 to 61% >60-m., 14 to 20% >90-m., and 12 to 19% <90-m. Life was 4 1/2 yr., except at points of division and at the feed intake, where replacement was made at the end of 2 yr. A launder similarly lined carrying stamp-mill discharge showed little wear after 2 yr. The cost of lining 100 ft. of a 12×14-in. launder and using 3,600 lb. of discarded steel was estimated at $19.50 for labor and material; this was about one-seventh of the cost of new belt lining, which was estimated to last only 6 mo.

Glass is sometimes used in launders carrying fine material. The smooth surface reduces frictional resistance so that a flatter slope than otherwise can be used. Wear is long but the glass tends to crack.

At the HILLSIDE fluorspar mill (*IC 6621*) most of the wooden launders are lined with chilled cast-iron, but a few of the wider ones are lined with wire-reinforced plate glass 3/8 in. thick, cut to measure by the manufacturer; the slight waviness of the surface is no detriment. This glass is cheaper than cast-iron and lasts longer. A launder carrying fluorspar concentrates (sp. gr., 3.2) sized between 5/8-in. and 30-m., with 30 parts of water, has a slope of 2 in. per ft.

Resistance of different lining materials to flow. Schmitt (*2 RMP*) says that cement, wood, and rubber belt give practically the same resistance and that canvas belt decreases velocity.

Browning (*29 M & M 300*) found that a given flow of water carried more angular tailing and pyrite on flat slopes in linoleum-lined and wood launders than in glass-lined ones. The capacity for rounded gravel was greater in every case in the glass-lined launder, probably owing to absence of eddy currents and ease of rolling the rounded particles on the glass surface. In general, high velocities cause increased wear on lining.

Splitting the stream cannot be done satisfactorily by taking the laterals off directly; the best method is to use vanes to split into parallel streams and subsequently lead the streams apart. Linke (*loc. cit.*) describes two methods practiced at UTAH COPPER CO., one discharging over weirs, the other through bushed orifices. In both cases the essential feature is a box to receive flow from the main launder, supplied with a cross-baffle under which the pulp has to pass before discharging through the two or more outlets; the latter must all be parallel with the incoming launder. The top of the baffle should be far enough below the upper edge of the box to prevent overflowing of the latter in case of choking beneath the baffle.

Pipe launders. Pipes running partially full are sometimes used as launders. Ordinary IRON PIPE is most common, but WOOD-STAVE and VITRIFIED CLAY pipe are also used. Large-sized iron pipes are sometimes lined with wood; when worn, a new surface is presented by turning the pipe. Rubber-lined pipe has proved an efficient means of conveying mill tailing to mine stopes, and should be equally serviceable inside a concentrator.

At GUANAJUATO (*95 P 78*) 8-in. pipe was used for transporting <30-m., sharp, granular quartz-calcite tailing 5,440 ft. The pipe was 5/8-in. thick; bell-and-spigot joints were calked with tarred hemp rope loosely driven; the outside was asphalted for protection against rust; curves were mostly 14-ft. radius; slope was 3 1/2% for the first 800 ft. and 2 1/4% for the remainder. The pulp was reduced to 25% solids before entering the pipe; occasional increase in thickness caused some deposition of sand; delays due to clogging totaled 4 hr. in 13 mo. At full mill capacity, 250 t.p.d, the pulp ran 1 3/4 in. deep, and traversed the pipe in 12 min., equivalent to 7.5 f.p.s. The pipe could carry 1,000 t.p.d. No appreciable wear was noticed after 13 mo. (100,000 tons transported) and the life was estimated at 50 yr. At about 500 tons per 24 hr. with 5 : 1 dilution the pipe ran a little less than half full (*95 P 457*). A 12-in. pipe running partially full carried sandy tailing at HOMESTAKE (*22 IMM 87*). Joints were made with a loose sleeve coupling held in place by wedges, which permitted turning without shutting down; pipes were turned 120°, so that three different wears were obtained from the same length of pipe by turning twice. At the HILLSIDE fluorspar mill (*IC 6621*) a 3-in. pipe 70 ft. long, suspended by hangers to give a total drop of 18 in. (1/4 in. per ft.), and oscillated by a table head-motion at its upper end, conveys 5/8-in. ~ 8-m. galena concentrates from Richards jigs.

At CLIMAX, tailing up to 15,500 t.p.d. is discharged to a pond 2 1/2 mi. distant and 500 ft. lower through two roughly parallel lines of 18-in., machine-banded Douglas-fir stave pipe, either of which can carry the whole volume (*153 A 588*). The unthickened pulp (49 to 65% water) may contain grains as coarse as 20-m., with 55 to 80% <100-m.; the solid is silicified granite, highly abrasive. Preliminary tests indicated 1.2% grade as the maximum necessary Since the natural ruling grade would have been 3% for the longer (16,700-ft.) and 3.3% for the shorter (15,200-ft.) line, producing destructively high velocities, the lines were laid in sections, some horizontal and others rarely exceeding 0.3%, connected

Table 50. Data on tailing pipe lines at Climax

a Unobstructed by sediment; calculated from volume and velocity.
b Directly observed, by salt method.

by vertical, open penstocks 4 × 5 ft. in area and of such height as to impose a mean hydraulic gradient of 1.5% on each succeeding section. The longest section, 3,094 ft., at 0.3% grade, has a head penstock 42 ft. high, affording a total head of 51.3 ft., or about 5 ft. more than necessary. The penstocks usually are about half full, the depth at a given moment being self-adjusted to produce the required rate of flow. The reduced velocity thus secured allows coarser grains to collect on the bottom of the pipe, thereby saving wear; the depth adjusts itself to the volume and fineness of the pulp. In one short section where a sustained grade of 1.6% was unavoidable, wear is many times more rapid than elsewhere in the line. Table 50 gives same test data on the performance of a 1,900-ft. section on 0.3% grade fed by a penstock 25 ft. high.

17. CENTRIFUGAL PUMPS

Single-stage centrifugal pumps are limited, in general, to lifts under 50 ft., but in several instances these pumps work against heads of 60 to 80 ft. MULTI-STAGE PUMPS may be used for larger lifts. Lifts greater than 50 ft. are rarely encountered in handling mill pulps, so that few multi-stage centrifugal pumps are found in mill work. The open-runner single inlet volute pump has been most used, but enclosed impellers, as shown in Figs. 90 and 92, are now common features in many types of sand pump. Material enters through a pipe at one side, fed either by suction or by gravity, and is delivered to the center of the revolving impeller, whence it is thrown by centrifugal force imparted by the blades to the periphery of the pump chamber and is discharged through a (usually) vertical pipe. Pressure to lift the fluid is obtained by the conversion of a large part of the velocity head produced by the impeller to pressure head. The direction of motion of the fluid at the instant it leaves the impeller is the resultant of motions tangential to the periphery of the impeller and to the surface of the impeller blade. The volute chamber is designed so that the cross-sectional area increases gradually toward the discharge pipe, and the change from velocity head to pressure head thus takes place with the smallest possible loss. The head which the pump must develop equals the difference in head between the intake and discharge levels, plus the velocity head required to give motion to the fluid, plus losses in the pump and losses due to friction in the pipe lines. The shape and curvature of the impeller blades are important considerations in design for any given service. Fig. 91 (*A*) shows characteristics of a single-stage centrifugal pump operating

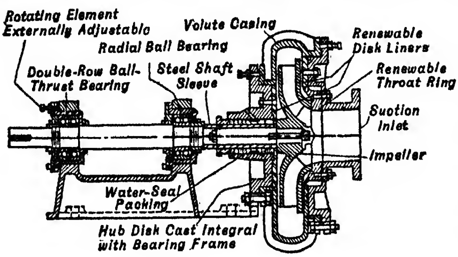

FIG. 90. Centrifugal sand or slime pump (*Morris Machine Works*).

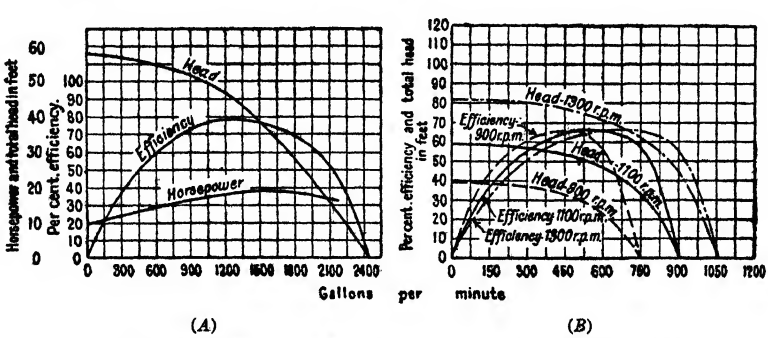

FIG. 91. Characteristic curves of centrifugal pumps (*Morris Machine Works*).

at constant speed. Fig. 91 (*B*) shows the effect of change in speed. The general shape of the curves is the same for all speeds; it is determined by the design of the pump and especially the inclination and position of the vanes of the impeller. The curves for any given pump indicate the variations that occur with changes in operating conditions. The SIZE of a centrifugal pump is usually designated by the size of the discharge pipe. Table 51 gives sizes of pumps made by one manufacturer, together with operating data

corresponding to points of maximum efficiency; Table 52 gives the sizes, speeds, and power provision recommended by the same manufacturer to afford the most economical service at various heads and capacities.

a Open-type impellers; all others enclosed-type.
b Lift plus suction plus hydraulic friction.

Impellers may have 4, 6, or more blades; the shells may enclose replaceable liners or the shell itself may be designed to take the wear. Impellers and liners are generally made of white cast-iron or manganese steel. For special work with hot, acid, or corrosive liquids, brass, hard lead, high-silicon irons, rubber, or other resistant materials are used. Rubber liners and rubber-cased impellers are standard features in many modern pumps designed for abrasive pulps. The greatest wear is on the impellers and liners; it varies with the size of particles in the pulp, hardness of the ore, shape of pieces, and with the dilution; coarse material causes greater wear than fine; very dilute and very thick pulps wear less than those of intermediate density. Table 55 records the life of wearing parts, together with other operating data, at a few installations selected as typical of many others. Where pumps are required to run continuously, duplicate units are either installed, ready for instant use, or are held in readiness for a quick substitution.

Feed may be either suction or gravity; the latter is better, especially for the handling of bulky flotation froths. With suction feed, the pump must be primed when starting. Priming is best done by introducing water into the discharge pipe just above the level of the top of the pump; the water should be supplied through a separate water line with a valve. A tee in the discharge line with nipple, elbow, and removable plug furnishes manual means of priming. Steam ejectors or rotary vacuum pumps are sometimes provided for priming large pumps. Priming is complete and the pump ready to work when the suction line and the pump itself are completely filled with water. A petcock let into the top of the pump allows the escape of any air which may be pocketed there during priming or accumulates during running. The SUCTION PIPE is usually one or two sizes larger than the discharge pipe and should be as straight and free from bends as possible. Bends should be of long radius to decrease friction losses. FOOT VALVES and STRAINERS are usually provided on the suction pipe; the free area through these should be about twice the inside cross-sectional area of the pipe. All joints in the suction pipe should be made carefully to prevent leakage of air, which would reduce or destroy suction.

At CONSOL. MIN. & SM. Co. a Wilfley sand pump, transferring galena flotation concentrates to a dewaterer, was adversely affected by excessive accumulations of froth in the sump (*139 #5 J 54*). A water-spray with weighted valve controlled by a float in the sump automatically corrected this condition.

Stuffing box. Leakage of air into the pump or leakage of fluid from the pump where the shaft passes through the shell is prevented by a stuffing box and gland. Water at a pressure slightly higher than that developed by the pump (about 1 lb. for every ft. of lift) is forced into the bearing through a small hole tapped in the top and connected to the water line; this keeps gritty or acid material from getting into the bearing and also aids in keeping the packing in the stuffing box from hardening and cutting the shaft. Square flax PACKING treated liberally with oil and graphite and cut in rings to go just once around the shaft is used in the stuffing box. The GLAND should be made just tight enough so that 5 or 10 drops of water per min. leak out; excessive tightening causes heating and wear on the shaft with loss of power. Water-lubricated rubber has been used satisfactorily both in glands and in bearings of pumps exposed to particularly severe abrasion. See also descriptions of special sand pumps, Figs. 92 and 93.

Suction lift. Table 53 gives the approximate theoretical maximum suction lifts in ft. at 60° F. for various altitudes and fluid densities; actual lifts ordinarily will not exceed one-half the theoretical. Increase in temperature reduces the maximum suction lift, owing to increased liberation of vapor at higher temperatures. Table 54 shows the effect on suction lift with increase in temperature; very hot fluids should be fed by gravity.

Table 53. Approximate theoretical suction lifts at 60° F. (*17 CME 629*)

Altitude above sea level, ft.	Specific gravity of fluid							
	1.0	1.1	1.2	1.3	1.4	1.5	1.6	1.7

9,000	24	22	20	18	17	16	16	14
10,000	23	21	19	18	17	16	15	14

Discharge pipe layout should be carefully made; a level run may cause clogging; bends should be as few as practicable and of long radius; valves should not be placed in pulp lines, since closing may cause solid material to pack so that the line will not clear again when the valve is reopened; stopping the pump may cause similar trouble. Provision of a by-pass to be opened just before stopping the pump will clear the pipe; shutting off the pulp supply and substituting clear water before shutting down is also effective. The by-pass is the best arrangement, as the pipes can then be drained immediately, if the pump stops accidentally.

Velocities of 350 f.p.m. in discharge pipes and 200 f.p.m. in suction pipes will, in general, prove satisfactory.

Size of feed. Centrifugal pumps successfully handle pulps containing coarse particles. They are frequently used to elevate pulps containing up to 1/4-in. particles; large pumps used in hydraulicking operations successfully handle gravels containing fair-sized rocks.

A 12×24-in. pump in one mill was reported as handling 600 tons per 24 hr. of 1 1/4-in. ~ 20-m. material together with 4,500 g.p.m. of water.

Efficiency of well-designed pumps doing good work will range from about 50% for the smaller sizes to about 75% for large sizes. These efficiencies are not always attained in practice as the pumps may not be working under the most favorable conditions. In handling pulps, the high velocity attained keeps the solid material in suspension. Possibly undesirable dilution of certain pulps by the water admitted to the gland may make some other means of elevation advisable.

Performance. See Table 55. The highest proportion of lost time reported (*Q*) for 96 pumps was 2.5%; some large mills reported less than 1%, and many operated with negligible or no time lost by reason of pump failure, avoided usually by the installation of a duplicate. Repairs and renewals were the main causes of delay, though one group of large mills had some trouble with choking. About equal numbers of pumps were fed by gravity and by suction.

Rubber-lined centrifugal sand pumps of different types and sizes have been applied to a considerable variety of operating conditions by Hollinger (*42 CMI 50*) with the results shown in Table 56. The outstanding conclusion is that the highest mechanical efficiency (attained when operating close to maximum capacity) usually entails the largest expense for replacement of linings; hence the two factors must be considered together for arriving at the most economical conditions. Further conclusions: (*a*) Deterioration of a rubber-covered impeller is much more rapid than that of the case linings; in most of the Hollinger pumps, white-iron impellers were retained. (*b*) Wear is greatly accelerated by overloading and by unnecessarily high speeds; also by presence of angular metal fragments; coarse ore, if hard and sharp, is more destructive than fine. (*c*) Wear even on an uncovered impeller is diminished by rubber-lining of the case, owing probably to the better streamlined flow obtainable in the absence of pits, such as inevitably develop on metal liners. Several of the Hollinger pumps were manufactured on the premises. They were rectangular in section, flat plates forming both sides, had a square outlet, and

f Based on average operating conditions, and power input at motor.
g Items correspondingly numbered refer to the same pump differently situated.
h Material to the 8-in. rubber-lined pump had sp. gr. of 1.47.
i Variations due to changes in elevation at point of discharging tailings.

were lined with LINATEX (an acid-vulcanized rubber), the chief advantages of which are its ease of application and of repair; serviceable patches can be applied with cold cement. Provided the customary clearances are maintained, a pump of this shape has about the same efficiency as the conventional type; the inward extension of the suction inlet, found on the usual type, proved unnecessary and was omitted without loss of efficiency in the shop-made pumps.

a All <48-m.

AT NACOZARI, five centrifugal pumps circulated middling from Callow and MacIntosh flotation machines, and four pumps handled general mill tailing (58% <200-m.), the latter operating in two stages (*IC 6358*). All pumps were 4-in. with 18-in. impellers. They were cast locally in white iron from a design which entails no machining; the cost was thus reduced to about 15% that of imported pumps, and justified scrapping for remelting when worn out. For further details see Table 57.

Table 57. Centrifugal pumps at Nacozari (*IC 6358*)

	Middling circuit		Tailing disposal	
	Callow	MacIntosh	Lower	Upper
Pulp: G.p.m.	154	112	852	852

At MT. LYELL the restricted area of millsite has led to an unusually large dependence upon pumps, cheap power also contributing. The examples listed in Table 55 are selected from 26 pumps reported (*Q*), of which only 3 are idle spares. In several cases, 2 or 3 pumps operate in parallel, thus insuring uninterrupted service. The Hydroseal pumps have been found particularly adapted to bulky flotation froths when suction lift is unavoidable. All pumps except the 8-in. are rubber-lined. SAN FRANCISCO DE MEXICO is also liberally equipped with centrifugal pumps, about 60 altogether, of which the two examples cited are among the smaller.

Advantages. The centrifugal pump is simple, requires little space, and the attendance while running amounts to only a small portion of a man's time, to determine whether it is functioning properly. It has displaced bucket elevators for sand and slime pumps in the great majority of mills. With gravity feed and a properly designed discharge line it is equally or more dependable than the elevator, and is tremendously more flexible.

Wilfley centrifugal pump (Fig. 92) has a centrifugal seal where the shaft passes out of the pump casing and thus avoids the need of a stuffing box. The success of the centrifugal seal in protecting the bearings from gritty and hot solutions permits the use of ball bearings on the shaft with consequent saving in wear and power. The pump has no suction; feed enters intake *a* thence through a passage to the enclosed-type impeller *c*. The discharge pipe is screwed into the keeper *l*, which is raised or lowered by bolt *m*, when removing the case; the joint between the keeper and the case is made with a ring of square packing. The centrifugal seal consists of a revolving expeller *d* having radiating wings similar to an open runner and a stationary member having a projecting groove *e*. Material leaking

by the edge of the expeller encounters the groove e and is directed toward the wings of the expeller which eject it again. When the pump stops, an automatic check valve closes around the shaft, preventing any leakage. Wearing parts are easily and quickly removable by loosening two nuts which hold the shell f, when the shell can be swung aside on arm g, giving access to the impeller, the follower plate h, and expeller. The joint between the follower plate and the frame is made with a ring of square packing i, set in a groove in the frame; the joint between the follower plate and the case is made with flat faces and a round rubber gasket k, cemented into a groove in the follower plate.

This pump has been very successful in handling gritty or sandy materials; several examples are given in Table 55. Tables 58 and 59 give manufacturer's data on capacity and speed of the various sizes.

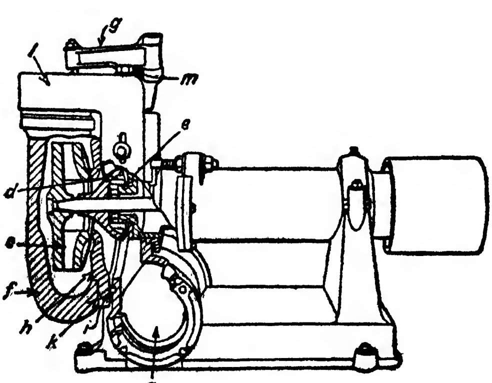

FIG. 92. Wilfley centrifugal pump.

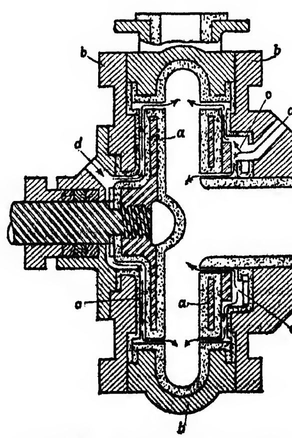

FIG. 93. Hydroseal sand pump (rubber lined).

Hydroseal pump (Fig. 93) has an enclosed-type impeller a sufficiently close fitting and water-sealed so that it is capable of maintaining a suction lift up to 20 ft. The impeller is isolated from the sectional casing b by channels c through which clean water, amounting to 2 to 5% of the delivered volume, is forced at a pressure slightly above that developed by the pump. In the sand and gravel pumps, sealing water enters both sides of the casing through ports d and flows around all sides and edges of the impeller as shown; in the slime pump, only the driven side is thus protected. In sand and slime pumps, all surfaces subject to abrasion are protected by molded jackets of soft rubber (shown

stippled). In the gravel pump, only the sides of the casing are protected by rubber, the impeller, shell, and suction sleeve being made of manganese and other alloy-steels. Delivery heads up to 160 ft. of water are attainable; for heavier pulps or higher lifts, two pumps may be placed in tandem, both driven by the same motor Direct-connected, flat-belt, and overhead V-belt drives are all available. Table 60 gives manufacturer's data applying only to completely rubber-lined sand and slime pumps (except as noted), and to a 50-ft. head of water; for heavier pulps, power is proportional to specific gravity of pulps. The relation of power to head varies with the different pumps, and with the speed and capacity of a given pump.

c For a pulp, multiply by its specific gravity.

At Wright-Hargreaves (*140 #4 J 37*) an 8-in. Hydroseal pump lifts 3,600 (dry) tons per 24 hr. to a total height of 55 ft.; the pulp is nearly all <10-m. and 10% >35-m., and contains 50% solids. The pump is driven at 850 r.p.m. by a short V-belt from a 75-hp. motor, consuming 60 hp. Wear of replaceable parts is given in Table 61. See also Table 55.

Table 61. Wear on Hydroseal pump at Wright-Hargreaves

			0.0952¢

Vacseal pump (*50 pt. 2, SAMEJ 630*) avoids the necessity for a water-fed or tightly packed gland. The rubber-covered, open-type impeller has vanes on both sides, those facing the gland or driven side (smaller than the others but rotating in a narrower space) being so designed as to maintain a pressure on that side which shall exceed the delivery pressure by an amount never less than the inlet pressure; this forestalls any tendency for sand to move toward the gland, which requires only enough packing to prevent excessive leakage when the pump stops. As wear on these inside vanes is negligible compared with that on the others, this balance cannot be lost through use; neither can it be upset by irregularity in rate of flow. The pump is made in 2- to 6-in. sizes, with capacities of 1,000 to 100,000 g.p.h.; it is not recommended for heads over 90 ft.

18. SPIRAL PUMP

Frenier pump (Fig. 94) consists of a spiral wheel *a* revolving in a box *b* which contains the fluid to be elevated. Material entering the spiral through the opening *c* advances toward the center and is discharged through hollow shaft *d* and the stuffing box and gland connection *e* to discharge pipe *f*. The weighted lever *g* forces the gland packing into tight contact with the outwardly flaring face of the shaft extension. With each revolution of the wheel, fluid is scooped into the spiral and air enters during the remainder of the revolution so that a portion of each succeeding turn of the spiral is filled with the fluid to be

lifted. The lifting force is the sum of the hydrostatic heads in the spiral plus the pressure induced as the fluid enters the spiral, minus the head of liquid in the discharge pipe. The lifting force is thus independent of the speed of revolution; it can be increased only by increasing the number of turns of the spiral or the diameter of the wheel. The makers recommend 20 r.p.m. as the most satisfactory speed. The radial distance between successive turns of the spiral is generally 2 $^1/_2$ in. Table 62 shows maximum capacities and lifts for the various standard sizes of pumps.

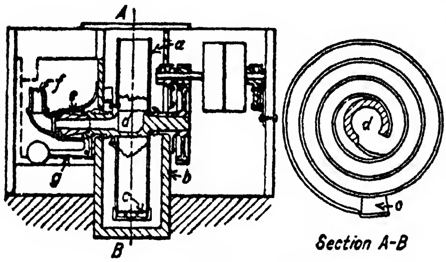

Fig. 94. Frenier pump.

The Frenier pump is suitable for elevating solutions or pulps to heights of 10 or 12 ft. The level of fluid in the feed box should be 7 in. below the shaft. The pump will not operate satisfactorily under changing conditions. If overloaded, it will stop working; neither does it work well when underfed. The greatest wear occurs between the rotating tube at the end of the hollow shaft and at the bend of the discharge pipe. For most efficient operation the discharge pipe should be vertical and have a vertical discharge opening with free fall to allow the escape of air. The construction is simple and little attendance is required.

Table 62. Sizes and capacities of Frenier pumps

Size of wheel, in.		Capacity, g.p.h., maximum	Maximum lift, ft.	Shipping weight, lb.
Thickness	Diameter			
6	44	3,000	12	1,100

8	48	4,200	16	1,300
8	54	4,500	22	1,500
10	44	5,000	12	1,400
10	48	5,200	16	1,500
10	54	5,500	22	1,670

19. DIAPHRAGM PUMP

The elements of this pump (Fig. 95) are a chamber *a*, with suction feed pipe *b* and inlet valve *c* at the bottom, and diaphragm *d* with outlet valve *e* at the top. Diaphragm *d* is reciprocated perpendicularly to its plane by any suitable mechanism. In the form shown (Hardinge Co.) the drive comprises the rocker arm *f* actuated by rod *g* from eccentric *h*, and rod *i* connected to block *j* mounted on the diaphragm. Stroke length (and thus capacity) is adjustable while running by moving block *k* by means of handwheel *l*. The valves may be flat, as shown in Fig. 95, or of ball type, as in Fig. 96, or of any other suitable gravity type. Valve seats are usually of high-grade rubber, and the valves may have rubber molded on the working faces; wear of such a combination is long, and substantial closure occurs even when wood chips get on the seat. Diaphragm is of sheet rubber about $^3/_8$ in. thick, usually lightly reinforced with imbedded duck. Chamber *a* is ordinarily built so that spout *m* can be turned to any quadrant.

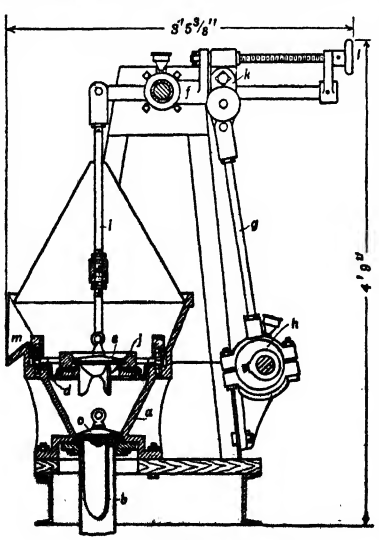

Fig. 95. Diaphragm pump.

To start operation the system is primed with water to fill the suction pipe and chamber *a* to overflow. Thereupon, when the pump is started, valve *e* remains closed on the upstroke, pressure is reduced in *a* below that in *b*, valve *c* is lifted by the excess of liquid pressure beneath, and liquid flows into *a*. On the downstroke the excess volume of liquid in *a* pushes up *e* and flows onto the top of the diaphragm, to be lifted over *m* on the succeeding upstroke.

Height of lift of diaphragm pumps is limited by atmospheric pressure and also by the strength of the diaphragm; lifts should never exceed half the theoretical lifts of Table 54; ordinarily lifts are less than 8 ft. Speed recommended by most manufacturers is 40 to 60 s.p.m.; higher speeds cause splashing and, with flat valves (Fig. 95), a tendency to throw the valves so high that they stick or leave the

ports entirely; this is particularly likely with thick pulps. STROKE may be lengthened as much as the diaphragm will stand; usual maximum is 1 1/2 in. for the smallest to 4 in. for the largest pumps. Size of pump is designated by the diameter of the suction pipe; standard sizes (not all of which are made by all manufacturers) range from 2- to 6-in. The number of units driven from a common shaft ranges from one to five, but seldom more than three pumps larger than 4-in. are consolidated. CAPACITY may be varied by changing the speed or length of stroke or it may be controlled by admission of small quantities of air into the chamber through a pipe with a needle valve. Table 63 gives one manufacturer's data on simplex pumps (multiple-units in proportion) at 40 r.p.m. and maximum stroke.

The diaphragm pump has found its greatest application in elevating and controlling the underflow from thickeners. It is simple to operate and requires little attendance and repair. Pulps containing as much as 50% solids are easily handled.

At HOLLINGER (*57 A 150*) a No. 4 Goulds diaphragm pump with 3-in. stroke performed as follows:

No. strokes per min.	Vol. per stroke, cu. ft.	Sp. gr. of pulp	Per cent. solids	Tons solids pumped per day	Per cent. increase in speed	Per cent. increase in volume per stroke	Per cent. increase in tonnage
14.5	0.139	1.54	54.5	76.3	....	....	....
23.0	0.148	1.48	50.5	114.5	58.5	6.5	50.0

The life of a diaphragm was more than one year when operating at 14 to 18 s.p.m. while rubber valves and seats showed no perceptible wear in 6 mo.

Diaphragm pressure pump (Fig. 96) is a modification of the diaphragm pump, designed to lift pulp as much as 20 ft. above the pump chamber, while maintaining the usual suction

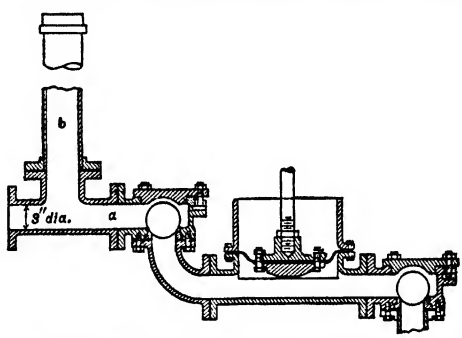

FIG. 96. Diaphragm pressure pump (*Hardinge Co.*).

lift. This is accomplished by enclosing the discharge chamber, *e.g.*, as at *a*. Standpipe *b* provides an air chamber to decrease shock on diaphragm and drive. Another form for lower lifts is shown in duplex type in Fig. 97.

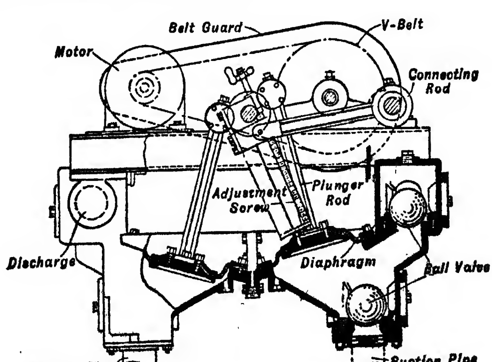

FIG. 97. Dorrco V-type diaphragm pump.

20. TAILING WHEEL

Tailing wheel (Fig. 98) consists of large rotating wheel with projecting buckets on one or both sides of the rim. When at the bottom the buckets scoop up pulp from a pit and at the top deliver it into a receiving trough or launder. The older wheels were constructed of wood but newer ones are of steel, either rigid or of bicycle-spoke construction. Tailing wheels have been most used on the Witwatersrand to elevate stamp-mill tailing. Wheels up to 60-ft. diameter have been made. The net lift, *i.e.*, the distance between the level of the feed launder and that of the receiving launder, is less than the diameter of the wheel by an amount determined by the inclination of the bucket vanes to the wheel radius. Julian and Smart give the RATIO OF DIAMETER TO NET LIFT as about 1.3 : 1 and recommend an angle of 65° between the radius and the bucket vanes. Usual SPEED is about one-third the critical speed at which centrifugal force would prevent bucket discharge. (See Sec. 5, Art. 2.) The time required for buckets to discharge is given by Wood and Laschinger (*77 J 482*) as not less than 3 sec. on 40-ft. wheels or 5 sec. on 60-ft. wheels. DRIVE may be by belt and pulley mounted on the shaft, or by pinions and gear, or by a sheave built into or around the outside of the wheel itself. Manila-rope drive on sheaves has been most favored.

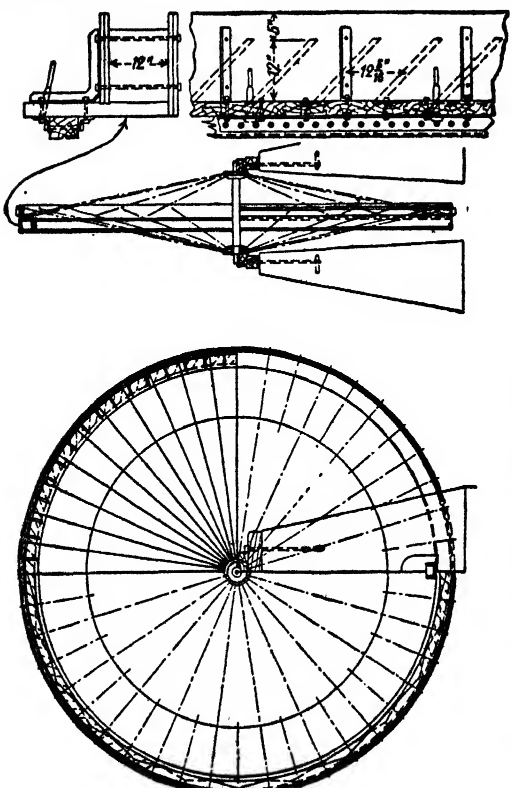

Fig. 98. Tailing wheel.

The first COST of tailing wheels is high; large wheels require heavy construction and massive supports for the shaft bearings. Maintenance and repair costs are low, and reliability and durability are high. POWER EFFICIENCY is usually from 40 to 50%. Centrifugal pumps and bucket elevators cost less, require less space, and are generally more desirable than tailing wheels.

At Calumet & Hecla conglomerate mill (*IC 6364*) two 50-ft. and one 60-ft. sand wheels are the only important lifting devices in the plant, delivering coarse sands to regrinding, and fines to leaching or flotation. Each wheel has two rows of buckets, made of flat steel plate, on opposite sides of a central rim which is driven by spur gear from a pinion shaft. A separate launder feeds each row of buckets; at the top, these discharge into a launder on each side, the two launders uniting as soon as they clear the wheel. The 60-ft. wheel has 272 buckets on each side, the dividing plates sloping at 30° to the tangent of their inner circumference; effective width of bucket is 4 ft. 3 1/2 in.; radial depth, 20 in. Diameter of wheel is 58 1/2 ft. to the inner edge of the buckets, 60 ft. 2 in. at center line of buckets, and 65 ft. to the pitch line of the gear. Effective lift (diff. in flow levels) is 49 ft. 10 in. Capacity per 24 hr., 40,000,000 gal. water and 6,500 tons of sand; wheel is rotated by a 700-hp. motor with rope drive to a pulley on the pinion shaft. The 50-ft. wheels have 222 buckets on each side, pitched at 36° from the tangent; diameter of inside circle, 47 ft. 10 in. They lift 30,000,000 gal. water and 3,500 tons sand per 24 hr. each to an effective height of 39 ft. 7 in.; the pinion shafts are belt-driven from 350-hp. motors. The Kennedy Mining & Milling Co., California, used four 56-ft. tailing wheels in tandem to elevate stamp-mill tailing to flumes (*97 J 517*). A wooden flume delivered to the first wheel about 1,500 ft. from the mill; the second wheel was 100 ft. distant, the third, 820 ft., and the fourth, 200 ft. The lift was about 35 ft. in each wheel; the flumes were set on 2 1/2% grade. The mill capacity was about 400 t.p.d. At the old Belmont Mill, Millers, Nev. (*106 P 282*), stamp-mill pulp was lifted 48 ft. to classifiers by a tailing wheel. Operation was reliable and upkeep low; 87,952 tons was elevated in 1 yr. at a cost, including classifying, of 3.6¢ per ton. The Tonopah Mill, Millers, Nev. (*106 P 282*), had two wheels. No. 1 was 30-ft. diameter and elevated 500 tons of dry ore and 3,500 tons of solution per day with a 7 1/2-hp. motor. First cost was high but the wheels were efficient and maintenance was low compared with bucket-elevators. The cost of elevating and separating was 8¢ per ton. At the City and Suburban Mine, Witwatersrand (*77 J 481*), a 25-ft. wheel lifted 5,549 lb. of tailing pulp per min. 19 ft. 1 in. The theoretical power requirement was 3.208 hp.; the actual power, including two intermediate countershafts, was 6.635 hp.; total efficiency, 48.35%. At Henry Nourse mine, Witwatersrand (Julian & Smart), a 60-ft. wheel was operated at 45% efficiency and consumed 15 hp. The drive sheave was 55-ft. diameter, driven at 3 r.p.m. by 1 3/4-in. manila rope from an 11-ft. sheave on the countershaft. The wheel axle was 20 ft. × 14 in. with bearings 2 ft. 6 in. × 12-in. diameter. The life of the rope was 3.5 yr. (*77 J 481*). At the Bullfinch Proprietary mill, W. A. (*13 CME 331*), a tailing wheel elevated the product of stamp mills to hydraulic classifiers. Diameter of wheel, 40 ft.; 112 @ 720-cu. in. buckets; peripheral speed, 400 f.p.m.; driven by manila rope, 6 in. in circumference, which lasted 60 da.; power consumption, 7.3 hp.; about 2,500 tons of ore and solution was lifted per day.

21. AIR-LIFT

The air-lift (Fig. 99) is used to elevate solutions, slime, and, in certain cases, sand pulps. It consists of a delivery pipe *a* submerged for a part of its length in well or sump *b*; compressed air is introduced into the delivery pipe at the foot-piece *c* through an air pipe *d*. The air causes a decrease in the density of the fluid in the delivery pipe and consequent elevation by hydrostatic pressure and discharge at *e*. Efficient operation depends on proper design of the lift and regulation of the air pressure. The known factors in any particular case are the amount of fluid to be elevated and the height to which it must be raised; the important items to be determined are the volume of air required, the pressure at which it must be delivered, the size of delivery and air pipes, and the depth to which the delivery pipe must be submerged below the normal level of the liquid in the well or sump.

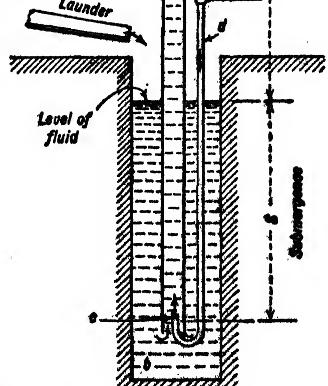

Fig. 99.—General arrangement of air-lift

Table 64. Submergences for air-lifts(*Sullivan Machinery Co.*)

Lift in feet (L)	Submergence, per cent. $\left(\frac{100S}{S+L}\right)$
Up to 50	70 to 66
50 to 100	66 to 55
100 to 200	55 to 50
200 to 300	50 to 43
300 to 400	43 to 40
400 to 500	40 to 33

The depth of submergence S (Fig. 99) for most efficient operation at any lift L cannot be exactly

determined in advance; if the air-lift is to handle large quantities of material so that a slight improvement in efficiency will cause considerable saving, provision should be made to vary submergence after operation is started. The figures in Table 64, based on average practice, may be used for calculation in design.

Air pressure. The pressure at which air must be delivered to the foot-piece is governed solely by the depth of submergence S and should be just sufficient to force air into the delivery pipe; $P_1 = 0.434gS + P$, where P is the atmospheric pressure in lb. per sq. in., P_1 is absolute pressure of air entering the foot-piece, and g the sp. gr. of the fluid to be elevated. A slightly higher pressure will be required in starting up. The pressures at which air is supplied at the foot-piece in operating lifts conforms closely to the theoretical pressures thus calculated. Excessive pressure causes air to escape from the bottom of the delivery pipe into the well; this reduces the density of the fluid therein and may stop the lift; at any rate, to keep the lift in operation under such conditions will require a large excess in volume of air and so reduce efficiency.

Table 65. Values of C in Equation 1

Lift in feet	C
10 to 60	243
61 to 200	233
201 to 500	216
501 to 650	185
651 to 750	156

Volume of free air required may be calculated by the following formula:

$$V_a = 0.8L/C \log [(S + 34)/34] \quad (1)$$

in which V_a = cu. ft. of free air per gallon of fluid (at normal pressure, P_a, 14.7 lb. per sq. in. and 60° F.) and C = a constant varying with height of lift, L. Values of C are given in Table 65. Results obtained closely approximate actual values.

The size of delivery pipe required can be calculated from the amount of fluid to be delivered in a given time and the volume of air used during that time. Certain values for velocity have been found satisfactory in practice, and by taking pipe of a size to keep within these limits losses due to friction will be kept within reasonable amounts. The VELOCITY OF THE FLUID in the discharge pipe increases as the top is neared owing to expansion of the contained air. The velocity at the foot-piece may be taken at 4 to 8 ft. per sec. and the velocity at discharge should be kept under 20 to 25 ft. per sec. Velocities should never be so low that solid material will settle out of the rising liquid or less than the velocity at which the largest air bubbles will rise in the fluid.

Let V_1 = cu. ft. of air per min. at pressure P_1; P_1 = absolute pressure of air at the foot-piece, lb. per sq. in.; Q = cu. ft. of liquid per min.; v_1 = velocity in ft. per min. at foot-piece (assumed between 250 and 450); A = internal area of the delivery pipe in sq. ft.; q = gallons of liquid per min. Then $Q = q/7.48$ and $V_1 = qP_aV_a/P_1$. The total volume of air and liquid at the foot-piece equals $Q + V_1$ cu. ft. per min. and the required area of the delivery pipe $= A = (Q + V_1)/v_1$. Standard pipe nearest this size may be used.

The velocity of the air-liquid mixture at the discharge should be calculated to insure that it is not greater than 20 to 25 ft. per sec. Expansion of the air on rising may be considered isothermal since the air is in small bubbles surrounded by water.

Some authorities allow capacities of 10, 12, or 15 gal. of fluid per min. per sq. in. of cross-section of the delivery pipe and calculate the size of pipe on this allowance, but it is wise to check by calculating actual velocities at the foot-piece and discharge.

Size of air pipe can be found by reckoning air velocity at 20 to 30 ft. per sec.; velocities up to 70 ft. per sec. are sometimes used but friction loss is higher.

Foot-pieces are of various designs; the simplest is merely the projection of the air pipe into the lower end of the delivery pipe (Fig. 99). Other forms are shown in Figs. 100 and 101. The air should be dispersed as completely as practicable; large air bubbles rise faster than small, with consequent greater slippage of the liquid past the bubbles. To reduce SLIPPAGE to a minimum, the more complicated foot-pieces introduce the air through many small holes, thus obtaining smaller bubbles and better dispersion.

TESTS have shown that the efficiency of the system is increased appreciably by use of properly designed foot-pieces. At the EAST RAND PROPRIETARY MINES, LTD. (*105 EL 26*), efficiencies were 17.7% and 27.5% with a foot-piece admitting air through a single 4-in. opening, compared with efficiencies of 37.15% and 30.55% with the improved style shown in Fig. 101. These tests were made on lifts elevating slime mill pulps weighing 63.3 lb. per cu. ft. about 30 ft. A slight flare at the lower end of the foot-piece is advantageous in furnishing a gradual increase in velocity of entering fluid.

Discharge pipe is sometimes increased in size upward on long lifts to reduce the velocity. The advantages of changing to a larger size with ordinary reducers is questionable, as a sudden change of velocity with consequent eddy losses occurs; with a long gradual reducer eddy losses are diminished but gradual increase in pipe diameter is impractical except possibly for low lifts in agitating and aerating machines such as Pachuca or Parral tanks. The best arrangement for discharge end is a vertical opening with a cusp-shaped umbrella

(Fig. 102) to deflect the stream downward. The discharge may be turned horizontally by use of a long-radius elbow, but it will not be as efficient; if the discharge pipe is turned and run any considerable distance horizontally allowance must be made for further losses.

Losses in an air-lift are friction in the pipe lines, slippage of fluid past rising air bubbles, and velocity head lost at the discharge. Friction losses can be kept within reasonable limits and slippage can be reduced by increased dispersion of air. Ordinarily the velocity head lost is unavoidable on account of the necessity to keep the solid in suspension; some saving could be made by the use of increasing-diameter pipe, but this is generally impracticable.

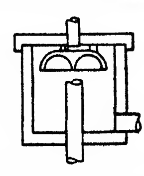

FIG. 102. Umbrella top for air-lift.

Efficiency of the air-lift may be expressed as the ratio (multiplied by 100) of the theoretical horsepower needed to raise the liquid to the air horsepower required for adiabatic compression, or the indicated horsepower of the air-compressor cylinders, or the input horsepower to the compressor as determined from steam-indicator cards, or the motor power consumption. WATER HORSEPOWER = $62.5QgL/33{,}000$. AIR HORSEPOWER WITH ADIABATIC COMPRESSION = $\dfrac{144PVn}{33{,}000(n-1)}\left[\left(\dfrac{P_1}{P}\right)^{\frac{n-1}{n}} - 1\right]$, where $n = 1.406$ for single-stage adiabatic compression.

In making comparisons of air-lift efficiency with the efficiency of other systems, the work of the air-lift should not be condemned because of an inefficient compressor plant nor should the lost work occurring in the compression of the air be disregarded.

Efficiencies for good work in practice range between 35 and 40%; instances of efficiencies up to 45% are claimed.

ADVANTAGES. The air-lift is easily constructed; lack of moving parts reduces wear, expensive repairs, and shutdowns; attendance for the lift itself is insignificant but a proportionate part of compressor charges must be borne by it. Where aeration and agitation of the fluid to be elevated are desired it is especially suitable. Flexibility can be obtained by provision of a valve on the air line operated by a float on the surface of the liquid in the sump so that the air supply can be regulated to the amount to be lifted. When large variations occur for considerable lengths of time lift columns of various sizes may be provided so as to be easily interchanged. An air-lift can generally be easily cleaned out by shutting off the discharge and turning on the air at as high a pressure as possible, thus forcing out and mixing any accumulations in the pipe lines; these will be removed readily on again opening the discharge. The first cost ordinarily will be less than for other devices. The greater power as compared with other systems may be compensated by savings in attendance and repairs. Air lifts have been successfully applied to the elevation of sand and slime pulps. Where acid or other corrosive fluids are to be elevated the air-lift has a distinct advantage over pumps.

DISADVANTAGES. Proper design is essential for operating efficiency. It is necessary to provide a sump or well of considerable depth; great depths can be avoided by compounding the lift, making it a series of short lifts, but this complicates and increases the piping. When compressed air is not already available, air-lifts would be of doubtful advantage unless large volumes were to be handled.

Application of air-lift to mill work is generally limited to lifts under 20 ft., owing to the depth of submergence necessary. In such cases, especially where comparatively small tonnages are handled,

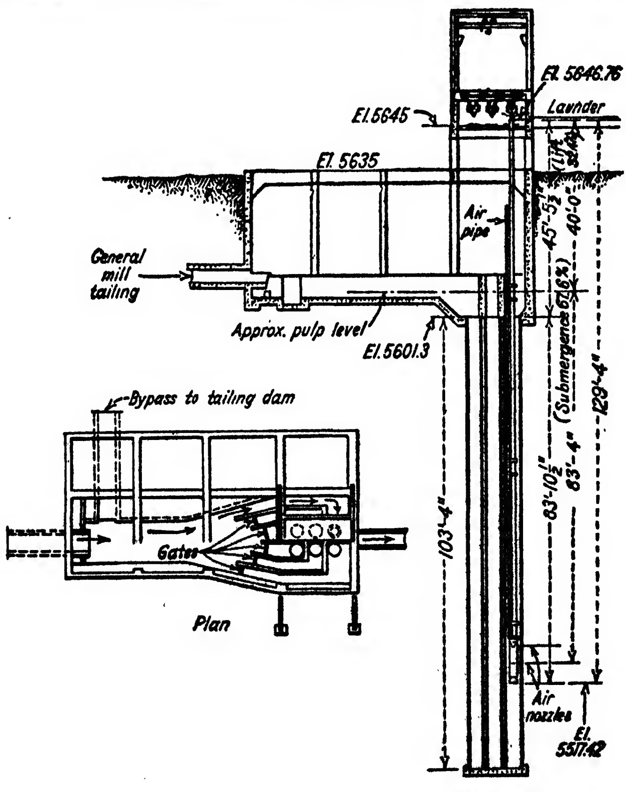

FIG. 103. Arrangement of tailing air-lift at CHINO COPPER CO.

little attention has been given to the refinements of design necessary for efficient operation, as the total power consumed is small. However, close attention to design and efficient operation have resulted in the installation of several plants for handling large tonnages of mill tailing at considerable

saving over elevators, centrifugal pumps, or tailing wheels. At CHINO COPPER Co. (*112 J 806*) an air-lift to elevate 12,000 dry tons per 24 hr. of mill tailing in a pulp containing about 15% of solids was installed in preference to a bucket-elevator system because of lower first cost and an estimated operating cost of 72% of that with bucket elevators. Actual operation showed that operating costs were about 50% of those for bucket elevators. The general arrangement is shown in Fig. 103. Six well pipes were provided in a single shaft, with gates arranged to deflect the incoming pulp-stream to whichever one was being used. Three sizes of lift columns of standard, wrought-iron, flange-connected pipe were made as shown in Fig. 104 to be used with varying capacities and to determine which gave the highest efficiency. Details of the foot-piece are shown in Fig. 105, *A*. A traveling crane on a steel framework was installed to facilitate changing the lift columns; concrete umbrella deflectors on a movable carriage over the discharge ends of the columns caused the rising pulp to drop into a concrete box from which it flowed away in a launder. Air was furnished from the main powerhouse, 530 ft. distant, by two Ingersoll-Rand, Imperial-type *XPV*-4 steam-driven compressors with compound steam cylinders 13- and 29-in. diam. and duplex single-stage air cylinders 22-in. diam. by 20-in. stroke. Special oil-pressure governors controlled the speed of the compressors so that with decrease of pressure or lowering of pulp in the well the governor caused the compressor to slow down until the wells filled again with pulp and the reverse action took place. Table 66 presents operating details for 16 mo. of 1919 and 1920. For cost data see Sec. 20, Art. 3. The air-lift proved very successful in taking care automatically of fluctuations in feed rate, without change of lift columns. Although ample provision was made for reserve wells and columns in case of clogging it was found that the lifts could free themselves and start up even after 32 ft. of sand had settled in the pit.

Efficiency based on total horsepower, %	37.2	24.8	32.2

Fig. 105, *B*, shows a foot-piece designed by Ingersoll-Rand to improve the efficiency of the CHINO lift. This foot-piece was attached to 43 ft. of standard 14-in. O. D. pipe followed by 76 ft. (to the discharge) of special welded pipe increasing uniformly from 14 to 16 in. outside diameter. With this column it was expected that power consumption would be cut 5 to 10% with a corresponding increase in efficiency of 2 to 4 units per cent.

At another large copper mine in the southwest (*105 J 1177*), three air-lifts replaced three 10-in. centrifugal pumps direct-connected to 150-hp. motors to lift 7,000 g.p.m. of tailing having 4 or 5 parts of water to 1 of solids. The air-lifts consisted of 10-in. discharge pipes in 20-in. wood stave pipes; a 40-hp. motor drove the compressor for each. Operating costs and repairs on the air-lifts were a small fraction of those when pumps were used since excessive wear of sand in the pumps reduced the life of runners and liners to about 4 da., continuous running. At the Angelo and Cason mills of EAST RAND PROPRIETARY MINES, LTD., tests were made to determine best operating conditions (*105 EL 26*). The foot-piece used is shown in Fig. 101. The lower 35.4 ft. of discharge pipe was lined with wood, thus reducing the internal diameter of pipe on No. 1 from 14- to 11 1/2-in. and on No. 2 from 16- to 13 1/2-in. Table 67 gives results of some of the tests on slimes and sands. The slime pulp weighed 63.3 lb. per cu. ft. and the sand, 64.56 lb. per cu. ft. Columns 1, 2, and 3 show the effect of submergence on efficiency. Plotting the results of these and other tests gave a curve indicating a submergence of 1.83 to 1 for a maximum efficiency of 36.2%. Column 5 on Cason slimes shows higher efficiency than this, but it was attained with an increased amount of pulp.

22. FEEDERS

Feeders are necessary whenever it is desired to deliver a uniform stream of dry or moist ore, since such ore, whether coarse or fine, will not flow uniformly from a reservoir of any kind through a gate except when regulated by some type of feeding mechanism.

The requirements of a satisfactory feeder are: (*a*) It must be positive. (*b*) Once set for a given rate it must deliver at that rate irrespective of the amount of ore ahead of it. (*c*) It must be readily subject to adjustment to vary its delivery rate. (*d*) It must start under load, and stop without spill. (*e*) It should be adapted to the size of material to be handled. The commonest types of feeders are: (1) traveling bands of articulated pans, called APRON FEEDERS, or of belting, called BELT FEEDERS; (2) revolving pulleys or rollers with smooth or irregular surfaces, called ROLL or PULLEY or ROTARY FEEDERS; (3) shaking or reciprocating plates; (4) plungers; (5) screws; (6) revolving disks; (7) traveling endless chains. Movable grizzlies (Sec. 7, Art. 4) are used for feeding coarse ore and special forms of feeders are used with cylinder mills (Secs. 5 and 6).

Apron feeder (Fig. 106) is used for coarse ore. It consists of a short pan conveyor (Art. 7) set underneath a bin or hopper in such a way that a part of the weight of the filling rests on the carrying surface. This surface should be sufficiently uneven to make the feeder positive. If the lumps are large and there is considerable pressure of material above the feeder tending to cause the material to pack, the pans should be deeply corrugated, but if the material is fine or does not tend to bridge at the hopper mouth, a smooth

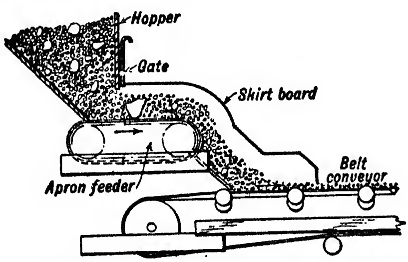

FIG. 106. Apron feeder delivering to belt conveyor.

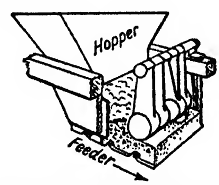

FIG. 107. Swing-hammer feed regulator.

surface may be used. If desired, the bin gate can be eliminated and replaced by a swing-hammer regulator (Fig. 107). This device automatically adjusts itself to the passage of large lumps, while acting in general to maintain a layer of even thickness on the apron. Heavy chains, steel rail, and the like are used as substitutes for the swing hammer. A disadvantage of this device is that if the swinging part breaks for any reason the broken steel is apt to go into the crusher. A means for preventing this contingency (*112 J 660*) consists of, say, three steel rods bolted at several places to the swinging part and fastened to the support; these will hold the parts of a broken hammer until it is discovered and removed.

Usual widths of apron conveyors are 24, 30, 36, 42, 48 and 60 in.; length c–c. of sprockets is normally 1 $^1/_2$ to 2 times the width.

For very heavy material, such as coarse ore containing large lumps, several types of apron conveyors with overlapping pans of cast carbon or manganese steels have been developed recently. One of these, the Robins-Oro apron feeder, consists of a series of double-beaded, overlapping, interlocked manganese-steel pans heavily ribbed on the underside. Cast integral with each pan, and near each end, there is a wide link-hub under the rear edge, and two narrow link-hubs under the front edge; the wide link-hubs on one pan fit between the narrower hubs on the next pan. Between the hubs at the front and rear edges of each pan there is a pair of integral-cast ribs which take the form of a chain; they are flanged on the bottom to present a continuous flat surface which runs on idler rollers. Connections between the pans are made by nickel-steel, heat-treated pins turning in ground manganese-steel bushings, which the link-hubs are ground to fit. The idler rollers are keyed to steel shafts running in extra heavy bearings. Four lugs on each pan serve to make the apron a continuous rigid surface in which there is no possibility of buckling. To prevent spill, the pans have 4-in. vertical flanges, cast integral, which lap outside the skirtboards. Raised smooth surfaces, just inside the end flanges and directly under the edges of the fixed steel skirtboards, form continuous sealing strips. The frame supporting the feeder is constructed of longitudinal girders, and braced by I-beam cross-ties. Standard widths are 18 to 72 in.; special sizes up to 84 in. may be constructed.

Speed of apron FEEDERS ranges between 5 and 20 f.p.m. They are usually equipped with push-button control, and often have variable-speed motors.

Capacity depends upon rate of travel, width, and size of material. The depth of the layer must be at least as great as the size of the maximum lump, if a fixed slide gate is used on the bin, but if a swing-hammer regulator or its equivalent is used, the layer may be thinner. Tons per hour approximately equal $3wts$, where w, t, and s are width of the feeder in ft., thickness of the layer in ft., and speed in f.p.m. respectively. This assumes 20 cu. ft. of broken material as piled on the conveyor to weigh 1 ton, which is equivalent to an allowance of 50% voids. Table 68 gives data on some installations of pan and apron feeders.

Pan conveyors are used in place of apron feeders when it is desired to both transport and feed the material (see Fig. 108). At UNITED COMSTOCK a 48-in. pan conveyor with wood-cushioned pans was

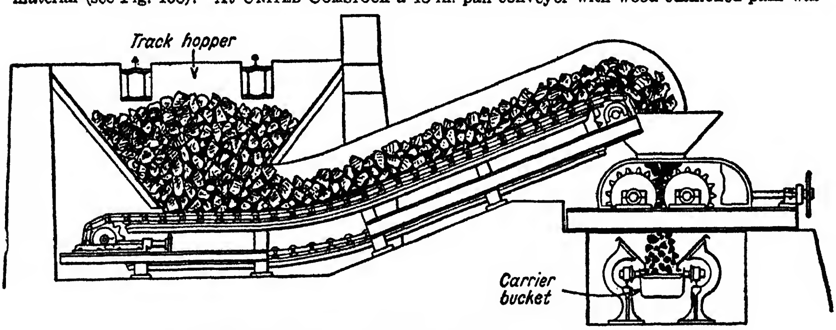

FIG. 108. Pan-conveyor feeder from bin to crusher.

used to feed from the coarse-ore bin. It was driven at 9 to 15 f.p.m. from the head shaft by a direct-connected motor with double-gear speed reducer (*114 J 848*). This conveyor both fed and elevated to a grizzly preceding the primary crusher. At INSPIRATION (*121 J 726*) special feeders with manganese-steel plates (PLATENS) of the form shown in Fig. 109 were used to feed run-of-mine ore from bins to the primary breakers. Instead of having rollers on the link pins to run on a track, the rollers were stationary and supported the links on the loaded run and the platen flange on the return. The platen width was 4 ft.; width between skirt plates, 42 in.; length between sprocket centers, 42 ft. 6 in.; maximum thickness of ore stream, 2 ft.; maximum load, 7 cu. ft. per ft. of length (= 0.35 ton); average maximum load delivered, 300 t.p.h., including many stops for picking waste and to prevent overloading the crusher. Motor input at 20 f.p.m., 5.36 hp. empty and 7.50 hp. loaded; at 10 f.p.m., 3.43 and 4.29 hp. respectively. Short feeders (7 ft. 8 in.), the same width drew 3.21 hp. empty and 3.75 hp. loaded when running 40 f.p.m. and fed about 12 t.p.m.

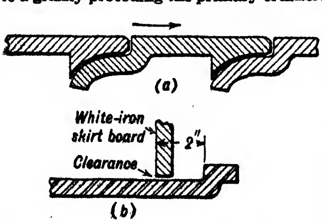

FIG. 109. Transverse (*a*) and longitudinal (*b*) sections of manganese-steel platens on apron feeders at INSPIRATION.

Belt feeders are essentially short belt conveyors so placed under an inclined chute that they control the discharge of material therefrom. The method of placing relieves them

from any part of the static load of the material in the bin. The head pulley must be placed so that the surface of the material at rest in the chute falls behind the vertical plane

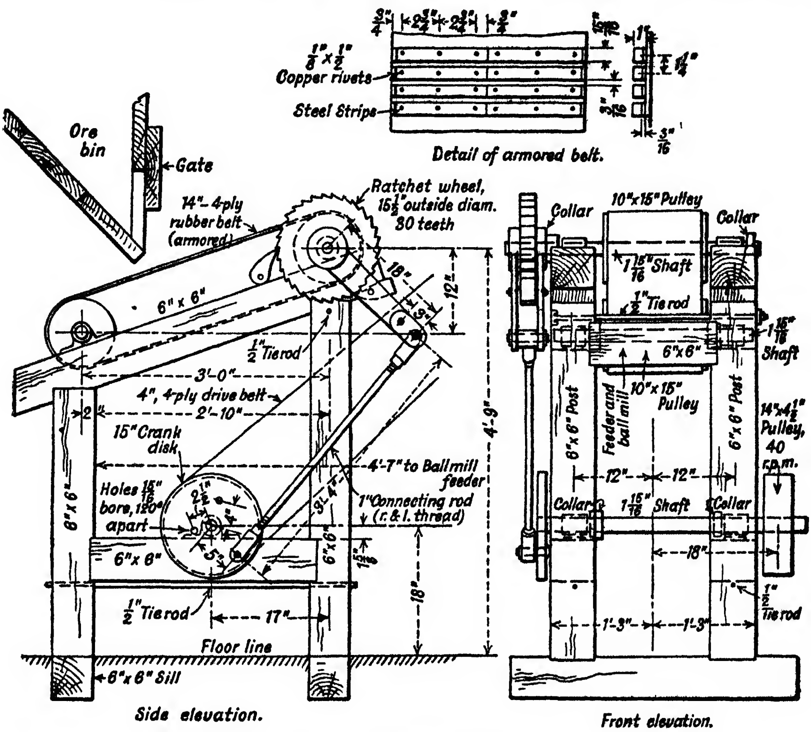

FIG. 110. Belt-apron feeder.

through the pulley shaft. Belt feeders frequently and properly replace apron conveyors for fine ore but are unsatisfactory for coarse ore since uneven loading by heavy lumps deforms them so that material spills, and because wear is excessive. Occasionally the belt surface is armored as shown in Fig. 110 (*111 J 63*). The material list for the feeder pictured follows:

Six common flat journal boxes, 1 15/16-in. 12 bolts 1/2×7 1/2-in. for same. 12 1/2-in. mal. washers, for same. 1 shaft 1 15/16 in. × 3 ft. 2 in.; keyseated for 10 × 15 pulley and ratchet wheel. 1 shaft 1 15/16 in. × 2 ft. 6 in.; keyseated for 10 × 15 pulley. 1 shaft 1 15/16 in. × 3 ft. 4 in.; keyseated for 14×4 1/2-in. pulley and crank disk. 6 split safety collars, 1 15/16-in. 9 ft. 3 in. of 4-ply rubber belt, armored as shown. 2 c.i. solid pulleys 10 × 15 in., 1 15/16-in. bore. 1 c.i. solid pulley 14 × 4 1/2 in., 1 15/16-bore. 1 ratchet wheel (15 1/2 in. outside diam., face 2 1/2 in. ±), with arm; 1 15/16-in. bore. 1 crank disk, 15 in. diameter, face 2 in. ±; 1 15/16-in. bore as shown. 1 crank pin 15/16 in. × 4 in. ±. 1 connecting rod with ends, as shown. 1 pin, 15/16 in. × 6 in. ±, with washers and keys. 1 pawl, 2 in. × 6 in. × 2 1/2 in. with pin, washers, and keys. 1 pawl, 2 in. × 6 in. × 2 1/2 in. with pin, washers, keys, and box. Armor plates and rivets for belt.

The price in 1921 was $157 against $285 to $350 for plunger feeders and $300 for roll feeders of equal capacity.

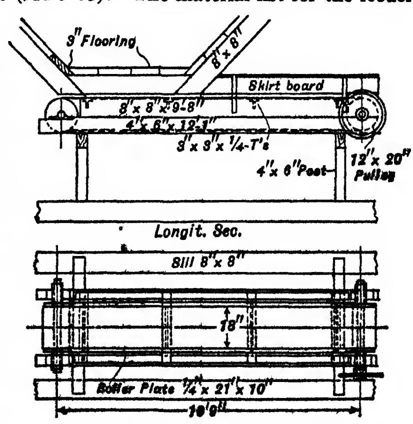

FIG. 111. Plate-supported belt feeder at EAGLE-PICHER.

Fig. 111 shows construction of a locally built feeder. Four such feeders are installed under a 400-ton fine-ore bin (5% >1 in.; 5% moisture) at the Montana mine of Eagle-Picher Co., each delivering 140 t.p.d. (three feeders at a time) to a collecting conveyor leading to a ball-mill. Distinguishing feature is the use of a 1/4-in. steel sole-plate to support the entire length of the loaded run of the 18-in. belt and enable it to carry the whole vertical pressure from ore in the bin. The 12-in. head pulley is driven by sprocket; the sloping skirtboards are lined with belting.

Capacity may be calculated by the same formula as for apron feeders. Table 69 gives data on several belt feeders.

a A 10-hp. motor drives this feeder and a 54-in. pan conveyor 8 ft. long.
b Belt. *c* Constant speed. *ch* Chain. *d* Per hr. *r* Reducer. *ra* Ratchet.

Morse Vari-stroke feeder is a short belt conveyor passing under a feed hopper at one end and discharging over a head pulley at the other, to which an intermittent motion is applied. A horizontal rocker-arm, fulcrumed on the head-pulley shaft, is oscillated vertically at its outer end by a circular cam on a driven shaft. A lug on this arm engages loosely the edge of a disk keyed to the head-pulley shaft and causes it to turn, on the upstroke of the arm, through friction supplied by a small roller in the wedge-shaped space between lug and edge of the disk. Amplitude of the downstroke (controlling the rate of belt travel) is limited and adjusted by a setscrew.

Roller feeder (drum or pulley feeder) is shown in Fig. 112. The diameter and setting of a feeder of this type should be such that a tangent to the front surface of the roll, drawn from the lower edge of the hopper gate, makes an angle with the horizontal less than that of the angle of repose (ϕ) of the material and less than the sliding angle (θ) of the material against the roll face, and at the same time the angle of the tangent to the roll face at the rearmost point of contact of the ore therewith should be less than θ. Skirtboards must be used to confine material on the roller. Rolls from 12×12-in. to 48×48-in. are commonly used, the larger diameters for coarser feeds and the greater widths for larger capacities.

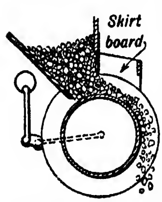

Fig. 112. Roller feeder.

Advantages are simplicity of design, large capacity, low speed, and low power consumption. Disadvantages are that delivery is almost directly below the feed point and there is considerable loss of headroom.

a Per hr. *c* Constant speed. *ch* Chain. *d* Direct connected. *r* Reducer. *ra* Ratchet.

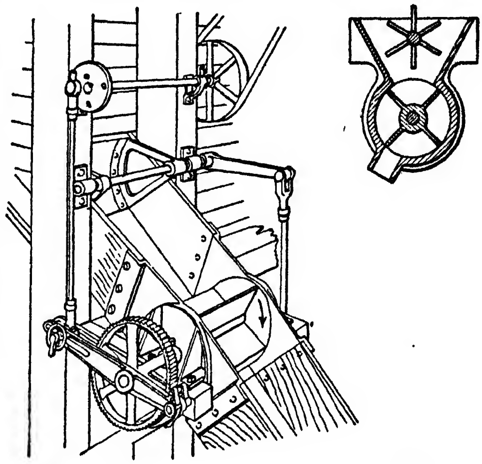
At Miami Copper Co., a 48×48-in. roller feeder had two spiders; face, 1 1/2 in. thick, protected by 1/2-in. manganese-steel plates bolted on. It was driven by ratchet and pawl with six possible speed changes.

Wear on drum surfaces can be materially lessened by grooving the surface transversely or by bolting on transverse angles, thus preventing sliding. Such provision is useful also when material tends to pack and bridge at the hopper mouth. Rubber bands (see Sec. 13, Art. 4) should be useful in this service.

Peripheral speed of 5 to 20 f.p.m. is usual.

Capacity in tons per hr. is given approximately by the formula $T = 3\pi dwtn$, where d, w, and t are respectively diameter of roll, width of roll, and thickness of layer of material thereon, in feet, and n = r.p.m. of roll.

Table 70 gives data on several roll feeders.



(a) (b)

Fig. 113. Rotary feeder.

Rotary feeder (Fig. 113) is used where close regulation of fine feed is desired. It is usually placed in a hopper chute (item b) and lacks the positive features of the apron and roller feeders but with a free-flowing fine feed, or one that can be stirred by revolving prongs as indicated in (b), a remarkably close estimation of the quantity passed may be made by attaching a revolution counter to the feeder shaft and carefully calibrating the quantity delivered against r.p.m. The chute form (item a) is less common. The figure illustrates the use of ratchet-and-pawl drive, which is probably the best for a slow-moving feeder. Also called a STAR FEEDER.

Fuller rotary feeder, Fig. 114, is of drum type, modified for controlling the flow of fine, dry materials liable to flooding. That is prevented by the shear-plates a; the shafts to which these are keyed are connected by the levers b and the tension springs c, allowing the plates to give outward and pass any accidental piece of hard material. Clearance between shear-plates and the drum is maintained by stops on the levers b. The lower edges of the shear-plates are not horizontal (*i.e.*, not parallel with the drum corrugations), whence the discharge from each pocket, and from the feeder as a whole, is continuous, not spasmodic. Bumping of the cast-iron balls inside the drum tends to counteract any clinging tendency of the material.

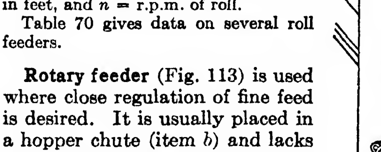


Fig. 114. Fuller rotary feeder.

Reciprocating-plate feeder (Fig. 115). In moving forward into the position shown in (a), a layer of material is carried forward on the plate and more material settles from the hopper onto the rear portion of the plate. On the reverse stroke the plate slides under the material and that material at the forward end of the plate has its support withdrawn and falls. Widths range from 12 to 48 in. The plate may be supported on wheels, as indicated in the figure, or suspended by rods.

(a) (b)

Fig. 115. Reciprocating-plate feeder.

The SPEED is usually below 30 r.p.m. STROKE LENGTH depends upon the size of material; it should be great enough to prevent bridging above the plate at the end of the forward stroke; usual lengths are between 4 and 12 in. CAPACITY may be estimated from the equation $T = 3ltwn$, where w, l, and t are respectively effective width of feeder, length of stroke, and average thickness of layer on plate in front of hopper gate, in feet, and n = r.p.m. This feeder is suitable for both coarse and fine ore, provided there is no tendency to pack and bridge in hopper mouth. Wear on the plate is considerable and the hopper must be emptied in order to make renewals. The drive should be through a gear, and a flywheel to overcome the inertia at reversing is advisable.

When this type of feeder can be mounted so as to remove the static weight of the column of ore, *e.g.*, under the end of a chute, it may be run at higher speeds and becomes a shaking feeder. The operation is then the same as that of shaking screens (see Sec. 7, Art. 6) and, in fact, screen or grizzly bottoms

are often provided. Such an arrangement is particularly desirable in loading a mixture of medium-coarse and fine material onto a belt conveyor, as it permits the fine material to load onto the belt first (see Fig. 116) and thus decreases wear and lessens slip and tumbling of the coarse lumps; material thus loaded is also excellently arranged for hand picking.

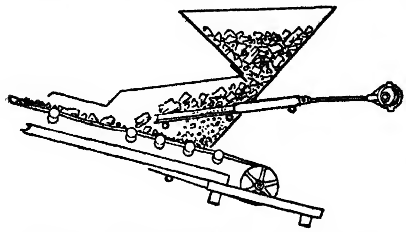

Fig. 116. Shaking grizzly loading conveyor.

Vibrating-tray feeder is a form of shaking feeder. In the mechanical type, the feed trough, inclined slightly (5 to 10°), is hinged at the upper end and supported on an adjustable stirrup at the lower end so that it is just lifted by a projection on a revolving shaft, *e.g.*, a square corner or cam ear, and then dropped. The vibration thus set up is sufficient to move dry, pulverized material readily and, if the number of vibrations is between 240 and 600 per min., will give substantially continuous, uniform movement. Such a feeder is not suitable for heavy loads nor coarse material.

Tray or pan feeders are also vibrated electromagnetically, by devices substantially identical with those applied to the Jeffrey-Traylor and Utah vibrating screens (Sec. 7, Art. 7); the Syntron vibrator is another and similar device, producing a differential throw. Two outstanding advantages of the magnetic vibrating principle are: (*a*) entire absence of rotating or sliding bearings to be lubricated and protected against dust; (*b*) ease of adjustment, since the intensity of vibration (which governs the rate of flow at a given inclination) depends upon electrical input at transformer or rectifier, the latter being subject to simple rheostatic control. In the Magna mill of Utah Copper Co., a magnetically vibrated feeder delivers 3,000 (dry) tons of $<3/4$-in. ore carrying 5% moisture in 24 hr., with expenditure of 0.3 kw. and at cost of 0.083¢ per ton (*PC*).

Plunger feeder (Fig. 117) consists of an eccentric-driven plunger working in an open-top trough placed below the mass of ore to be fed, or replacing a side-draw chute; unless the hopper is shallow, the latter is the better position.

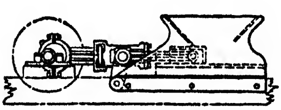

Fig. 117. Plunger feeder.

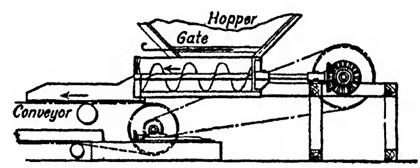

Fig. 118. Screw feeder.

Speed is usually less than 30 s.p.m. and stroke length from 3 to 6 in. Capacity is estimated similarly to that of the preceding feeders.

Screw feeder (Fig. 118) is sometimes used for closely regulated positive feeding of fine, free-running soft material; it is useless for sticky material and wears rapidly with gritty substances. Screws range from 6 to 12 in. diameter, speed up to 80 r.p.m., capacity of a 6-in. screw at 80 r.p.m. is roughly 90 cu. ft. per hr. and of a 12-in. screw, 700 cu. ft. (See also Art. 10.)

Automatic diaphragm feeder. The magnetic separating section of the Franklin mill, New Jersey Zinc Co., contains 43 feeders of the type shown in Fig. 119, ranging in capacity from 5 to 120 t.p.d. (*PC*). The ore is fine, bone-dry, and dusty, and the aim of the feeder is to deliver this material to a conveyor in such manner as to escape the necessity for installing an exhaust dust collector at each place. The bottom of the hopper terminates in a vertical, rectangular chamber *1*, having a small, rectangular, hoppered opening *2* at its lower end. The side of the chamber facing the approaching belt consists of a rubber diaphragm (two 1/8-in. thicknesses in the size illustrated) firmly secured on all four edges. The outward bulge of this diaphragm, roughly proportional to the height of ore within, presses against the vertical lever *3*, which is hinged at top and at its lower end carries a shutter *4*; the rate of discharge is thus automatically adjusted to maintain a column of ore in the chute, insuring steady and nonturbulent flow with minimum fall through the air.

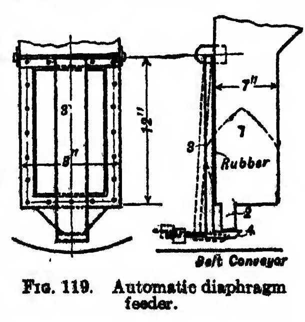

Fig. 119. Automatic diaphragm feeder.

Challenge feeder (Fig. 120), of the revolving-disk type, consists of an inclined circular plate *J* forming the bottom of a chute or hopper *L* which is open at *M*. Disk *J* is revolved slowly and intermittently by bevel gears on shaft *I*, which is driven by the friction pawl *D* attached to lever *B*. When the feeder is used with gravity stamps, *B* is actuated by connecting rod *F* and lever *G* from a tappet *H* on the middle stem of the battery. The feeder may also be pulley driven, in which case a cam on the pulley

shaft lifts *B*. Speed of *J*, and hence feed rate, is varied by adjusting the height to which the outer end of the tappet lever *G* may rise, under the tension supplied by the spring *N*. When applied to a stamp mortar, as shown, the speed adjustment is partly automatic, since the fall of the tappet *H* depends upon the depth of ore in the mortar.

Hardinge disk feeder has a horizontal, circular plate of 30- or 60-in. diameter, continuously rotated by a geared motor situated beneath it. A circular hopper occupies the center of the disk and has an opening in its lower edge partly closed by an inwardly projecting scraper, the position of which is adjustable; space between disk and lower edge of hopper is likewise adjustable, as is also the motor speed, thus offering three means for controlling rate of delivery over the edge of the disk. Maximum capacity, t.p.h., is 20 for the 30-in., and 75 for the 60-in. feeder, the latter rate requiring a 1-hp. motor.

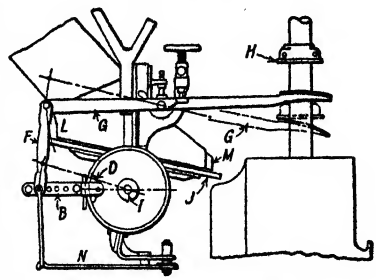

Fig. 120. Challenge feeder.

Ross chain feeder. Chain-type feeder is one of the most effective.for controlling the flow of very large and heavy stone or ore from a bin or in chutes. It is based on the principle of opposing a yielding surface to the material and controlling the flow at the top of the stream. The Ross chain feeder (Fig. 121) consists of a curtain of heavy endless steel chains *a* mounted on an overhead tumbler *b* and so suspended as to lie on top of the material and to travel with it. The drum is mounted on a structural steel frame and is driven through a spur gear *c* receiving power from any suitable source. This feeder is made in sizes to handle practically any desired capacity, size of material, and bin opening. SPEED depends upon capacity desired and material handled; it is frequently adjustable. Push-button control is usual for primary-crusher feeders.

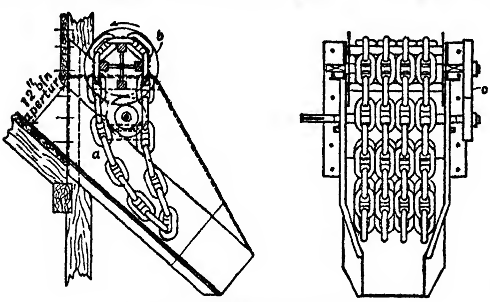

Fig. 121. Ross chain feeder.

Stirrup feeder is essentially an undercut concave gate (Fig. 33) eccentric-driven, with a transverse baffle placed centrally in the box above the swinging gate and clearing the latter sufficiently to prevent wedging. This baffle holds material that falls onto the gate in place so that the gate moves from under and drops it at each oscillation. It has been used frequently for fine-roll feeding.

Constant-weight feeders. In many milling and metallurgical operations, constancy of weight fed to a given device is more important than constancy of volume, particularly if the ore is subject to segregation due to a mixture of sizes (see Art. 2). The above-described feeders (also conveyors) are all capable of maintaining a fairly constant rate by volume, the rate being fixed or adjusted from time to time by varying the size of an opening or the speed of a rotating or traveling mechanism. Several devices are now available for performing this function automatically; others still more elaborately equipped to record the weights actually delivered are described in Art. 23.

Jeffrey-Traylor feeder is a trough or chute magnetically vibrated in substantially the same manner as the screen of the same name described in Sec. 7, Art. 7. It is adjustable as to feed rate by rheostatic control of the electrical input. Constancy in weight of feed is therefore attainable (reportedly within 1%) by discharging over a short, balanced, and counterweighted belt conveyor, depression of which by an overload automatically adds resistance to the electromagnetic circuit and damps the vibration of the feeder. A vibrating feeder was used at HALKYN (*38 IMM 706*) for returning classifier sand to a ball mill; power consumption was low and the arrangement was immune to damage from spill.

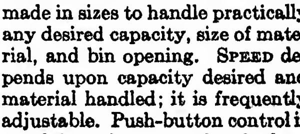

Fig. 122. Hardinge constant-weight feeder.

Hardinge constant-weight feeder, shown diagrammatically in its simplest form in Fig. 122, is a short belt conveyor of which the whole weight is carried by a pair of rocking beams *K* (one each side), balanced on the pivot *F*. The inner ends of these beams carry the motor *B* and the adjustable counterweight *A* (also other equipment in the more elaborate forms), and are connected through suitable linkage and levers with the gate *H* at bottom of the feed hopper *E*. With a given setting of the counterweight, any excess weight of ore on the conveyor thus lowers the gate until equilibrium is restored

and *vice versa*. Rate of feed is adjustable through variable-speed motor or reduction gear, or (at constant speed) by shifting of the counterweight and varying the minimum opening of the gate.

Tell-tales of some kind should be installed on conveyors, elevators, feeders, chutes, bins and the like to warn of failure of function. The principle underlying substantially all of them is a lever actuated by the ore, the other end of the lever actuating a bell, light, etc. Usually, with moving streams, a weighted down leg above the stream hangs vertically at rest when no stream is running, and in this position closes an electric circuit which energizes the signal; the level of the running stream is high enough to strike the down leg and impart sufficient horizontal motion to open the circuit. Obvious modifications warn of a bin overload or underload; with a bucket elevator the tell-tale is usually installed either in the feed or discharge chute.

23. AUTOMATIC WEIGHING DEVICES

Besides maintaining constancy in weight of a stream of material, it is often desirable to secure a record (whether or not at constant rate) of the tonnage in transit or delivered. Such information is advantageous: (*a*) for ascertaining the total tonnage per day or other unit of time delivered to a section or the whole of a mill, or to any individual machine (such as a grinding mill); (*b*) for maintaining constant proportions in a mixture of two or more materials, as of ore, fuel, and fluxes at a smelter, or of limestone and shale at a cement plant; (*c*) for recording the weight of a given batch of ore, as at a sampling mill.

Hardinge Feedometer (Fig. 123) employs the same method for maintaining constant rate as the Hardinge constant-weight (Fig. 122) feeder, with the addition of automatic devices to perform any or all of the following functions: (*a*) indicate rate of feed in any desired units; (*b*) totalize tonnage delivered during any elapsed time; (*c*) furnish a printed record of that total, itemized as to batches, if required; (*d*) trace a continuous record of feed rate on a chart covering a month's operation; (*e*) permit remote control of feed rate; (*f*) provide, through interlocking, for maintaining a fixed ratio between the rates of two or more feeders, and trace their individual rates on the same record; (*g*) stop the feeder, and record, upon failure of ore supply, resuming automatically when feed is restored. Other adjuncts include track mounting, whereby one feeder may serve multiple outlets; a magnetic pulley for tramp iron, a metal belt for hot materials, completely enclosed housing for dusty or corrosive atmosphere, or when the feeder is required to work at either above or below normal atmospheric pressure. The machine is made in three sizes adapted to 2-, 4-, and 12-in. material, at corresponding maximum capacities (based on 85 lb. per cu. ft.) of 12, 150, and 500 t.p.h. Extreme range in rate adjustment (the minimum being as small as desired) is 3 : 1 through variable-speed belt drive alone, or 6 : 1 when such drive is combined with a two-speed motor.

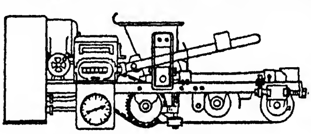

Fig. 123. Feedometer.

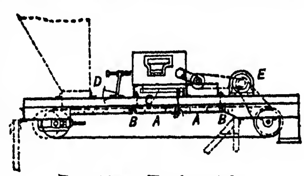

Fig. 124. Feedoweight.

Merrick Feedoweight (Fig. 124) is a short (9 1/2- to 12 1/4-ft.) flat belt conveyor having the central portion of its upper run carried on a group of idlers which are mounted on two (sometimes only one) articulated supports *A*. Opposite ends of these supporting frames are hinged at *B*, while the adjoining ends are linked to the scale beam *C* communicating with adjustable counterpoises. Uniform rate of discharge from the hopper is maintained by the gate *D*, the position of which is mechanically adjusted through reducers and reversible clutch from the main driving motor *E*, power to which is controlled by the scale mechanism in response to variation in the load on the belt. The device includes a rate indicator, a totalizer, and a recorder. It is designed for belt widths of 16 to 48 in.

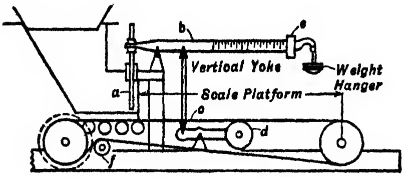

Fig. 125. Poidometer.

Schaffer Poidometer, shown diagrammatically in Fig. 125, is designed to feed materials at a constant rate, by weight, and register the total amount handled by attaching the feed gate *a* to one end of a scale beam *b*, the other arm of which is weighted by the running load on conveyor *c* passing over roller *d* at the exact center of the weighing section of the belt. Setting is effected by sliding weight *e*. At a given setting, an excess of material on the belt depresses the roller, elevates the yoke and scale beam, lowers the gate, and reduces the flow of material, and *vice versa*. The weighing and recording functions involve a correlation (not shown)

between the weighing roller and the measuring roller *f*, the latter serving both as revolution counter and as a snub pulley for the drive.

Richardson Convey-O-Weigh is a self-testing combination of conveyor and automatic weigher; it weighs and registers a pre-set quantity of loose material at every cycle and conveys that definite quantity in nearly a continuous stream to any desired destination. It consists of five main elements and various accessories: (*a*) main supporting steel frame; (*b*) feed hopper and feed conveyor unit; (*c*) scale levers hung on shackles carried on cross-members of the main frame; (*d*) weighing conveyor unit hung on four rods and shackles from the scale levers; (*e*) beam box with graduated scale lever, hanger weights, sliding poises, electrical controls, etc. The machine receives its supply from any convenient overhead source; the feeder, driven by its own motor and speed-reduction unit, feeds material to the weighing conveyor. When the pre-set weight has been delivered to the weighing unit, the scale beam rises, tips a mercury switch which opens the circuit to the motor driving the feed conveyor, and thus stops the supply of material. The feed conveyor operates intermittently while the weighing conveyor runs continuously (unless otherwise specially arranged). The weighing conveyor is driven by its own motor and speed-reduction gearing. After a certain amount of material has run off the end of this conveyor, the weighted end of the scale beam descends, closing the mercury switch and restarting the feed conveyor.

24. DISTRIBUTORS

It is almost invariably necessary to split the stream of ore passing through a mill at some point or points in its flow in order to distribute the parts to parallel treatment processes; thus the product of a primary breaker must, frequently, be sent to two or more secondary breakers; the product of intermediate crushing to a battery of grinding machines, and the product of one grinding machine to a battery of concentrators. The method employed for distribution of moving streams depends primarily upon accuracy required. CRUDE SPLITTING may be done by spreading the stream into a shallow and roughly rectangular section and then inserting diverting vanes; at the central point, if halving is desired, etc. ACCURATE SPLITTING may be effected by the method employed in many mechanical samplers (Sec. 19), *i.e.*, by contracting the stream to a substantially equidimensional section and delivering it to a compartmented vertical drum, either the drum or the delivering mechanism being made to revolve on a vertical axis in such relation to the other that when the dividing walls cut the stream the stream is flowing substantially in the plane of the wall.

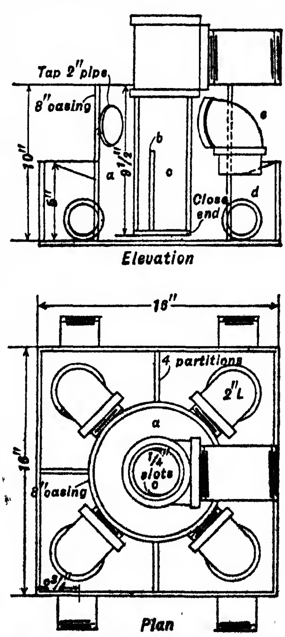

Fig. 126. Wet-pulp distributor, overflow type.

Coarse material. Except in sampling, distribution of streams of coarse material rarely requires accurate splitting; for crude work the stream from a chute, conveyor, or the like is allowed to fall freely onto the upper edge of vertical partition walls between fixed chutes. Only a two-way split makes any approach to accuracy owing to the fact that the center of the stream flows most rapidly and is coarsest. Bins with multiple gates are probably best for distribution of coarse dry material to a number of parallel machines.

Launder splitting is frequently employed for fine fluid pulps. The simplest arrangement is to fork the launder and place a hinged metal plate extending the partition wall upstream; this may be moved until the desired proportion passes down each fork before fastening into place. Multiple splitting is best effected by repetition of two-way splits. For methods by UTAH COPPER Co., see Art. 16.

Stationary pulp distributors (OVERFLOW TYPE) divide a stream by first collecting it all in one receptacle and then discharging radially through as many outlets as required. Accuracy depends upon the thoroughness of the preliminary mixing and upon impartiality as between the several outlets.

At a ST. JOSEPH LEAD Co. mill at Flat River, Mo. (*IC 6658*), primary and some secondary flotation feed (3,800 dry t.p.d.) is divided among 23 cells by a stationary distributor of overflow type. The pulp contains 20% solids, all <65-m. and 54% <325-m. Feed enters vertically at the bottom of a conical tank, 9 ft. across the top, through a 16-in. pipe leading from a surge tank at slightly higher elevation, and overflows through 24 rectangular holes around the rim of the cone, just below its edge. Partitioned receptacles form a ring 12 in. wide around the top, each delivering through a 4-in. pipe in its bottom Uniformity of distribution is assisted by a perforated cylindrical baffle surrounding the inlet at the apex

of the cone, and another, larger and unperforated cylindrical baffle of which the upper edge is higher than the outlets.

A 4-way pulp distributor for capacities up to 3 t.p.h., having no moving parts, and capable of construction in any mill shop, is shown in Fig. 126 (*136 J 188*). Equality of distribution is gained by imparting a vortex motion to the pulp, which enters the distributing chamber *a* through two tangential $1/2 \times 5$-in. slots *b* in the wall of the 3-in. delivery pipe *c*, closed at bottom. Flow through any one (or more) of the 2-in. outlets *d* can be stopped by simply turning the loosely threaded elbow *e* upward, whereupon the remaining outlets automatically redivide the whole stream. At Sherritt-Gordon 5,000 (dry) tons of ore a day, in pulp containing 45% solids (70% <200-m.), is distributed to its flotation units by terminating the pump line from the classifiers in the bottom of a vertical section of 10-in. pipe having 2×12-in. slots spaced around its wall, each discharging into a separate pocket.

Revolving pulp distributor consists of a circular, usually conical, vessel, suspended vertically, free to rotate about a central axis, and having two or more orifices near its lowest point. The issuing streams successively traverse partitioned compartments arranged in a ring, each compartment having its separate outlet. Accuracy depends largely upon the manner in which the whole pulp is delivered to the revolving vessel; the orifices are usually so proportioned to the rate of feed as to maintain a considerable depth of pulp above them. Rotation may be mechanical or self-induced by application of the Archimedes principle.

At Wright-Hargreaves (*140 #4 J 37*) a mixture of primary classifier overflow and tube-mill product is divided among six bowl classifiers by a self-actuated revolving distributor. This consists of a vertical cylindrical tank, 3×3-ft., with conical bottom, suspended by a central shaft which is welded at the bottom and supported at top in such a manner (an old Wilfley pump unit) as to be free to rotate. Near the bottom of the cone are four equally spaced tangential outlets (6-in. elbows). Surrounding and attached to the central shaft is a rubber-covered spiral flight 16 in. in diameter, on which the incoming pulp impinges; this, together with the back pressure developed by the outlets, provides the necessary motive power. A circular launder with six adjustable gates receives and distributes the discharge.

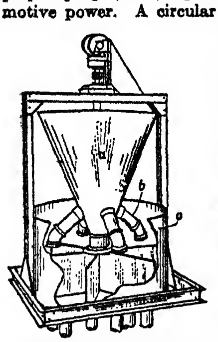

Fig. 127. Concenco distributor.

At the Pecos mill of American Metal Co. (*IC 6605*) classifier overflow was divided between two flotation units by a self-actuated distributor. It consisted of a 24(diam.)$\times$18-in. cast-iron tub suspended by a vertical central shaft and rotating at 18 r.p.m. Four equidistant 4-in. holes in the wall, close to the bottom, were bushed for $2\,1/2$-in. nipples and 90° elbows, the latter discharging backward and about 45° downward. Feed entered through a vertical tube surrounding the suspension shaft, delivering at 6 in. above the bottom of the tub, the pulp in which usually stood about 12 in. deep. No method of feeding from an inclined spout was found to give accurate distribution; too large an outlet was also undesirable. The outside collecting receptacle had four compartments, each with 5-in. flanged outlet, each pair of opposite outlets feeding one flotation unit.

Concenco revolving distributor (Fig. 127) comprises a conical hopper *a*, 3 ft. across the top, supported at the bottom on a sealed step-bearing, and revolved by a central vertical shaft driven by worm gear from a $1/3$-hp. motor. Pulp enters the top of the cone as near the center as practicable and discharges through four downward-pointing outlets *b*. The lower half-depth of the splitting tank *c*, the wall of which is 2 ft. high, is divided by radial partitions into as many segments (2 to 10) as desired, each segment having its separate bottom outlet.

Fine dry ore. The method illustrated in Fig. 128 is adopted in the magnetic separating department of the Franklin mill (N. J. Zinc Co.) for insuring equal distribution of fine, dry ore to a number of screens operating in parallel. Each screen is fed by its own roll or "star" feeder 6 (see Fig. 113), all rotated at the same speed by a common shaft driven by variable-speed motor. Supply is delivered to the hoppers of these feeders through openings in the bottom of a horizontal scraper conveyor, each hopper being kept level full. The hopper of the last feeder of the group has the construction shown in section in Fig. 128. It is pivoted at *2*, and normally held vertically by the spring *5* and the counterweighted arm *7*. If, at their momentary speed, the preceding feeders are unable to dispose of their allotments, the surplus arrives at this tilting hopper, depresses it, and through the connecting-rod *8* and rheostat *4* increases the speed of the motor driving all feeders. When the tilting hopper is relieved of its overload, it tends to return to its normal position and speed is correspondingly reduced.

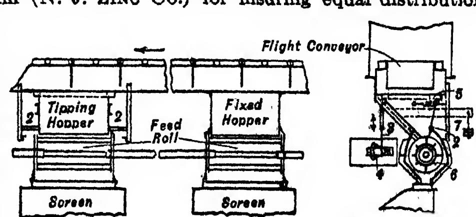

Fig. 128. Dry distributor.

TESTING

REVISED BY

M. D. HASSIALIS

1. PRINCIPLES OF SAMPLING

Sampling is the operation of removing a part, convenient in size for testing, from a whole which is of much greater bulk, in such a way that the proportion and distribution of the quality to be tested (*e.g.*, specific gravity, metal content, recoverability) are the same in both the whole and the part removed (SAMPLE). The conditions of the more stringent definition, that the sample shall be completely representative of the whole as regards all aspects save bulk, are practically never fulfilled when heterogeneous mineral mixtures are sampled.

Elements of sampling problem are: (1) precise definition of the quality to be tested, (2) character of the quality under test, (3) character of the material to be sampled, (4) relation of the quality to be tested to the material to be sampled, (5) character of the sample necessary to supply the information as to the quality about which information is desired, (6) degree of accuracy necessary, (7) way in which the parent lot occurs, (8) sample size required for (*a*) testing and (*b*) to satisfy, theoretically, the standard of accuracy and the desired degree of assurance, (9) method of taking the sample, and (10) mechanism for taking the sample in accord with (9).

Sampling theory has for its objects the exposition of the determinative variables of the operation, and explanation of their interdependence, with the ultimate object of controlling sampling operations and predicting their results. In this respect, present-day theory is in rudimentary form, applicable only to a highly idealized technique. PERFECT SAMPLING TECHNIQUE is assumed to yield samples such that any deviations from complete representation of the quality to be tested in the sample are ascribed to chance causes. For example, if a sphalerite-chert mixture was sampled with perfect technique, it would not be required that the sample have the same zinc assay (the quality under test) as the original mixture, but merely that the difference between the zinc assay of the whole and that of the sample was due to chance causes. With this stipulation the theory of probability may be applied to the problem of sampling.

Application. Count 250 black beans (used to denote valuable mineral particles) and 750 white beans (used to denote gangue particles) into a container, mix the contents, and withdraw 100 beans as a sample. The probability that the sample will assay 25% (*i.e.*, will contain 25 black beans) is the ratio of the total number of 100-bean samples containing 25 black beans to the total number of ways in which 100 beans can be taken from 1,000 beans. The number of combinations of 1,000 objects taken 100 at a time is given by $C_{1000}^{100} = 1000!/100!\,900!$. The number of ways in which 25 black beans can be taken from 250 black beans is, similarly, $C_{250}^{25} = 250!/25!\,225!$. But for each of these methods of taking 25 blacks from 250 blacks there are C_{750}^{75} ways of taking 75 white beans from 750 white beans. Hence the total number of ways of taking 25 blacks and 75 whites from the original mixture is $C_{250}^{25} \times C_{750}^{75} = 250!/25!\,225! \times 750!/75!\,675!$. Therefore the probability P that the random sample will assay 25% is

$$P = \frac{C_{250}^{25} \times C_{750}^{75}}{C_{1000}^{100}} = 0.0968 \qquad (1)$$

This means that if 10 samples were taken from the lot (replacing the previous sample each time before resampling) 0.968 or approximately 1 out of these 10 would have the same assay as the whole; 9.7 out of 100 would give correct assay; approximately 97 out of 1,000, etc.

Table 1. Probability *vs.* performance in sampling mixtures of 250 black and 750 white beans *c*

1	2	3	4	5
Assay, % black	Probability of assay *a*	Number of samples		
		From Col. 2	Observed	From normal law *b*

37	0.00170	0.2	1	0.1
		99.5	100	98.9

a By Eq. 2.
b $P = C_{\alpha+\beta}^{\alpha} p^{\alpha} q^{\beta}$ where $p = 0.25$ and $q = 0.75$.
c Based on 100 @ 100-bean samples.

Eq. 1 can be generalized in the form

$$P = \frac{C_{a}^{\alpha} \times C_{b}^{\beta}}{C_{a+b}^{\alpha+\beta}} \qquad (2)$$

where a = number of mineral particles in the whole, b = number of gangue particles in the whole, and α and β equal respectively the number of mineral and gangue particles in the sample. Using this generalized equation, the probability that a random sample will assay any given percentage of valuable mineral may be calculated.

Test results (T. Morris and M. Hassialis, *CU*) are shown in column 4 of Table 1, compared with calculated predictions according to two statements of probability. Fig. 1 is a graphical comparison. Agreement was reasonably close; it would have been excellent for 1,000 samples.

Size of sample, finite lot. The larger the sample taken, the smaller the probability of its complete accuracy, but the greater the probability that the error will be small. Thus the probability that a random sample of 200 beans from the lot of 1,000

tested will have a correct assay is 0.0727; for a 400-bean sample it is 0.0594. A change of one particle in a 40-particle sample produces a change of 2.5 units in the assay, in a 100-particle sample the change is one unit, for a 200-particle sample it is 0.5 units, in general the change in assay is $100/n\%$, where n is the number of particles in the sample. Consequently increasing the sample size increases the number of values that the assay of the sample may have, and it follows that the probability of hitting a particular assay with a random sample will decrease. On the other hand, the probability that a random sample will have an assay between, *e.g.*, 23.99% and 26.01% increases as the size of the sample increases. Thus for a 40-particle sample the only assay lying within this range is 25%, found when the sample contains 10 mineral particles. The probability that the assay lies between 23.99% and 26.01% is therefore the probability that the assay is 25%; this is 0.153. But for a 100-particle sample, the assays in the range are 24, 25, and 26% and the corresponding probabilities are 0.0951, 0.0968, and 0.0929, a total of 0.285. For a 400-particle sample the following assays lie in the range: 24.00, 24.25, 24.50, 24.75, 25.00, 25.25, 25.50, 25.75, and 26.00; their corresponding probabilities are 0.050, 0.054, 0.057, 0.0588, 0.0594, 0.0587, 0.0568, 0.0536, 0.0496; the sum is 0.4979.

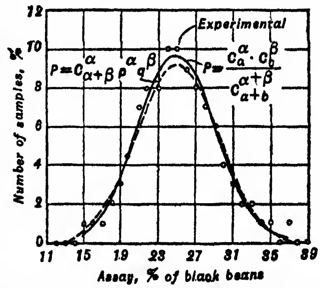

FIG. 1. Probability *vs.* performance in sampling (see Table 1).

Binomial equation of probability. Calculation of sampling probabilities by means of Eq. 2 is difficult when the original mixture contains a large number of particles, and impossible when this number becomes infinite. For a lot containing an infinite number of particles, the probability p of taking a mineral particle is unaltered by any previous sampling, the probability q of withdrawing a gangue particle is similarly constant. The probabilities p and q are the proportions of mineral and gangue particles in the infinite lot. The probability P that a sample of n particles taken at random will contain m mineral particles and $n - m$ gangue particles is given (Uspensky, *Introduction to Mathematical Probability*, McGraw-Hill, Chap. 3) by

$$P = C_n^m p^m q^{n-m} \tag{3}$$

The right-hand member of Eq. 3 is, by inspection, a term of the expanded binomial $(p + q)^n$. For low values of n, when $p \neq q$, the polygon of the binomial is asymmetric, but does not coincide with the asymmetric polygon given by Eq. 2 (see Fig. 1); when $p = q$ the binomial polygon is symmetrical, but still does not coincide with the polygon of Eq. 2. As n increases, both polygons become symmetrical and congruent regardless of the values of p and q. Calculation of sampling probabilities by means of Eq. 3 becomes impossible when sample size is large, because it involves such large factorials and is a discontinuous function, as is shown in Fig. 2, where the individual probabilities of Table 1 are plotted as ordinates P at unit assay-particle intervals on the assay axis. Intermediate values on the assay axis have no physical significance.

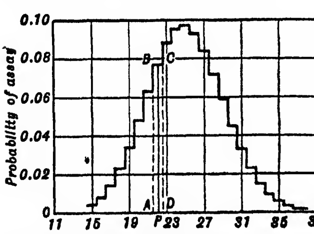

FIG. 2. Probability polygon of test results (see Table 1).

Approximation of probabilities. A rectangle of unit width, *e.g.*, *ABCD*, erected as shown (Fig. 2) upon each ordinate has an area equal to the probability of the corresponding assay value. Omitting the vertical sides of the rectangles, the histogram shown in the figure is obtained. This has the properties (*a*) that the area under each step is the probability that the corresponding assay value will be obtained, and (*b*) that the total area under the histogram is unity. As the sample size increases, the proportional width of each step decreases until finally the histogram approaches a continuous curve. The symmetrical polygon or histogram may be approximated very closely by a continuous function. The analytic expression of this function involves a somewhat different method of plotting, as follows: the maximum probability (maximum ordinate of Fig. 2) is determined, and the corresponding value of m (most probable assay) is noted. All ordinates y are then expressed as fractions of the maximum probability, and abscissae x are expressed as deviations from the mean number of mineral particles. For example, if 0.0968 is the maximum probability and 25 the mean number of mineral particles, then a probability of 0.0929 for 26 mineral particles will now be plotted by $y = 0.0929/0.0968 = P/P_0$ and $x = 26 - 4 = 1$. When so plotted the approximation function y is given by

$$y = \frac{P}{P_0} = e^{-x^2/2npq} = e^{-x^2/2\sigma^2} \tag{4}$$

where σ = standard deviation = $\sqrt{npq}$ (see Yule and Kendall, *An Introduction to the Theory of Statistics*, C. Griffin & Co. Ltd.; p. 179) and P_0 is the probability of the most probable assay. The area under this curve is equal to $\sigma\sqrt{2\pi}$, hence to make the area under the curve unity Eq. 4 must be divided by $\sigma\sqrt{2\pi}$ which gives a new function Y as

$$Y = \frac{y}{\sigma\sqrt{2\pi}} = P/P_0\sigma\sqrt{2\pi} = e^{-x^2/2\sigma^2}/\sigma\sqrt{2\pi} \tag{5}$$

and

$$P = \int_{x_1}^{x_2} Y dx \tag{6}$$

For each value of the standard deviation σ (a constant for any given values of n, p, and q) a different curve is generated by Eq. 6. For increasing values of σ the base of the curve increases and its peak flattens out, though the area under the curve remains unity. All such curves have in common the property that the same proportion of the area is contained between the same deviation limits (expressed in terms of the standard deviation). For example, in all such curves 50% of the area is found between $x = \pm 0.6745\sigma$, 68.27% of the area between $x = \pm\sigma$, 95.45% between $x = \pm 2\sigma$, and 99.73% between $x = \pm 3\sigma$.

Sample size, infinite lot. If instead of the number of mineral particles, the proportion of mineral particles in the sample is used, the standard deviation of the proportion of mineral particles in the sample $\sigma_p = \sqrt{pq/n}$. If the mineral particles have a specific gravity δ_1 different from the specific gravity δ_2 of the gangue particles, the standard deviation on a weight basis σ_w may be calculated as follows: Let a = per cent. of mineral (by weight) in the whole; then assuming mineral and gangue particles have the same size and shape

$$a = \frac{100p\delta_1}{p\delta_1 + q\delta_2} = \frac{100p\delta_1}{\delta_2 + p(\delta_1 - \delta_2)}$$

Since (Brunt, *The Combination of Observations*, Cambridge; p. 48)

$$\sigma_w = \frac{da}{dp}\sigma_p; \quad \sigma_w = \frac{(100 - a)\delta_1 + a\delta_2}{100\sqrt{\delta_1\delta_2}}\sqrt{\frac{a(100 - a)}{n}} \tag{7}$$

Example. To compute the size of the sample that should be taken such that its assay will be within 0.2% of the true assay, say 5%, with a probability of 0.99.

If the mixture is chert and sphalerite, $\delta_1 = 4.0$ and $\delta_2 = 2.6$. From Eq. 7

$$\sigma_w = \frac{95 \times 4 + 5 \times 2.6}{100\sqrt{4 \times 2.6}} \times \frac{\sqrt{5 \times 95}}{\sqrt{n}} = \frac{26.8}{\sqrt{n}}$$

Now derive the value of σ_w to find what the deviation limits, expressed in terms of the standard deviation, must be in order that the area under the curve between these limits will be 99% of the total area. Table 2 will facilitate the calculation; it is calculated for a standard deviation of unity. To use it in the present problem enter at the probability 0.99 and read X = 2.576. Since $X = x/\sigma$, the standard deviation σ_w = 0.2/2.576 = 0.078. Substituting in the preceding equation and solving, n = 117,650. Assuming 1-in. particles of an average weight of 0.051 lb. (the error involved in averaging particle weights is within the limits of error of the estimate), the weight of sample necessary to give an assay within the range 5 ± 0.2%, 99 times out of 100 is 117,650 × 0.051 = 6,000 lb. If the particles were, say, 100~150-m., the sample weight necessary to give an assay within the prescribed limits with the same degree of assurance would be 0.0007 lb.

Table 2. Probability P, *vs.* deviation X, relative to unit standard deviation

P	X	P	X
0.90	1.645	0.97	2.170
0.91	1.705	0.98	2.326
0.92	1.750	0.99	2.576
0.93	1.812	0.999	3.291
0.94	1.881	0.9999	3.890
0.95	1.960	0.99999	4.417
0.96	2.054	0.999999	4.892

Application of probability theory to actual sampling. The results of the theory above developed are applicable only to large nonsegregated mixtures of particles of pure minerals sampled with perfect sampling technique, a situation which has no practical counterpart. In practice, the particles of the mixture have a wide range of composition, are usually of large size range, values are invariably segregated, the sample is ordinarily a composite of a number of smaller samples or increments, and stage sampling at different sizes may have been used. A workable sampling theory must be able to take these factors into account.

Variation in composition of individual particles may be taken into account as follows: Divide the material into a number of density fractions (*e.g.*, sp. gr. 2.6 to 2.8) d_1, d_2, d_3, ··· etc., varying from the density of pure sphalerite to that of pure chert inclusive; let p_1, p_2, p_3, ··· etc., denote the propor-

tion (= probability p that a single particle taken from a parent lot of infinite numbers will belong to this density fraction (p. 03)) of particles in each density fraction with corresponding assays $a_1, a_2, a_3, \cdots$ etc. If a denotes the over-all assay then

$$a = \frac{p_1d_1a_1 + p_2d_2a_2 + \cdots}{p_1d_1 + p_2d_2 + \cdots} \tag{8}$$

If $\sigma_1, \sigma_2, \sigma_3, \cdots$ etc., are the standard deviations of the corresponding density fractions $d_1, d_2, d_3, \cdots$ etc., then

$$\sigma_j = \sqrt{\frac{p_j(1 - p_j)}{n}} \tag{9}$$

where the subscript j denotes any density fraction. The standard deviation σ of the assay a is given (Brunt, *loc. cit.*, p. 169) by Eq. 10.

$$\sigma^2 = \sum_j \left(\frac{\delta a}{\delta p_j}\right)^2 \sigma_j^2 + \sum_k \sum_l c_{kl} \left(\frac{\delta a}{\delta p_k}\right)\left(\frac{\delta a}{\delta p_l}\right) \sigma_k \sigma_l \tag{10}$$

When $k = l$, terms of the double summation are omitted. The coefficient of correlation c_{kl} for the pair of density fractions k, l, is given (Yule and Kendall, *loc. cit.*, p. 395) by

$$c_{kl} = -\frac{p_k p_l}{n\sigma_k\sigma_l} \tag{11}$$

Eq. 10 is an approximation applicable when the deviations of the p's are small; the complete equation contains higher-order terms of the Taylor expansion (see Worthing and Geffner, *Treatment of Experimental Data*, John Wiley & Sons, p. 208). The values of p_j, d_j, and a_j may be determined from a sorting-assay test. Using these values, σ_j and σ may be calculated from Eqs. 9 and 10 respectively, the latter being given in terms of the unknown n. From the desired degree of assurance for the prescribed limits of error in assay, σ may be calculated from Eq. 6 and n then calculated.

Example. To compute the size of sample that should be taken such that its assay will be within 0.2% of the true assay, say 5%, with a probability of 0.99; the mixture having a density distribution as follows: A sphalerite fraction, 0.15% by weight with an average density = 4.00, a middling fraction, 70.85% by weight, average density = 2.71; a chert fraction, 29.00%, average density = 2.65. The results of the various steps in the calculation are given under Example 1, Table 3. (For explanation of table see p. 06.)

Assuming 1-in. particles, a sample weight of 249 lb. is calculated. By a comparison of the figure with that obtained on p. 04 it appears that the effect of "locked" particles upon sample size is to reduce it. A similar result is reported by Manning (*9 JIF 132*), who calculated for a 1-in. mixture of coal (p_1 = 80.1, d_1 = 1.3, a_1 = 1.7), middling (p_2 = 8.5, d_2 = 1.5, a_2 = 10.8), and dirt (p_3 = 11.4, d_3 = 2.2, a_3 = 67.7) that a sample containing 3,075 particles, weighing 77 lb., is required in order that the sample shall not deviate from the true assay of 10% ash by more than ±1% (10 ± 1%) more often than one time per hundred. For a mixture of pure coal and pure dirt 9,950 particles, or a weight of 249 lb., is required under the same conditions.

Variations in composition and size may be taken into account in similar fashion by computing the contributions to the standard deviation of the sample assay (Eq. 9) made by changes in the proportions of different density fractions in a given size fraction, and to changes in the proportion of the size fractions, and proceeding as before. Thus let the material be divided, by means of a sizing-sorting test, into N density fractions $d_1, d_2, \cdots d_n$, and each density fraction be divided into M size fractions of average diameter $D_1, D_2, \cdots D_m$; this test yields MN products. Let w_{ij} denote the weight per cent. of material belonging to the ith size fraction and the jth density fraction; similarly the corresponding assay and proportion of particles by number will be denoted by a_{ij} and p_{ij}. The assays are given, if a sizing-sorting-assay test has been made; in the case of binary mixtures the assays may be computed, for approximate work, by means of

$$a_{ij} = \frac{d_v(d_{ij} - d_g)100}{d_{ij}(d_v - d_g)} \tag{12}$$

where d_v = density of valuable mineral, d_g = density of gangue. The proportion of particles in the i-j fraction p_{ij}, may be calculated from

$$p_{ij} = \frac{w_{ij}/D_i^3 d_j}{\sum_{ij}(w_{ij}/D_i^3 d_j)} \tag{13}$$

The over-all assay a of the sample is calculated from

$$a = \sum_{ij} D_i^3 p_{ij} d_j a_{ij} \Big/ \sum_{ij} D_i^3 p_{ij} d_j \tag{14}$$

and the standard deviation σ_{ij} of the i-j fraction by

$$\sigma_{ij} = \sqrt{p_{ij}(1 - p_{ij})/n} \tag{15}$$

The standard deviation σ of the sample assay is given by

$$\sigma^2 = \sum_{ij} \left(\frac{\delta a}{\delta p}\right)^2_{ij} \sigma^2_{ij} + \sum_{ij} \sum_{i'j'} c_{ij,i'j'} \left(\frac{\delta a}{\delta p}\right)_{ij} \left(\frac{\delta a}{\delta p}\right)_{i'j'} \sigma_{ij}\sigma_{i'j'} \tag{16}$$

where terms of the double summation, in which $i, j = i', j'$, are omitted. The correlation coefficient $c_{ij,i'j'}$ is given by

$$c_{ij,i'j'} = -p_{ij}p_{i'j'}/n\sigma_{ij}\sigma_{i'j'} \tag{17}$$

The calculations, though tedious when the sizing-sorting test yields a large number of products, present no particular difficulty.

Example. Example 2 of Table 3 gives the results of a sizing-sorting test on a sphalerite-chert ore, in which the material was divided into 30 fractions. A sample weight of 35 lb. is computed.

Explanation of Table 3. Fractions of sizing-sorting or simple sizing or sorting tests are labeled with two-digit figure; the first digit represents the size fraction to which the product belongs, the second the density fraction. Col. 3 gives the assays a_{ij} of the fractions. The proportion of particles in each fraction appears in Col. 9; these are obtained by dividing each member of Col. 8 by the sum of the same column, as in Eq. 13. Cols. 6, 7, and 8 represent computational steps required to compute Col. 9. Cols. 10 to 15 represent the different steps in the calculation of the partial differentials $\left(\frac{\delta a}{\delta p}\right)_{ij}$ in Col. 16. These come from Eq. 18, which gives the partial differentials of Eq. 14 with respect to p_{ij}.

$$\frac{\delta a}{\delta p_{ij}} = \left\{ \left[\sum_{ij} D_i^3 p_{ij} d_j\right] D_i^3 d_j a_{ij} - \left[\sum_{ij} D_i^3 d_j p_{ij} a_{ij}\right] D_i^3 d_j \right\} \Big/ \left[\sum_{ij} D_i^3 p_{ij} d_j\right]^2 \tag{18}$$

The first bracketed term of the numerator in Eq. 18 is the sum of Col. 10; the second bracketed term of the numerator is the sum of Col. 11; the first term of the numerator is given by Col. 13, the second term is in Col. 14 and their difference is Col. 15. The partial differentials in Col. 16 are obtained by dividing the members of Col. 15 by the square of the sum of Col. 10 as is required by Eq. 18. The ratio of the sums of Cols. 11 and 10 gives, according to Eq. 14, the over-all assay (composite of Col. 3; see Art. 18) and thus provides the computer with a partial check on calculations. Col. 18 is computed from Col. 9 by means of Eq. 15. The sum of Col. 19 yields the first member of the right-hand side of Eq. 16 divided by n. To compute the second term of this equation, a simpler, symmetrical, and equivalent term, obtained by substituting the value for $c_{ij,i'j'}$ given by Eq. 17, is determined, as:

$$\sum_{ij}\sum_{i'j'} c_{ij,i'j'} \left(\frac{\delta a}{\delta p_{ij}}\right) \left(\frac{\delta a}{\delta p_{i'j'}}\right) \sigma_{ij}\sigma_{i'j'} = -\frac{1}{n} \sum_{ij} \sum_{i'j'} \left(p_{ij} \frac{\delta a}{\delta p_{ij}}\right) \left(p_{i'j'} \frac{\delta a}{\delta p_{i'j'}}\right) \tag{19}$$

Cols. 20 and 21 are the computational steps required to calculate the right-hand side of Eq. 19, which is given by Col. 22. Total of Col. 20 should be zero, if a sufficient number of significant figures is carried in relation to the magnitudes of the numbers in Cols. 9 and 16. The sum of Col. 22 is the second right-hand term of Eq. 16. $n\sigma^2$ may now be calculated from this equation. (See *Solution.*) Eq. 6 is used to calculate σ from the conditions imposed as to assurance and deviation limits as in example on p. 04, and this value squared is substituted above to determine n. Sample weight is computed using the same assumption as to particle shape as was used in Eq. 13. The weight of the i-j product is given by $\frac{62 \cdot 4\pi}{6 \times 1728} D_i^3 d_j n p_{ij}$ lb. where D_i is in inches. Col. 23 is the product of Col. 9 and n, and gives the number of particles in each fraction. Col. 24, obtained by multiplying Col. 10 by n, gives $np_{ij}D_i^3d_j$, and its sum, when multiplied by the constant factor 0.0189, gives the weight of the sample in pounds. If the distribution of the weight is of no interest, weight may be found directly by multiplying the sum of Col. 10 by $0.0189n$.

Variability. A mathematical investigation of Eq. 16 and the effect thereon of changes in the variables is beyond the scope of this article. One conclusion of practical importance, drawn from such an investigation, is that the effect of a fraction upon sample weight depends upon the variability $(a_{ij} - a)$, *i.e.*, the greater the deviation of the fraction assay from the over-all assay, the greater is its effect upon sample weight. Exs. 3, 4, and 5 of Table 3 illustrate this effect. All three parent lots assay 5%. In Ex. 3 the material is divided into two fractions, one pure chert whose assay deviates from the sample assay by 5%, and a mixed fraction for which $(a_{ij} - a) = 0.49\%$; a sample weight of 20.1 lb. is required. The material in Ex. 5 is also divided into two fractions, one pure chert with $(a_{ij} - a) = 5\%$ but the other fraction is pure sphalerite for which $(a_{ij} - a) = 95\%$; hence a much larger sample weight, 5,810 lb., is required. In Ex. 4 the material is divided into three fractions for which $(a_{ij} - a)$ is 5, 0.49, and 38% respectively; hence an intermediate sample weight (436 lb.) should be and is required.

Effect of mixing materials of different sizes is an increase or decrease of sample weight according to whether the admixed size is coarser or finer than the original material. The extent of the change in sample weight is not proportional to the difference in sizes or any power thereof. This is illustrated by Exs. 3, 6, and 7 of Table 3. Comparing Exs. 3 and 6 it is seen that a 50-50 mixture of 1- and 0.5-in. material requires a sample weighing 11.3 lb., as compared with the 20.1-lb. sample required for 1-in.

material with similarly distributed values. A 50–50 mixture of 1- and 1/16-in. material with similarly distributed values requires a sample weight of 10.1 lb. (Ex. 7), only 1.2 lb. less than that of Ex. 6, although the admixed size of Ex. 7 is 1/8 that of Ex. 6. In other words, the coarse size is more effective than the fine size in controlling sample weight. If, as is the case with natural ores, the finer size has a larger variability than the coarse size, these conclusions must be modified accordingly.

Degree of assurance affects sample weight through its effect on the standard deviation of the sample. In general, sample weight increases slowly with an increase in the degree of assurance until a degree of assurance of about 0.999, thereafter the rate of increase of sample weight is very great. The following figures calculated for Ex. 4 of Table 3 are illustrative:

P..........	0.90	0.95	0.99	0.999	0.9999	0.99999	0.999999
W (lb)......	179	255	436	715	1,002	1,285	1,585

Permissible limits of assay similarly control sample weight through the standard deviation of the sample. In general, a decrease in deviation limits increases the sample weight, other things being equal. The increase in sample weight is slow at first but becomes very rapid as the limits decrease past 5% of the assay. The following sample weights were computed for Ex. 4 of Table 3:

Deviation limit........	2.0	1.0	0.2	0.1	0.01	0.001	0.0001
Limit (per cent. of assay)	40	20	4	2	0.2	0.02	0.002
W (lb.)...............	4.4	17.6	436	1,755	87.8T	8,780T	878,000T (T = tons)

Ores containing two or more economic minerals are considered as binary ore mixtures, first with respect to one valuable mineral, then with respect to the other valuable mineral, and sample weight is computed as above. The largest sample weight thus computed is taken as the proper sample weight. Exs. 8 and 9 of Table 3 show the calculations for a galena-sphalerite-chert ore assaying 14.5% galena, 4.5% sphalerite, the values distributed as shown. Assuming the ore to be a binary mixture of galena and chert, a sample weight of 606 lb. is computed for the sample to assay 14.5 ± 0.2%, with a degree of assurance of 0.99. When the ore is considered as a binary mixture of sphalerite and chert, a sample weight of 1,027 lb. is computed for the same tolerance and assurance. (This larger sample weight required when zinc is the quality under test is due to the greater variability of the sphalerite values.) Hence if a weight of 1,027 lb. is taken, both Pb and Zn assays will be properly represented by the sample.

Stage sampling may be taken into account by calculating the standard deviation of the sample taken at each stage and compounding these deviations to give the standard deviation of the final sample as follows:

$$\sigma^2 = \sigma_1^2 + \sigma_2^2 + \cdots + \sigma_n^2 \tag{20}$$

where $\sigma_1, \sigma_2, \cdots \sigma_n$ are the standard deviations of the samples taken at each stage. It follows from this equation that the permissible standard deviation of a sample at some particular stage is less than that of the final sample, *i.e.*, the sampling practiced at the various stages is and must be better than the over-all sampling. For example, if 8-in. material is to be sampled to yield a sample at 100-m. with $\sigma = 0.02$ and four stages are to be used, then $\sigma^2 = 0.0004 = 4\sigma_i^2$ (assuming $\sigma_1 = \sigma_2 = \sigma_3 = \sigma_4$) and $\sigma_i = 0.01$. It also follows that errors made in sampling at coarse sizes cannot be corrected by taking large samples at the smaller sizes.

Segregation cannot be taken into account by the theory developed above, for by its very nature it invalidates the basic assumption that deviations are due to chance causes. Although most heterogeneous materials exhibit variations in quality in all directions, the segregation in one, two, and sometimes three directions is marked. An example of unidirectional segregation is the car uniformly loaded with unsized ore which develops marked vertical segregation after transit (providing values are differently distributed in the coarse and fine sizes). A car loaded by a conveyor discharging a bin wherein vertical segregation exists might show longitudinal (or more complex horizontal) segregation, in addition to the vertical segregation produced by vibrations due to transit. Cars loaded directly from a bin might show more complex horizontal segregations with vertical axes of symmetry located at the loading points. Knowledge of the type of segregation existing in the lot to be sampled may be used to devise a sampling procedure which yields representative samples. Such sampling is variously known as biased, or purposeful, or increment sampling.

Increment sampling comprises removal from the parent lot of a number of increments which are composited to form the sample. The number of increments taken, their size, shape, and disposition in the parent body are determined by the known segregation of values and the rate of change of value with position (see p. 87). Correct increment sampling should produce a normal distribution curve when the assays of the individual increments are plotted against increment frequency. Probability theory is then applicable to correct increment sampling, for it may be safely assumed that the increments are independent, and that positive and negative assay deviations are equally likely.

Number of increments, n, that should be composited to give a sample whose assay shall be within prescribed limits with the desired degree of assurance may be calculated from Eq. 6 (*219 JFI 483; 222 ibid. 337*). Since the normal distribution law is symmetrical about the y-axis, Eq. 6 can be written as

$$P = \frac{1}{\sigma\sqrt{2\pi}}\int_{-x_1}^{x_1} e^{-x^2/2\sigma^2}dx = \sqrt{\frac{2}{\pi}}\int_0^{x_1} e^{-x^2/2\sigma^2}d\left(\frac{x}{\sigma}\right) \tag{21}$$

a See Eq. 18, p. 06. b From Eq. 15, p. 05.

Deviation from the most probable assay $\bar{a}$, is measured by x; hence if z denotes $\frac{x}{\bar{a}}$, Eq. 21 may be written as

$$P = \sqrt{\frac{2}{\pi}} \int_0^{z_1\bar{a}/\sigma} e^{-\left(\frac{z\bar{a}}{\sigma}\right)^2/2} d\left(\frac{z\bar{a}}{\sigma}\right) \tag{22}$$

If n increments assaying $a_1, a_2, \cdots a_n$ are taken from the parent lot then $\bar{a} = (a_1 + a_2 + \cdots + a_n)/n$ and $\sigma_s = \sqrt{\sum_n (a_i - a)^2/n}$, where σ_s = standard deviation of the increments. This deviation is related to the standard deviation $\sigma_{\bar{a}}$ of the mean $\bar{a}$ by $\sigma_{\bar{a}} = \sigma_s/\sqrt{n}$ (Atkin and Colton, *Statistical Methods*, Barnes & Noble, N. Y. (1938), p. 120). Substituting in Eq. 22

$$P = \sqrt{\frac{2}{\pi}} \int_0^{h1} e^{-h^2/2} dh \tag{23}$$

where $h = \frac{z\bar{a}\sqrt{n}}{\sigma_s}$. To illustrate use of this equation consider the following:

Example. Ten 5-lb. increments taken from a lot of ore assay 5.0, 4.3, 6.0, 4.7, 5.0, 5.5, 4.0, 5.3, 4.5, and 5.7% zinc. How many increments must be composited in order that the sample shall assay within 4% of the true assay with an assurance of 99%?

The average assay = 5.0%, the standard deviation $\sigma_s = \sqrt{\frac{3.66}{10}} = 0.605$ and, from Eq. 6 or Eq. 23, letting $P = 0.99$, $h = 2.576$. Since $z = 0.04$ and $n = \left(\frac{h\sigma_s}{z\bar{a}}\right)^2$, the number of increments required is calculated as 60.6 or 61 × 5 = 305 lb. sample.

Increment size is determined by the variability and size of the ore. Generally, uniform ores permit use of small increments, whereas spotty ores require larger increments. It can be shown that a sample composited of a large number of small increments is more representative than an equal-weight sample composited of a small number of large increments. There is, however, a minimum weight of increment for each size such that samples composited of smaller increments are less representative. The minimum increment weight is best determined by experiment, although it may be estimated by calculation if the variability and segregation of the ore are known.

Bushell (*37 JCM 361*), Morrow and Proctor (*119 A 227*), Grumell and Dunningham (*15 Fuel in Science and Practice 55*) and others have determined experimentally minimum increment weights for coals of American, English, and South African origin. Fig. 3, plotted from Bushell's data (*loc. cit.*), shows the variation of σ with increment weight; any increment weight corresponding to a point on the flat part of the curve may be used in increment sampling. Table 4 (*A TP 1044*) gives recommended increment weights to be used in sampling British and American coals; the latter, being less homogeneous, require somewhat higher increment weights.

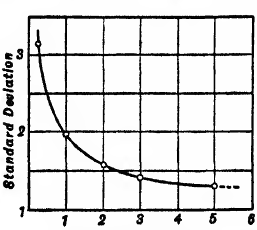

FIG. 3. Standard deviation *vs.* increment weight (*after Bushell*).

c ASTM tentative standard.

Disposition and shape of increments depend primarily upon the segregation of values and secondarily upon the applicability of various sampling methods. Lots possessed of unidirectional segregation are best sampled by taking increments in the direction of segregation. For example, if ore in a car were vertically segregated with assay ranging from 5% at the top to 25% at the bottom, a cylinder sample cut through the ore from top to bottom would be completely representative since the sample would contain correctly apportioned material from every part of the assay range. Any increment shape generated by vertical lines and cutting through the material would give representative

samples. It is also possible to take increments in a direction perpendicular to the direction of segregation providing the increments are properly spaced and located (see p. 37). With close spacing and proper location, samples composited of increments thus taken will approximate the true value of the quality under test very closely but will never completely represent it. Moreover, since spacing and location of increments require more exact knowledge of the rate of change of value with position than for a sample cut in the direction of segregation, this method of taking increments should be used only when the latter is inapplicable.

For bidirectionally segregated materials, the increments should be parallelopipeds whose principal parallel planes are determined by the two directions of segregation. Increments may also be taken in a direction perpendicular to the plane determined by the directions of segregation, but as before, proper spacing and location are predicated upon detailed knowledge of the segregation. The state of segregation existing in a lot to be sampled is rarely known; most available information is of the nature of a guess based on knowledge of the previous history of the material. Hence, increment sampling which does not completely cover the lot involves the risk that some high- or low-value region will be missed and consequently that the determined magnitude of the quality will be too low or too high. For this reason, most operators prefer to sample materials in motion, when frequent cuts of all of the stream taken part of the time reduces the danger of a biased sample (see p. 38).

Buyer's problem. The sampling problems previously considered are of the type where the assay or the proportion of mineral particles in the parent lot is known and it is required to calculate the number of particles or weight of sample that must be taken in order that the sample assay shall lie within the range delimited by the tolerance limits with some desired degree of assurance. Problems involving calculation of assurance, given sample weight and tolerance limits, or problems requiring calculation of tolerance limits, given assurance and sample weight, are only minor variations thereof. However, the converse problem, hereinafter referred to as the BUYER'S PROBLEM, where the sample assay and sometimes the weight are given, it being required to calculate the degree of assurance that the assay of the parent lot lies within prescribed limits, is entirely different.

Example 1. Seventeen identical containers are each filled with 16 particles of chert and/or sphalerite as follows: container 0 with 16 chert, container one with 1 sphalerite and 15 chert particles, container 2 with 2 sphalerite and 14 chert, · · ·, container 15 with 15 sphalerite and 1 chert, and container 16 with 16 sphalerite particles. One of these containers is chosen at random and from it a 4-particle sample, assaying 1 sphalerite and 3 chert particles, is withdrawn. What is the probability that the container held 4 sphalerite and 12 chert particles, *i.e.*, that container 4 was sampled?

Bayes' theorem may be applied to this problem (Uspensky, *loc. cit., p. 61*) expressed in the form

$$P_k = \frac{A_kC(m, n, k)}{\sum\limits_k A_kC(m, n, k)} \tag{24}$$

where A_k is the presampling probability that the kth container was sampled (presampling probability of kth hypothesis). $C(m, n, k)$ is the probability that an n-particle sample taken from the kth container will assay m-particles of sphalerite (conditional probability), and P_k is the postsampling probability that the kth container was sampled (postsampling probability of kth hypothesis).

Since the containers are indistinguishable from one another and no known bias exists in favor of one or more containers, the presampling probability of choosing a particular container is $1/17 = 0.0588$. Assuming that container 2 was the container actually chosen, the probability that a 4-particle sample taken from it would assay 1 sphalerite particle is given by Eq. 1, *i.e.*, $P(1, 3,) = C(1, 3, 2,) = \frac{2!}{1!1!} \times \frac{14!}{3!11!} \Big/ \frac{16!}{4!12!} = 0.400$. Table 5 gives the details of the complete solution.

It should be noted that the postsampling probability of containers 0, 14, 15, and 16 being sampled is zero, for containers so constituted could not possibly have yielded the sample; this change in probability stems from the knowledge gained through sampling. It should also be remarked that whereas container 4 could have yielded the sampling results 48 times out of a hundred, that container would have been sampled only 14 times out of a hundred.

The compositions of the various containers represent the various hypotheses that could be made as to the composition of an unknown lot of material that was sampled. The postsampling probability of the kth container is the degree of assurance with which it may be said, after the sampling results are known, that the material sampled was composed according to the kth hypothesis.

Effect of sample size from a finite parent lot upon the postsampling probability of the kth hypothesis stems from the effect of sample size upon the conditional probabilities.

Example. 2. Instead of the 4-particle sample taken in the previous example, assume a 12-particle sample giving the same assay, *i.e.*, 3 sphalerite and 9 chert particles. Table 6 shows details of calculation.

The postsampling probability that the fourth container was sampled has increased from 0.143 to 0.370. Similar increases are observed in the postsampling probabilities of the 3rd and 5th containers, all others show a decrease, while the probabilities that containers 1, 2, 8, 9, 10, 11, 12, and 13 were sampled vanish. In other words, an increase in sample size increases the postsampling probabilities of some hypotheses while decreasing those of other hypotheses and thus narrows the range of the more probable hypotheses.

Repeated sampling of a finite parent lot has the effect of narrowing the range of the more probable hypotheses. This effect is not achieved by rendering some hypotheses impossible, but by decreasing the postsampling probability of some hypotheses until they are negligible.

Example 3. If in the preceding example, the sample was returned to the container (after observation) and a second 12-particle sample taken, this in turn being returned to the container and a third sample taken, etc., to determine the postsampling probabilities of the various hypotheses after 2, 3, $\cdots s$ samples have been taken, it is necessary to take into account all the information gained from previous samples. Before the second sample is taken, the presampling probabilities of the various hypotheses are not the same as the presampling probabilities before the results of the first sampling operation are known; in fact they are the postsampling probabilities after the first sample is assayed, *i.e.*, $A_k(2) = P_k(1)$ where $P_k(1)$ = postsampling probability of kth hypothesis after first sample, and $A_k(2)$ = presampling probability of kth hypothesis before second sample. Similarly

$$A_k(3) = P_k(2); \quad A_k(4) = P_k(3), \cdots; \quad A_k(s) = P_k(s-1)$$

Hence by repeated substitutions in Eq. 24

$$P_k(s) = \frac{A_k(1)C(m, n, k)^s}{\sum\limits_k A_k(1)C(m, n, k)^s} \tag{25}$$

The details of the calculation are shown in Table 7, which calculates the postsampling probabilities after 1, 2, 3, 4, 6, and 12 sampling operations.

Effect of previous knowledge as to composition is reflected in the postsampling probabilities through its effect upon the presampling probabilities. Such knowledge may derive from visual examination of the parent lot by a competent observer, from results of other tests, from previous experience with similar materials, etc. In general, the effect of such knowledge is to narrow the range and increase the postsampling probabilities of the more probable hypotheses.

Example 4. If in Ex. 3 a competent observer glimpsed the contents of the container that was taken at random and reported seeing at least four sphalerite particles, then the presampling probabilities of the various hypotheses must be changed, since all hypotheses that the containers hold less than four sphalerite particles are impossible. This eliminates the first 4 hypotheses and since the remaining 13 are equally probable the presampling probabilities thereof are $1/13 = 0.0769$. Table 8 gives the calculated postsampling probabilities after 1, 2, and 3 sampling operations.

Table 8. Solution of Example 4

No. of particles		$A_k(1)$	Sample 1		Sample 2		Sample 3

7	9	0.0769	0.019	0.021	0	0	0	0
Sum.		. . . .	0.915	1.000	0.332	1.000	0.142	1.002

An infinite parent lot will, in general, permit of an infinite number of presampling hypotheses as to composition, hence the presampling and postsampling probability of a particular hypothesis is vanishingly small; however the presampling and postsampling probability of the hypothesis that the assay value lies within some interval of the composition range will, in general, be finite. The probability that a sample of n particles will contain m mineral particles when drawn from a lot wherein the proportion of mineral particles is p is the conditional probability $C(m, n, p)$ and may be calculated from Eq. 3, *i.e.*,

$$C(m, n, p) = C_n^m p^m q^{n-m}$$

where $q = 1 - p$ = proportion of gangue particles. The presampling and postsampling probabilities that the parent lot contains mineral particles in proportion p are respectively

A_p and P_p. Substitution of Eq. 3 in Eq. 24 gives

$$P_p = \frac{A_p C_n^m p^m q^{n-m}}{\sum\limits_p A_p C_n^m p^m q^{n-m}} = \frac{A_p p^m q^{n-m}}{\sum\limits_p A_p p^m q^{n-m}}$$

The postsampling probability $P(0 \leq p \leq p_1)$ that the parent lot contains a proportion of mineral particles greater than 0 and less than p_1 is given by (Uspensky, *loc. cit.*, *pp. 67–68*)

$$P(0 \leq p \leq p_1) = \frac{\sum\limits_0^{p_1} A_p p^m q^{n-m}}{\sum\limits_0^1 A_p p^m q^{n-m}} = \frac{\int_0^{p_1} A_p p^m (1-p)^{n-m}\,dp}{\int_0^1 A_p p^m (1-p)^{n-m}\,dp} \tag{26}$$

Successful application of this equation to problems is dependent upon knowledge of an expression relating A_p to p. In many problems of interest, what is known about A_p is that all assays are equally probable, hence A_p is a constant independent of p, and Eq. 26 becomes

$$P(0 \leq p \leq p_1) = \frac{\int_0^{p_1} p^m (1-p)^{n-m}\,dp}{\int_0^1 p^m (1-p)^{n-m}\,dp} \tag{27}$$

Approximation of postsampling probabilities. The results of the indicated integration may be approximated (*after 8 Bell System Tech. J. 99*) by

$$P(0 \leq p \leq p_1) = \frac{1}{2} + \frac{1}{\sqrt{2\pi}} \int_0^{x\sqrt{2}} e^{-x^2/2}\,dx - \frac{S_i e^{-x^2}}{2\sqrt{\pi}} \tag{28}$$

where $x^2 = n \ln[(n+1)/n] + m \ln[m/(n+1)p] + (n-m) \ln[(n-m)/(n+1)(1-p)]$ **(29)**

and x is to be taken negative when $p < m/n$. S_i is the ith approximation to an infinite series, the first three approximations being

$$S_1 = R_1; \quad S_2 = \frac{R_1 + R_2 x}{1 + R_2/2}; \quad S_3 = \frac{R_1 + R_2 x + R_3(1+x^2)}{1 + R_2/2} \tag{30}$$

where

$$R_1 = \frac{4(n-2m)}{3\sqrt{2nm(n-m)}}; \quad R_2 = \frac{1}{6}\left(\frac{1}{n-m} + \frac{1}{m} + \frac{13}{n}\right); \quad R_3 = -\frac{4}{15} R_1 \left(R_2 + \frac{6}{n}\right) \tag{31}$$

The first approximation is usually sufficient to give results of extreme accuracy; however, when p is vanishingly small the second, third, or higher approximation terms may be required; higher approximation terms are also required when n is small. When n is very large and p very small Eqs. 29 and 31 may be written as

$$x^2 = m \ln \frac{m}{np} + np - m \tag{32}$$

and

$$R_1 = \frac{4}{3\sqrt{2m}}; \quad R_2 = \frac{1}{6m}; \quad R_3 = -\frac{4}{15} R_1 R_2 \tag{33}$$

Example 5. In Ex. 11 of Table 3 it was calculated that for the particular conditions there prevailing a sample containing 15.41×10^8 particles must be taken in order that the sample assay fall in the range $0.03125 \pm 0.0003125\%$ Au (corresponding to 10 ± 0.1 oz. Au per ton) 99 times out of 100 (assurance = 0.99). Similar calculation yields a figure of 6.27×10^8 particles in order that the sample shall assay within the same tolerance limits with an assurance of 0.90. To calculate the postsampling probability that a sample containing 6.27×10^8 particles and assaying 0.03125% Au came from a parent lot whose gold content lies in the range $0.03125 \pm 0.0003125\%$ Au proceed as follows: The tolerance limits correspond to $p_1 = 4.254 \times 10^{-5}$ and $p_2 = 4.340 \times 10^{-5}$, while the proportion (by number) p of gold particles actually found in the sample is 4.297×10^{-5} (Table 3, Ex. 11, Col. 9). Hence $m = np = 6.27 \times 10^8 \times 4.297 \times 10^{-5} = 26{,}930$. Substitution of these values in Eq. 32 gives

$$x_2^2 = 26{,}930 \ln \frac{26{,}930}{27{,}210} + 27{,}210 - 26{,}930 = 1.274$$

$$x_1^2 = 26{,}930 \ln \frac{26{,}930}{26{,}680} + 26{,}680 - 26{,}930 = 0.9876$$

Whence $x_1 = -0.994$ and $x_2 = 1.129$; x_1 is taken as negative since $p_1 < m/n$. The upper integration limits of the probability integral become: $\sqrt{2}x_1 = -1.405$ and $\sqrt{2}x_2 = 1.597$, hence

$$\int_0^{-1.405} e^{-x^2/2}\,dx = -0.4200; \quad \int_0^{1.597} e^{-x^2/2}\,dx = 0.4449$$

To calculate the first approximation term, first compute $S_1 = R_1 = 4/3\sqrt{2 \times 26{,}930} = 0.00575$; then $e^{-x_1^2} = e^{-0.9876} = 0.3723$ and $e^{-x_2^2} = e^{-1.274} = 0.2797$; hence $S_1e^{-x_1^2}/2\sqrt{\pi} = 0.0006$ and $S_1e^{-x_2^2}/2\sqrt{\pi} = 0.0005$. The desired postsampling probability may now be calculated, thus:

$$P(p_1 \leq p \leq p_2) = P(0 \leq p \leq p_2) - P(0 \leq p \leq p_1)$$

But

$$P(0 \leq p \leq p_2) = 0.5000 + 0.4449 - 0.0005 = 0.9444$$

and

$$P(0 \leq p \leq p_1) = 0.5000 - 0.4200 - 0.0006 = 0.0794$$

Therefore

$$P(p_1 \leq p \leq p_2) = 0{,}9444 - 0.0794 = 0.8650$$

Tools of calculation. A similar calculation gives a postsampling probability of 0.9913 that the parent lot assay within 0.03125 ± 0.0003125% when the sample contains 15.41 × 10[8] particles and assays 0.03125% Au. This should not be interpreted to mean that the postsampling probability equals the sample probability, but rather that calculational refinements must be employed to pick up differences of one part in a thousand. At least 4-place probability tables must be used for 0.99 assurance; for higher assurances, more significant figures must be carried. Values of the probability integral may be found in Czuber's *Wahrscheinlichkeitsrechnung* (J. Springer) or may be calculated from the series (*8 Bell System Tech. J. 102*)

$$\frac{1}{2} + \int_0^{x\sqrt{2}} e^{-x^2/2}\,dx = \frac{e^{-x^2}}{2x\sqrt{\pi}}\left(1 - x_1^{-2} + 1\cdot 3x_1^{-4} - 1\cdot 3\cdot 5x_1^{-6} + \cdots\right) \tag{34}$$

where $x_1 = \sqrt{2}x$.

Duplicate samples of an infinite lot increase the postsampling probability of the more probable assay range. If K samples containing $n_1, n_2, \cdots, n_k$ particles are taken of some infinite parent lot and found to contain $m_1, m_2, \cdots m_k$ valuable mineral particles, then the postsampling probability that the parent lot contains a proportion p of mineral particles such that $p_1 \leq p \leq p_2$ is given by

$$P(p_1 \leq p \leq p_2) = \frac{\int_{p_1}^{p_2} p^{m_1+m_2+\cdots+m_k}(1-p)^{n_1+n_2+\cdots+n_k-(m_1+m_2+\cdots+m_k)}\,dp}{\int_0^1 p^{m_1+m_2+\cdots+m_k}(1-p)^{n_1+n_2+\cdots+n_k-(m_1+m_2+\cdots+m_k)}\,dp} \tag{35}$$

The effect, therefore, of duplicate sampling is the same as that of an increase in sample size; the larger sample being a composite of the duplicate samples. This conclusion, based on sampling theory, presupposes that all other treatment accorded samples is free from error; in practice it must be modified since duplicate samples expose errors of assaying, handling, etc. Two independent duplicate samples which check within limits set by an assay method, and are each of such size as will give a sample probability of 0.9 or better, suffice to determine the most probable assay range of the parent lot with a probability of approximately 0.99, usually higher. If the samples are not independent, but have a similar history up to some particular stage, being independent thereafter, agreement thereof confirms only hypotheses relative to the composition of the stage where independency began. For example, if 10-in. material is reduced by four stages of crushing to 20-m. with sampling between stages and duplicate samples taken of the product of the last stage, agreement of the samples may be used to confirm hypotheses as to the composition of the <20-m. material only. This confirmation may be extended to the parent lot only by assuming knowledge as to the errors produced in the other three stages of sampling (p. 07). Although this fact appears to be well known, its importance, judged from practice, is not appreciated. The great importance attached to agreement or disagreement of buyer's or seller's samples with the umpire sample and with each other, when differentiation is made in the last stage, is entirely unjustified, since it is always possible to produce multiple samples of the last stage that agree within normal tolerance limits, because the cut is made at fine sizes. The truly important factor is the validity of the assumption made as to the accuracy of the previous sampling stages. The practice of withholding, until settlement, umpire samples taken at *the first* sampling stage is to be recommended; lacking this, competent judgment of sampling procedure is the only substitute.

Effect of a quality test upon the error of the final result may be calculated in terms of the standard deviation, from the following equation

$$\sigma^2 = \sigma_q^2 + \sigma_s^2 \tag{36}$$

where σ, σ_q, and σ_s are respectively the standard deviations of the final result, the quality

test, and the sample. The error of the final result cannot be less than either of the individual errors, and is usually greater than either.

Minimum weight of sample for a quality test. Specifying σ and knowing the value of σ_q, and using the value of σ_s calculated from Eq. 36, the minimum weight of sample may be computed by the method of Table 3. The sole function of this calculated minimum weight is that it sets a lower limit to the sample weight that may be taken; in general, larger weights are needed for other reasons. For example, whereas a minimum sample weight of 0.25 gm. may be calculated for a Cu ore ground to <200-m., the method of assaying may require a 0.5 to 1.0 gm. sample, and if assay is to be run in triplicate, three times that amount must be taken. In general, the total weight required for assays may range from 100 gm. to 1 kg. If the quality under test is response of ore to some milling operation the weight required may range from a few pounds to many tons, depending upon the extent of the investigation.

Allowable error is determined by the purpose for which the sample is taken. The least error is allowed in taking samples for assay. Great error is allowable in the case of samples taken for preliminary treatment tests, and the like. The allowable error in sampling for assay is least when the assay is to form the basis for settlement between buyer and seller. The limit is practically fixed by the accuracy of the methods of assay used, it being, of course, unnecessary to carry refinement in sampling beyond the point reached by ordinary commercial methods of analysis. Accuracy of analytical methods on different products is presented in the following paragraphs.

Gold. Duplicate assays by the same assayer should check within 0.02 oz. on low-grade ores; the discrepancy should not exceed 0.05 oz. on 5-oz. ore, while a 0.1-oz. discrepancy is permissible on 5- to 20-oz. ore. (Lodge, R. W., *Notes on Assaying*, John Wiley & Sons, 1919; Smith, E. A., *The Sampling and Assay of the Precious Metals*, Chas. Griffin & Co., Ltd., London, 1913.) Two assayers working on the same pulp or on samples cut from a small, finely pulverized lot should check within similar limits, according to most writers. Fulton (*TP 83 USBM*) states that differences of 0.02 to 0.05 oz. are usually split on 1- to 2-oz. ores and of 0.04-oz. on ores running above 2 oz. Barbour (*92 J 314*) gives 0.05 oz. as the splitting limit and Whitaker (*105 J 538*), 0.02 oz. Seamon (*A Manual for Assayers and Chemists*, John Wiley & Sons, 1910) states that 0.01 and 0.2 oz. covers the usual splitting range, but recommends that umpiring be resorted to when the difference between buyer's and seller's assays on a 50-ton lot exceeds 0.1 oz. Table 9, arranged from Brunton (*40 A 567*), presents figures of actual mill results on a variety of ores. By comparison of the last four columns, the degree to which sampling checks assaying may be observed. Table 10 was prepared from data given by Woodbridge (*TP 86 USBM*) based on results obtained from shipments of one mine to various sampling plants. It shows the degree to which buyer and seller may be expected to check on the same samples of various grades of ore. The detail (not presented here) shows that buyer's assays are rather consistently lower than seller's, which leads to the belief

a Probable difference $= \sqrt{\dfrac{\Sigma d^2}{n-1}}$.

that deviations shown in this table are not due entirely to physical difficulties. Table 11, arranged from the same source as Table 10, is a comparison to indicate the degree to which duplicate samples may be expected to check. Note that, in general, greater difference exists between duplicate samples than between assays by buyer and seller.

The above figures indicate that sampling should be accurate to within at least 1% on a 5-oz. ore while an error of as much as 5% would be allowable on 0.5-oz. ore. A hard and fast rule as to allowable difference cannot be set for all cases. Many ores present physical difficulties in sampling and assaying which must be taken into account when setting a standard for accuracy. In any case, however, although individual assays may not check closely, an average of several or many assays on a sample should closely approximate the true value of the sample.

Silver. Duplicate assays by the same assayer, doing the most careful work, should check within 0.2 to 0.5 oz. for ores up to 50 oz. In ordinary work differences up to 1.0 or 2.0 oz. maximum may be expected (*Fulton, Seamon*). On high-grade ores, duplicates should check within 1% of the total silver content. Assays on duplicate samples by different assayers should check within 0.5 to 1.0 oz. for average (10- to 20-oz.) ores (*Fulton*). On high-grade ores differences of 1% are allowable. The usual splitting limit between buyer and seller is 0.5 oz.

Tin. Ordinary cyanide fire assays by the same assayer should check within 0.2% metal for low-grade ores to 0.5% for high-grade ores. (W. A. MacLeod and C. Walker, *Metallurgical Analysis and Assaying*, C. Griffin & Co., Ltd., London, 1903.)

Other metals. Table 12 presents limits for commercial work using volumetric methods. Duplicate electrolytic assays for copper should check within 0.03% metal on 20% to 60% ores and 0.02% on ores less than 20% (*MacLeod and Walker*).

Table 12. Limits of accuracy in commercial volumetric assay

Worth of valuable mineral. The preceding text and tables show that on gold ores and concentrate the allowable error is, in general, under 0.05 oz.; on silver ores, under 0.5 oz.; on copper ores, from 1 to as high as 10 lb. per ton; and on zinc and lead, as high as 20 lb. per ton; increasing as the worth of the valuable mineral decreases.

Table of sample weights. Although a method exists, as outlined above, for computing sample weights required to give a result within specified limits of error and with a required degree of assurance, taking into account sampling and testing errors, difficulties in computation as well as inadequate dissemination of information concerning the method have militated against its general adoption. The usual way to determine the sample weight required at any size is to reckon on experience with the particular ore to be sampled or experience with ores in general. The tendency is to allow a sufficient factor of safety by taking a sample large enough to cover possible unforeseen sources of error. Variations in the weights taken in practice, on ores of same class, are not always due to disregard or misunderstanding of the principles involved, but to local conditions and the facilities available.

Brunton (*25 A 826*) presented diagrams based on mathematical calculations to determine the weight of sample at different sizes when the specific gravity of the richest mineral and the ratio of grade of the richest mineral to the average grade of the ore is known. The diagrams are based on the reasoning that the allowable error is equal to the difference between the value of the probable number of pieces of valuable mineral and the same number of pieces of average value which they would replace if in excess or deficit. Results show that if such conditions remain the same throughout all sizes the weight of sample should vary as the cubes of the diameters. Full account is also taken of the fact that larger pieces than the theoretical cube are found in the undersize of a screen, owing either to irregularity of the screen or the presence of elongated pieces. Use of these diagrams is limited to cases where conditions are known and where they remain the same throughout all sizes. This is not the case with ordinary ores.

Richards (*2 OD, Chap. 19*), reasoning from considerations of variability and noting that in several installations on a variety of different ores the weights at different sizes were taken proportional to the squares of the diameters, calculated a table for different grades of ore, using one figure from practice in each case and calculating the rest.

Cols. 1 to 6 in Table 13 were prepared from Richards' table. Col. 7 shows weights obtained by applying the rule that the sample weight should vary as the cube of the diameter. The calculation is based on the assumption that 0.1 assay ton (0.00643 lb.) is a correct sample of 100-m. material. Col. 8 gives figures presented by Philip Argall for sampling in successive cuts 200,000-lb. lots of 10- to 15-oz. gold ores from CRIPPLE CREEK. The weights in this column vary approximately as the squares of the diameters and lie somewhere between the figures in Cols. 5 and 6 from Richards. The larger figures in parentheses are recommended for an added factor of safety for certain ores. Col. 11 summarizes results obtained from examination of 55 flowsheets of sampling plants. The weights are based on 100,000-lb. lots, the figures being averages for different sizes. In averaging, some excessively high or low weights for any one size were omitted. The results lie between Cols. 3 and 4 for medium ores as given by Richards. This is as might be expected and indicates that practice generally has followed the rule that sample weights should vary as the squares of particle diameters. Cols. 9 and 10 give maximum and minimum figures from the flowsheets used in averaging; figures in parentheses are highest or lowest figures.

Cols. 12 to 15 inclusive present sampling standards suggested by Demond and Halferdahl for base and precious metals. These data were set down in an attempt to obtain logical figures based on a combination of experiment and mathematics rather than on arbitrary application of the rule of squares. Their method is based on the assumption that the sample weight w should vary as some power a of the diameter D or $w = kD^a$ where k is a constant for any given ore. One gram for base-metal ores and one assay ton for precious-metal ores, the amounts usually taken for assays, were assumed to be correct sample weights for 150-m. material. A portion of the ore at some larger size was divided into a number of equal parts and each part was crushed down and assayed. The probable error for any portion was then calculated and if larger than the allowable error the correct sample weight was calculated so as to obtain a probable error less than the allowable error in 90 to 95% of all cases. Substituting values of weights and sizes in the two instances in the formula $w = kD^a$, they solved for k and a, and then calculated the correct weights for other sizes. They demonstrated that values of a less than 1.5 should not be used, as the samples would be too small. The method is applicable to any given class of ores. With low-grade or very uniform ores a will have a low value and with high-grade or spotty ores a high value (see Table 13); for ores of intermediate grade or uniform value, a will lie between these extremes.

While the method of Demond and Halferdahl has much to commend it, it does not take into account the changes in relation between gangue and valuable mineral with change of particle size, but uses the same power of the diameter over the whole range of sizes. Cols. 17 and 18 use 1 assay ton for precious-metal ores and 1 gm. for base-metal ores as correct weights at 150-m. and take the exponent a as ranging from 3 for material between 150-m. and 65-m. to 1.5 for material between 2-in. and 4-in. This method tends to give larger samples at the smaller sizes and smaller samples in the larger sizes. If the assay charges need to be larger than 1 assay ton or 1 gm., the weight of any size may be found by multiplying the tabular figures by the number of assay tons or grams needed to give correct assays.

Col. 16 gives the minimum permissible sample weights suggested by Richards for GOLD ORES. For SILVER ORES take one-tenth of these values. Inspection of figures in this column shows that there is no constant or regularly changing ratio between weights and diameters. These sample weights are evidently based on no rule except experience and personal judgment as to what weights can be taken at various sizes.

Examination of sample-mill flowsheets indicates wide variation in sample size. The most obvious relation noticed is the taking of successive 20% cuts after each reduction in size by one-half or the use of a value for a of about 2.13.

Use of this table should be restricted to cases where the information necessary for a calculation of sample weight is not available; it should not be used as a substitute for the preliminary investigation necessary to intelligent sampling. The impossibility of giving one sample weight to cover sampling of, say, spotty ores without taking into consideration the variability of the ore at different sizes and the distribution of values among the various sizes is too apparent to require further consideration. Exs. 10 and 11, Table 3, illustrate the point. Ex. 10 gives the solution for a $<$14-m. gold-bearing sand with values distributed as shown; sample weight is 0.035 lb. if the sample is to assay 10 $\pm$ 0.1 oz. Au per ton with an assurance of 99%, when 58.3% of the gold is found in the 48∼65-m. material. From Col. 5 of Table 13 a sample weight of 28 to 14 lb. is required based on 14-m. or a weight of 1.8 to 0.9 lb. based on 48∼65-m. material. For Ex. 11, where 100% of values are found in 48∼65-m. material, a sample weight of 77 lb. is required.

Weight of coal samples adopted in the standard method of sampling coal (*ASTM: D 21–40*), based on an original gross sample of 1,000 lb. is given in Table 14.

A 15-lb. sample is taken by coning and quartering the 30-lb. lot (see p. 27). This sample is crushed to pass an 8-m. screen and divided by riffling (chute widths not over 1/2-in.) to give a 1 3/4-lb. sample. Further reduction of the sample yields 200 gm. after crushing to pass 20-m. and 50 gm. after crushing to pass 60-m.

Weight of samples for screen test should be great enough to give an accurate sample at the sizes that are important. The allowable error is influenced by the care with which the screen test is made. The weights ordinarily taken for screen-test samples range from,

say, 100-gm. for <65-m. material to 5 or 10 kg. of 1-in. material. Larger weights may be necessary in special cases, depending on the accuracy desired and the end in view.

Segregation. It is most desirable that the mass to be sampled be thoroughly mixed. Practical homogeneity is attained with solutions, and the maximum of uniformity, lacking homogeneity, with fine suspensions. In such cases, any part can be taken at random as an accurate sample. But in dealing with broken ore, uniform mixing is difficult. Ore as mined varies in composition from place to place and segregation increases in breaking, loading, and crushing. In crushing, some of the minerals present, owing to differences in hardness and friability, break into smaller pieces than others. Vibration of a car transporting ore tends to sift the finer and the heavier pieces down through the coarser, so that the material in the car is not uniform in value from top to bottom. If ore is transported by means of inclined chutes or launders, segregation takes place therein. Coarser pieces bound or roll down the chute while finer pieces slide slowly along the bottom. Heavier pieces tend to settle near the bottom in the sliding mass. If a chute ends in a free fall, the larger and heavier pieces, owing to their greater momenta, fall farther away from the end than the finer and lighter pieces. If the ore is piled in a heap, the coarser pieces roll down while the finer remain near the top. Thus, in order to take an accurate sample, either the material must be thoroughly mixed or the method must be so applied as to take segregation fully into account.

Table 14. Weight of coal samples

Largest size of coal and impurities in sample before division, in.	Weight of sample to be divided, lb.
1	1,000 (or more)
3/4	500
1/2	250
3/8	125
1/4	60
3/16	30

2. HAND SAMPLING

Hand sampling is usually expensive; it is slow in batch sampling and labor-wasting in stream sampling; and the personal element enters so largely that accurate results are difficult to obtain. Machine sampling should be used where possible and hand sampling applied only where material is not suitable for treatment by machine, as with sticky ore, or where machinery is not available, or the expense of its installation not justified.

Hand-sampling methods. The more common methods of hand sampling are: (*a*) grab sampling, (*b*) coning and quartering, (*c*) shovel sampling, (*d*) pipe sampling, (*e*) stream sampling.

Grab Sampling

This is the simplest form of hand sampling. It consists in taking small, equal portions by scoop or shovel at random or at regular intervals from the mass of material to be sampled. The following variations illustrate practice.

(*a*) **Large heaps** are grab sampled by taking a shovelful or scoopful at different points on the surface of the heap. The points may be located by dividing the surface into squares or rectangles, or the location may be left entirely to the judgment of the sampler. If large samples are desired, pits are dug at various points and the whole or part of the material excavated is taken for the sample.

(*b*) **Railroad cars or boats** may be sampled as in *a*. In this case a net is frequently placed over the surface of the ore and the sample is taken at the knots in the net, or the sampler measures off sample intervals from the sides and ends of the cars with a shovel or measuring stick.

(*c*) **Ore being loaded or unloaded.** Grab samples may be taken at intervals along the working faces as excavation progresses.

(*d*) **Ore being transported in small lots** by wheelbarrows, tram buckets, wagons or small cars. A GRAB may be taken from each load and thrown into a box. The box is emptied at the end of each day or shift and taken as a sample of the ore transported for such period of time.

Methods *a* and *b*, taking samples from the surface only, assume that the character of the ore does not change with depth in the heap. Correct results can hardly be expected on such an assumption on account of segregation. Method *c* is more likely to give results that are accurate, since samples are taken from all parts of the mass. Method *d* is also more commendable than *a* or *b* and should, over a long period, give a fair average with certain classes of ore. However, it is probable that the samples would run regularly high or regularly low.

Accuracy. At a small ALASKA mine (*35 SMQ 55*) a medium-grade copper ore containing chalcopyrite and pyrite in graywacke and slate was sampled by an experienced man who took a 2-lb. grab from each 1-ton car dumped into a boat for shipment. The ore was again sampled at the smelter in a mechanical sampling mill. Figures based on 2 yr. of work, with shipments ranging from 200 to

2,000 tons each, showed that the average difference in assay between grab and mechanical samples was 7.1% of the copper content and the maximum difference, 28.5%. The percentage of cases in which the grab sample was high was 55 and results were more than 10% wrong in 30% of the cases. Applying these figures to three ores running 2%, 10%, and 20% copper, respectively, errors and the expectation of errors would be as in Table 15. In this ore values did not tend to segregate in the fines to any great extent as shown by the sizing-assay test in Table 16. Usually more than 55% of the results would be high. It is general experience that grab sampling gives high results, owing probably to the fact that the sampler avoids large lumps.

Table 15. Errors in grab sampling

Item	% Cu		
	2% ore	10% ore	20% ore
Average error...........	0.14	0.71	1.42
Maximum error.........	0.57	2.86	5.72
Minimum error probable in 30% of the results..	0.20	1.00	2.00

Table 16. Sizing-assay test of ore of Table 15

Mesh	Weight, %	Per cent. of total Cu
60	30.6	24.8
80	9.5	8.7
100	6.6	7.0
<100	53.3	59.5
	100.0	100.0

Advantages of grab sampling are that it is cheap and quick. DISADVANTAGES: It is difficult, when taking a small portion such as a shovelful or scoopful, to get full representation of all sizes of particles, especially when lumps are present. Just what part of a lump or how much of the coarser and finer pieces should be taken at each grab is left to the judgment of the sampler, and either by over-zealousness or by carelessness, more of some size than is proper is almost certain to be taken. It is also practically impossible to take such an amount of material at each grab that every part of the lot shall have proportionate representation in the final sample.

Table 17. Grab samples *vs.* mill averages

Item	Case 1	Case 2
Weight of ore, tons..........	51,862	43,993
Value, mill average..........	$11.084	$10.254
Value, grab sample...........	$11.218	$11.193
Percentage excess of grab sample above mill average......	1.20	9.17

Applicability. The ore should be crushed to 0.5-in. or smaller before sampling. Grab sampling should be applied only to low-grade or very uniform ores, or in cases where approximate results only are desired, or in order to detect salting.

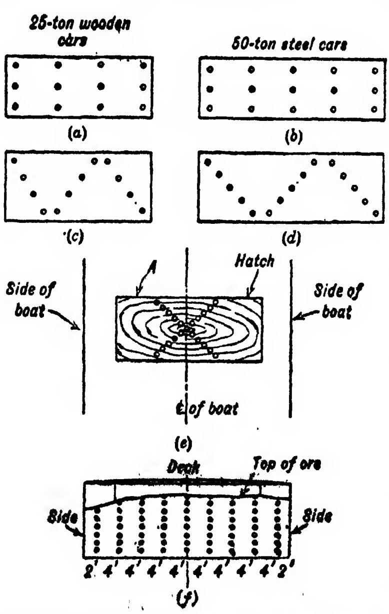

FIG. 4. Sampling iron ores in cars and boats.

Examples. MOGOLLON DISTRICT, New Mexico (*72 A 535*). The ore contained gold, silver, both native and in argentite, and pyrite, in a gangue of quartz, calcite, and andesite. Yearly averages of composite daily grab samples taken from cars at the scale seldom showed a variation of more than 10%, generally 3 or 4%, from the value determined from addition of the metal produced to that lost in tailing. (See *25 A 826.*) Comparison is given in Table 17.

Iron ores in cars or boats are usually sampled by grab sampling. The methods described below are those used by U. S. STEEL CORPORATION (*1 IEC 107*).

Car sampling. Samples of about 2 to 3 oz. are taken with a garden trowel or small scoop (3 1/2 × 2 1/4 × 1 1/4-in.) at 12 places in a 25-ton car and 15 places in a 50-ton car. Either the PARALLEL or ZIGZAG SYSTEM is used (Fig. 4, *a, b, c, d*). Lumps met at sampling points are sampled by breaking off a small piece about the size of the first joint of the thumb. Samples from ten cars are combined, making about 15 lb. for ten 25-ton cars and 20 lb. for ten 50-ton cars. With very lumpy ore the ROPE-NET SYSTEM is used. Knots are about 18 in. apart and the car is sampled in about 32 places. MOISTURE SAMPLE is taken at three places along the center of each car after several inches of surface has been removed.

Boat sampling. The boats range in size from 3,000 to 12,000 tons capacity, one or two decks, 6 to

36 hatches with widths from 12 to 24 ft. Ores range from very fine to all lump. The sample may be taken by small scoop (1/4-, 1/2-, or 1-lb. capacity) from grab buckets, while unloading. This method is expensive as one man is needed for each grab bucket.

Sampling of cones is the term applied to the following method: The sampler starts at point "A" (Fig. 4, *e*) directly under the edge of the hatch and midway between the center and side of the boat and takes samples at points 1 ft. apart (measured by the trowel, which is 12 in. long), up the side of the cone, over the apex and down on the opposite side, then similarly along the other diagonal. The amount thus taken is equivalent to about one-tenth of the total sample for the hatch. After the grab bucket has removed all ore within reach, samples are taken in parallel vertical lines up the face of the ore at 1-ft. intervals. The first line is 2 ft. from the side of the boat and succeeding lines are spaced at 4-ft. intervals (Fig. 4, *f*). This is repeated on the opposite face.

Round sampling is used when operation of the grab bucket makes sampling of cones impracticable or with boats with 24-ft. hatch centers and decks furnishing protection to samplers. When a 5- or 6-ft. face is exposed by the grab bucket, the sampler takes samples of the face by the same method as in Fig. 4, *f*. The amount taken on this round is about one-third of the total. The second round is taken similarly after the grab bucket has removed all ore within reach; this comprises the remaining two-thirds of the sample.

Sampling of concrete aggregate in cars is illustrative of sampling of a finite lot (see p. 02) since the number of pieces of broken stone (2 1/2~1/4-in.) is not large enough to be considered infinite. If size distribution is the quality under test, the major part of the car contents must be taken in order that the sample shall be representative of the lot within 5% with an assurance of 99%. The results of a series of tests (*42* #11 *RP 41*) designed to determine human error in sampling are shown in Table 18. Five individuals, working independently, took samples that differed as to increments in weight, number, location, and method of taking, as well as to total sample weight. The divergent results shown are, therefore, not surprising; actually the test was pointless since a correct sample would take the major part of the car contents.

Table 18. Sampling concrete aggregate in cars

Size (in.)	Cumulative per cent. through					Maximum–minimum

Truck sampling may be performed by taking samples from the bottoms of holes at least 1 ft. deep located on the diagonals at points one-third and two-thirds the distance from corner to center. If more increments are desired space evenly along the diagonals. Table 19 shows results of sampling coal trucks (*143 CG 1958*). The coal was sampled at the colliery by cutting the stream delivered by loading conveyor. The loaded trucks were sampled at destination by the diagonal method, taking 8 and 22 increments.

a British Engineering Standards Association method.

Coning and Quartering

This is one of the oldest forms of hand sampling. It was for many years the standard method of sampling throughout the western United States, especially for batches of ore whose value was to be determined between buyer and seller. It can be used on lots up to 50 tons. Where larger lots are to be sampled, the first cut is made by some other method and the sample thus obtained is further reduced by coning and quartering.

Procedure consists in piling the ore into a conical heap, spreading this out into a circular cake, dividing the cake radially into quarters, taking opposite quarters as sample and rejecting the other two. The ore should be crushed through 2-in. or smaller ring. The operation should be carried on in a room of sufficient size to allow convenient handling of material. The floor should be smooth and free from cracks, preferably smooth concrete or steel sheets; it should first be swept thoroughly clean to avoid salting from a previous lot. The ore is dumped on the floor in two or four piles, or in a circular ring. Shovelers then pile this ore into a right-conical heap conveniently placed, taking care to drop each shovelful directly onto the apex. The object of coning is to form a heap in which segregation shall be symmetrical with respect to the vertical axis. To insure this, successive shovel loads should be so taken as to contain similar sizes similarly segregated on the shovel and should be so dropped onto the cone that the segregation therein is symmetrical. This end is attained by having the shovelers take successive shovel loads from adjacent places around the periphery of the heaps from which they are shoveling and drop these loads from successively adjacent points around the cone that they are building. Each man should take a shovel load of the same size as each other shoveler, and shovel loads should be made smaller as the size of the heap being shoveled becomes less. When the material is placed in a ring the men move around the ring as they shovel onto the cone. When the ore is all heaped up into a cone, the floor is carefully swept and the fines collected are placed on the apex, not swept up against the bottom of the pile. The men then start at points near the bottom of the cone and, with their shovels held tangentially, drag the material down radially so as to form a truncated cone or flat circular cake. In this operation they should work around the cone. The cake is then marked off into quarters with a stick or board along diameters at right angles. Opposite quarters are shoveled out as reject. The remaining quarters, called the sample, are then shoveled into one or more piles or into a ring depending on the amount of material, and the coning and quartering operations are repeated until the sample is so small that further crushing is necessary before further reduction in bulk can be made. A cross made of

sheet iron or wood with sharpened edges is often used to mark the truncated cone into quarters. This is placed on top of the cake with the center of the cross directly over the center of the cone and is then pressed into the ore until it touches the floor. Such an arrangement is preferable to marking off with a single board. Lines of division will be more exact and the cross can be left in place to hold the sides of the sample quarters vertical while the reject quarters are being shoveled away. Or the cross may be laid on the floor before starting the pile and each shovelful dropped over the intersection. The cone is then spread out to the thickness of the cross and the reject shoveled away as above.

Coning does not mix the ore uniformly. As material is shoveled onto the cone the coarser pieces roll down the sides and come to rest on the floor while the finest particles remain near the apex. Pieces of intermediate size arrange themselves on the slopes of the pile according to their size. The ultimate result desired is that the segregation be symmetrical with respect to the axis of the cone. If this condition is attained, any sector taken should correctly represent the whole.

Bench or cobbing system, sometimes used to get better distribution of the material in the cone, consists in first making a small cone of some of the ore and spreading it out into a cake, then making another cone on the center of the cake and spreading it out and repeating until all the ore is thus disposed of. This method tends to reduce the effects of accidental errors in flattening the cone.

Advantages of coning and quartering are few. Expensive equipment is not required, the only tools necessary being wheelbarrows, shovels, and brooms. It can, therefore, be used in remote places where more elaborate sampling machinery is not available. It is applicable to practically all classes of ore and, in the case of small lots of high-grade material, there is no danger of such loss as might occur through leaks and holdbacks in a mechanical sampling mill. The fact that all ore is in plain sight throughout the period of sampling is probably the chief reason why this method has survived as long as it has, this being especially desirable where ore is being sampled for sale. DISADVANTAGES. The method is expensive, requiring frequent handling of the ore by crude means, and much sweeping. The danger of salting is considerable. From the standpoint of accuracy the method is susceptible, either through accident or intention, to such manipulation during the operation that a true sample will not be obtained. As the men shovel from the piles of ore or ring onto the cone, they should all push their shovels either radially or at a tangent into the piles or ring. Otherwise the coarse material will be in a different position on each man's shovel and when the ore is dropped onto the cone the coarse material will segregate unsymmetrically. Further, it is difficult to keep the axis vertical. If the axis is inclined, more fine material will accumulate on the side toward which it leans. This is called "drawing the center," and it has frequently been brought about in order to make the sample of higher or lower grade, as the operator desired. To avoid "drawing the center" a vertical rod is sometimes placed to mark the axis of the cone. When spreading the cone into a flat cake, there is danger that more fine material from the apex will be spread over one part than another. During dragging out, coarser pieces are pushed along to the outside by the shovels while the finer particles sift through and tend to remain nearer the center. As spreading progresses the finer material from the center is spread out and the cake obtained tends to have a separation of the coarser particles on the bottom and the finer on the top. There is also difficulty in spreading the last small portion of fines evenly. For these reasons chances of error are great and the effect of carelessness or willful abuse is difficult to detect.

Time and labor required. The following data are given by Johnson (*53 J 111, 132*): EL PASO SMELTING WORKS. Mexican labor, coning and quartering a 2-ton sample taken by the tenth-shovel method:

4,000-lb. lot, 4 men, 1 on wheelbarrow from platform to crusher, 1 man at crusher, 2 men with wheelbarrows carrying ore from crusher and forming circular ring, 45 min.; 4 men shoveling from ring to cone 6-ft. diam., 3.5 ft. high, 20 min.; 4 men spreading to truncated cone 9 in. high at center, 5-in. at circumference, 5 min.; 4 men cutting quarters and removing reject, 10 min.; total, 4 men, 80 min.

2,000-lb. sample; 4 men, shoveling to a ring, 6 min.; making cone, 9 min.; spreading, 3 min.; halving, 5 min.; total, 4 men, 23 min.

1,000-lb. sample; 4 men, making ring and cone, 12 min.; spreading, 2 min.; halving, 3 min.; total, 4 men, 17 min.

500-lb. sample; 4 men, sample recrushed in rolls, 10 × 20-in., 35 min.; total, 4 men., 155 min.

500-lb. sample; 2 men, sample piled in a heap, spread to a circle, pushed out to ring, 15 min.; making cone (3 ft. diam., 1.75 ft. high), 5 min.; spreading (6.5 in. thick at center and 3 in. at circumference), 3 min.; halving, 2 min.; total, 2 men, 25 min.

250-lb. sample; 2 men, sample ground in rolls to pass 10-mesh, 35 min.; making ring, 2 min.; making cone, 4 min.; spreading (5 ft. × 2 in.), 2 min.; halving, 3 min.; total, 2 men, 11 min.

125-lb. sample; 2 men, making two heaps, coning, spreading, halving, 8 min.

63-lb. sample; 2 men, making two heaps, coning, spreading, halving, 6 min.

32-lb. sample; 2 men, coning and halving, 5 min.; about 16 lb. sent to bucking room; total, 2 men, 90 min.

Labor, 4 men, 2 hr. 35 min. = 1.29 man-shifts; 2 men, 1 hr. 30 min. = 0.38 man-shifts; total, 1.67 man-shifts.

Total time to reduce 2 tons to a 15-lb. sample for delivery to assay office, 4 hr. 5 min.

Shovel Sampling

Shovel sampling, also called FRACTIONAL SHOVELING, or FRACTIONAL SELECTION, can be applied when ore is being loaded or unloaded, or moved from one place to another by

shoveling, or it may replace coning and quartering for cutting down a given lot, with intermediate coning of the sample as previously described.

Procedure. Every alternate, or every third, fourth, fifth, or tenth shovelful is taken for the sample, depending upon the size of sample permissible or desired. Common practice is to take the fifth or tenth shovels in unloading a car and to finish sampling by alternate shovels.

Advantages. Shovel sampling is applicable to larger lots than coning and quartering and when alternate shovel loads are taken, is more reliable and accurate; it is cheaper, quicker, and requires much less space. Accuracy is attained by making a large number of sample cuts, the number depending on the size of shovel used and the weight of the lot sampled. DISADVANTAGES: Shovel sampling should not be used if large lumps, say greater than 2-in., are present. It is subject to manipulation by the sampler in choosing the shovelful to be taken for the sample, both as regards the amount taken and the kind of pieces. The cheapest kind of labor is commonly employed and when other than alternate shovels are taken, it is difficult for the shoveler to keep count of shovelfuls. When ore is piled in a heap in which segregation has taken place and is sampled by this method there is considerable danger of the sample shovelfuls being taken more from either the coarser or finer parts of the heap, so that every size of material is not represented in proper proportion in the sample.

Time required by four Mexican laborers unloading a 20-ton car and taking at the same time a tenth-shovel sample is given by Johnson (*ibid.*) as 2.5 hr. At EL PASO smelter four men required 4 hr. to unload a 50-ton car of concentrate (15% moisture), taking every tenth shovel for sample (*117 J 13*). In this instance, the sample was shoveled onto boards placed across the car above the load; the sample remained in the car and was moved and dumped, samples from five cars being united.

Cost of shovel sampling varies with the character of material, moisture contained, facilities available for disposal of sample and reject, and cost of labor.

The labor cost of the old method of sampling wet, sticky flotation concentrate at GARFIELD smelter, consisting in taking every 15th or 20th shovel for sample and cutting down further by alternate shovels, was from 6¢ to 8¢ per ton of concentrate before 1917 and 20¢ in 1920 (*122 P 17*).

Method for high-grade silver ore. Ore from Cobalt (*17 CMI 239*), <0.25-in., was discharged into wheelbarrows and distributed in a long narrow ridge. The ridge was turned over once by shoveling and a new ridge formed, then divided by alternate shoveling into two ridges, the shovelfuls being carefully distributed over the tops of the ridges. These two ridges were each divided into two other ridges by the same method, four ridges resulting. Further reduction of each ridge was then made by successive crushing and riffling. Table 20 gives the assays of samples from each of the four ridges with five different ores and indicates that this method gives good results even on ores as difficult to sample as these.

Table 20. Results of shovel sampling Cobalt silver ores

Combination of hand-sampling methods has been adopted as a standard method of sampling coal for analysis (*ASTM D 21–40*). The original or gross sample of 1,000 lb. for ordinary lots (or 1,500 lb. when large pieces of impurities are present, or 500 lb. for slack or smaller sizes of anthracite) is taken by grab sampling or shovel sampling during unloading. The amount taken at each grab or shovelful ranges from 5 to 10 lb. for slack and smaller sizes to 10 to 30 lb. for run-of-mine coal. The sampling interval depends on the size of lot. When taking the sample from bottom-dump cars, while unloading, a special "ladle" is used having a handle 5 ft. long and bowl 1 ft. in diameter at top, 9 in. at bottom, and a depth of 9 $^1/_2$ in. The "ladle" holds from 25 to 30 lb. of coal. Generally two ladlefuls are taken from each car by holding the ladle underneath the car when dumping. The gross sample is cut down by alternate shoveling to 250 lb. and coning and quartering to 15 lb. as follows:

1,000-lb. gross sample. Crushed to 1-in.; mixed by shoveling into a conical pile, then shoveled into a pile 5 to 10 ft. long and alternate shovels taken giving a ***500-lb. sample,*** which is crushed to $^3/_4$-in. and treated as above, giving a ***250-lb. sample.*** This is crushed to $^1/_2$-in., mixed, by shoveling,

into a conical pile and then shoveled into another cone, flattened and quartered, giving a *125-lb. sample*, which is crushed to 3/8-in., placed on a blanket or canvas (6 ft. × 8 ft.), mixed by rolling, coned by drawing up the ends of the cloth, then flattened and quartered, giving a *60-lb. sample*. This is crushed to 1/4-in., placed on the blanket and the preceding operation repeated, giving a *30-lb. sample* which is crushed to 3/16-in. and again subjected to rolling, coning, flattening, and quartering, giving a *15-lb. sample*.

Every precaution as described in Art. 3 is taken in forming the cones and shoveling from them. The first shovelful for forming the long piles is spread out in a straight line, having a width equal to the width of the shovel and length of 5 to 10 ft. The next shovelful is spread directly over the top of the first but in opposite direction and so on, back and forth. The pile is occasionally flattened during this procedure. Alternate shoveling from the long pile begins at either end on one side and successive shovelfuls are taken the width of the shovel apart as the shoveler advances along one side and around the pile, always in the same direction. Crushing may be done mechanically or by hand with an iron tamping bar or sledge on a sheet-iron plate or solid floor. Flattening of the cone is accomplished by pressing the apex vertically with the flat of the shovel or a board.

Time required. According to Morrow and Proctor (*loc. cit.*) time required for *ASTM* procedure on a 1,000-lb. lot of <4-in. coal, one man working, was, in hours: Crushing 1,000 lb. from <4-in. to <1-in., 4.0; forming long pile, 0.75; dividing <1-in., 0.25; crushing 500 lb. <1-in. to <3/4-in., 2.67; forming long pile, 0.17; dividing <3/4-in., 0.08; crushing 250 lb. from <3/4-in. to <1/2-in., 1.08; coning and quartering <1/2-in., 0.12; crushing 125 lb. from <1/2-in. to <3/8-in., 0.75; rolling 10 times, coning and quartering <3/8-in., 0.17; crushing 60 lb. from <3/8-in. to <1/4-in., 0.83; rolling 10 times, coning and quartering <1/4-in., 0.12; crushing 30 lb. from <1/4-in. to <3/16-in., 0.92; rolling 10 times, coning and quartering <3/16-in., 0.05; total, 11.96. Others report that the time required to collect and prepare samples according to this method ranges from 13 to 16 man-hours, depending upon the friability of the coal. Charging labor at the rate of $1.50 per hr. the cost for preparing a sample is about $18. Total cost of sample and analysis is almost prohibitive except for large shipments.

Trench sampling (*Smith, loc. cit.*) consists in spreading the ore out into a flattened square or rectangle, about 2 or 3 ft. thick with 100-ton lots and from 1 to 2 ft. thick for smaller lots, and cutting trenches through the cake about 1 ft. wide, crossing at right angles at the center. All material thus excavated is taken for the sample, or alternate shovelfuls may be taken. Sometimes all of the material from the trenches is rejected and samples are taken with a shovel from the sides of the four piles left. The accuracy of this method depends on the degree to which material is mixed before making the flattened rectangle. If the rectangle is made by spreading out from a cone, the sample will probably contain too great an amount of fine material, as the same width of cut is taken from the center as from the edges. (See Art. 3.) As the sides of the trenches take the form determined by the angle of repose of the material, it is difficult to be sure that the same proportion of ore is taken from the top as from the bottom, and if there is a difference between the top and bottom layers, the sample will not be accurate.

Quartering shovel (Fig. 5, item *a*) is about 10 in. wide, with flanged edges and two partitions on the blade dividing it into three spaces. The two outside spaces cover three-fourths of the area of the shovel blade and are open at the back. The center space, about 2.5 in. wide (one-fourth of the area) is closed at the back. The sampler pushes the shovel into an ore pile and then, with a quick rotary motion, swings the loaded shovel. The ore in the two outside spaces slides off the back of the shovel and goes to the reject, while the portion in the center space remains on the shovel and is thrown into a wheelbarrow or other receptacle as the sample.

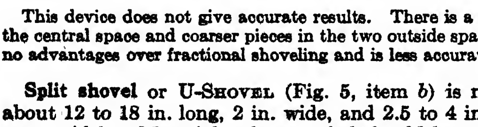

FIG. 5. Sampling shovels.

This device does not give accurate results. There is a tendency for fines to be more in evidence in the central space and coarser pieces in the two outside spaces. The method is seldom used, as it offers no advantages over fractional shoveling and is less accurate.

Split shovel or U-SHOVEL (Fig. 5, item *b*) is made up of several troughs, generally about 12 to 18 in. long, 2 in. wide, and 2.5 to 4 in. deep, with intervening spaces of the same width. Material to be sampled should be crushed to 0.5-in. or less. The shovel is laid on the ground or held by an operator and another man shovels the ore onto the split shovel with a square-end shovel. When the troughs are filled, the first man throws the split-shovel load to the sample heap. The troughs must not be allowed to overflow.

This method is slow, requires two conscientious and careful men, and is not as accurate as the alternate-shovel method.

Pipe Sampling

Several varieties of pipe or GUN SAMPLERS are used. The simplest form consists of a piece of pipe (0.5-, 1-, or 1.5-in. diam.), one end with sharpened edge, the other fitted with a

tee and two short nipples to form a handle. The pipe should be long enough to reach the bottom of the heap to be sampled; it is thrust vertically to the bottom at regular intervals, and then withdrawn, and pounded with a hammer to release the sample.

In Montana (*121 P 866*) the usual method is to make insertions of pipe in parallel rows spaced at 2-ft. intervals. The pipes are 4 to 5 ft. long, 3-in. diameter at top and 2-in. at the cutting edge. About 250 lb. is usually obtained from 40 to 75 insertions of pipe. Two men should sample the material in a 50-ton car in about 30 min.

Forms. Several forms are shown in Fig. 6. Form *A* consists of pipe and fittings made up as above, with a longitudinal slot cut out. It is pushed into the mass to be sampled, twisted around until filled, and then withdrawn. Form *B* is made up of two such slotted pipes, one smaller than and within the other. It is pushed into the ore with the pipes in position *a* until it reaches the bottom. The handle is then turned until the pipes take position *b* and is twisted back and forth until the inner pipe is filled with material. The pipes are then again turned to position *a* and withdrawn and emptied into the sample box or sack.

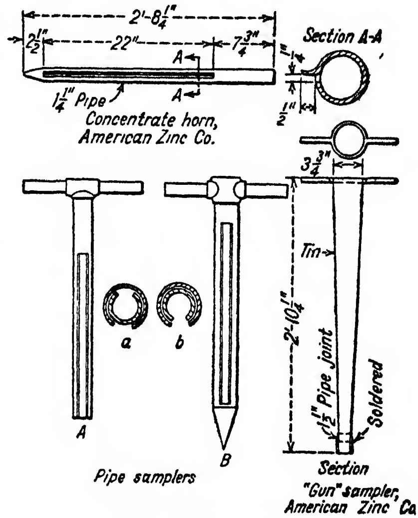

FIG. 6. Pipe samplers.

Applicability. Pipe samplers are satisfactory for sampling fine concentrate in railroad cars or bins, provided the material has not packed down too hard. They are also used for sampling sand in vats before or after treating with solution in percolation extraction processes. They can be used on tailing heaps or on any finely crushed ore. Small pipe samplers are used for sampling material in sacks or cans.

Accuracy. Pipe sampling, although used considerably because it gives quick results at low cost, may lead to serious errors unless the material is well mixed, in which case grab samples, taken with a spoon or the like, will do just as well. Wright (*34 CEMR 73*) has demonstrated that pipe samplers of form *A*, Fig. 6, yield samples representative of the top 3 or 4 in. and not of the underlying material, because when the sampler is inserted, a cross-section of the first few inches is forced up the pipe, and thereafter the frictional resistance of this plug is so great that no more material can be forced in. The operator does not notice this resistance because the wedge action of the point enables easy penetration of the material. A bag three-quarters full of sand with an overlying 4-in. layer of cassiterite was sampled with a pipe sampler of type *A;* the sample assayed 99.5% cassiterite. The use of wider longitudinal slots reduces the sampling error somewhat. Pipe samplers of type *B* give uniformly better results providing slot width is large compared with maximum particle size.

Auger samplers are used in the same manner and on the same classes of materials as pipe samplers. They have the advantage that they can be used on material that has packed so hard that it is difficult to force a pipe sampler into it.

Use of a ship auger to sample an old tailing pile was described by Sabin (*136 J 444*). The extension shanks were made of 3/4-in. pipe cut in suitable lengths, with a short nipple on the upper end, to which a T-handle was fitted with a quickly detachable device like that used in a pressure-grease fitting. Raising of pipe and auger was accomplished by means of a snatch block on a tripod which carried at the apex a guide for the pipe. The ship auger worked well in damp slime; the sample packed in the helical groove; a 12-in. auger pulled about 6 in. of core per lift.

For sampling sands a post-type auger, having two parallel curved blades 7 in. long, appropriately sharpened and shaped for digging at the points, was used. To prevent caving at the collar of the hole and to avoid losing sample by spill, a 16×16-in. box with a hole in the bottom was placed over the hole and a short length of 2 1/2-in. pipe with a sleeve on one end was driven into the hole up to the sleeve. Handling of the pipe was facilitated by putting DOGS on the box, consisting of two V-shaped irons made of 2×1/4-in. flat stock, hinged at opposite ends of the box so that the apices overlapped in the center above the hole. A near semicircle was cut in each apex, preventing downward movement of the pipe. A stop was placed under each dog to hold it just in contact with the pipe; pressure exerted on the dogs by the operator's foot induced friction sufficient to support the pipe.

Sampling Wet Streams

Hand sample cutters are used for wet pulp in practically all plants; in some plants all wet sampling is done by hand; others use hand sampling only for taking special and occa-

sional samples. Three forms are shown in Fig. 7. Hand sample cutters should be held with the edges perpendicular to the direction of motion of the cutter and passed completely through and out of the stream in one direction with a movement as nearly uniform as possible. The best results are obtained by taking cuts at regular intervals of time and by so using the cutter that its operation approaches that of a properly run mechanical sampler. The cutter should be large enough so that there is no danger of overflow while

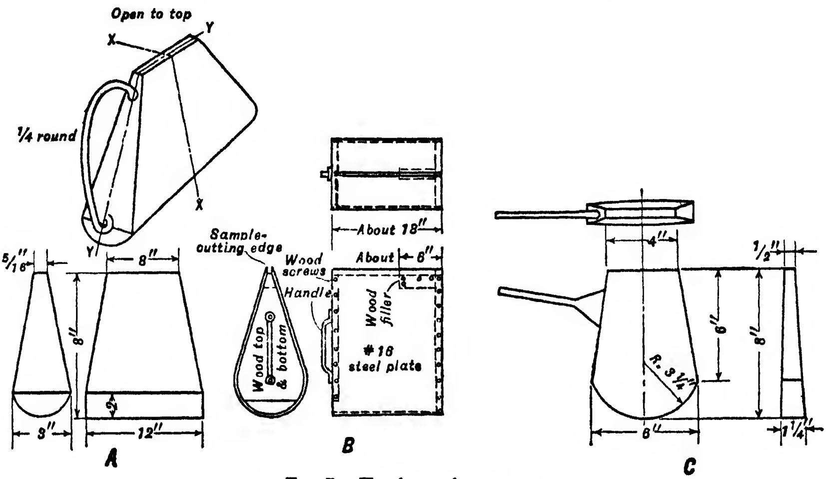

Fig. 7. Hand sample cutters.

making one passage through the stream of pulp. The aperture should be at least four times the diameter of the largest grain in the pulp; the cutter should be smooth inside, watertight, and designed to clean itself readily.

Sampling liquids. See p. 36.

3. SAMPLING MACHINES

Automatic machine samplers are devices designed to substitute mechanical processes for the undesirable human element in hand sampling. By so doing they lessen or eliminate the accidental and intentional errors introduced by the personal factor, shorten the time required for cutting a sample, and reduce the amount of operating labor. Against the reduction in labor and time are to be charged the consumption of a small amount of power, a capital investment with attendant interest and amortization, repair and maintenance charges. Further, in a custom sampling plant, cleaning out between different lots of ore is a tedious and difficult job. Machine samplers have difficulty in handling sticky ore.

The fact that ore being machine-sampled is not in sight throughout the operation in a custom mill delayed the substitution of machine for hand methods, but at present practically all large custom mills use machine sampling and find marked advantages in the ease and uniform accuracy of operations.

Sampling machines require the ore in motion in order to present it to the cutters as a thin ribbon or stream. They are of two general types: (*a*) Those that take part of the stream all the time (stationary devices); (*b*) those that take all of the stream part of the time (moving devices).

Stationary Machine Samplers

Principle. Stationary samplers are devices that divert a part or parts of a moving stream of material out of the stream, as a sample. Those which divert a single part only are designed on the assumption that the stream is uniform across its section in the characteristic sampled for. This is true only in a stream composed of a homogeneous single phase, *e.g.*, a well-mixed liquid solution; it is never true of a two-phase stream such as solid or gas in liquid, nor of a stream of broken solid. Generally the material in a moving stream varies more irregularly and less gradually in a transverse section than along its direction of flow. In broken ore sliding down an inclined chute, the coarse pieces slide

on top and toward the center, while the fines are on the bottom and against the sides. When such a stream changes direction, the coarser and heavier pieces are carried to the far side of the chute, owing to their greater momentum, while the finer particles are not carried so far. The result is a stream made up of coarse on one side and fine on the other, which does not subsequently mix and become uniform. The following conditions may cause similar results (*A. W. Warwick, Notes on Sampling*, Industrial Print. and Pub. Co., Denver, 1903): (*a*) Two elevators throwing ore into the same chute, one elevator raising low-grade ore and the other richer ore; if the streams do not cross, little mixing takes place. (*b*) Feeding an elevator from the side instead of from the front. (*c*) Irregular feed of coarse and fine material to a crusher, or coarse material on one side and fine on the other; (*d*) anything that produces an eddy causes segregation between different sizes in an ore stream. Stationary cutters can not be expected to deliver an accurate sample unless ore is presented thoroughly mixed.

Whistle-pipe sampler in its simplest form consists of a vertical iron or steel pipe with notched openings cut halfway through the pipe, each opening spaced 90° horizontally from the preceding. Rectangular steel plates are placed in the notches so that top edges coincide with a diameter of the pipe. Above each notch is placed a hopper-shaped cast-iron liner which gathers the ore into a compact stream before presenting it to the dividing edge. Ore is poured into the pipe at the top. When the stream reaches the first splitter, half is deflected outside the pipe and falls into the enclosing bin or housing as reject. The remainder continues down the pipe and is halved by each succeeding edge. The portion passing the last cutter constitutes the sample. Weight of sample is $1/2^n$ part of the total fed, where n is the number of splits.

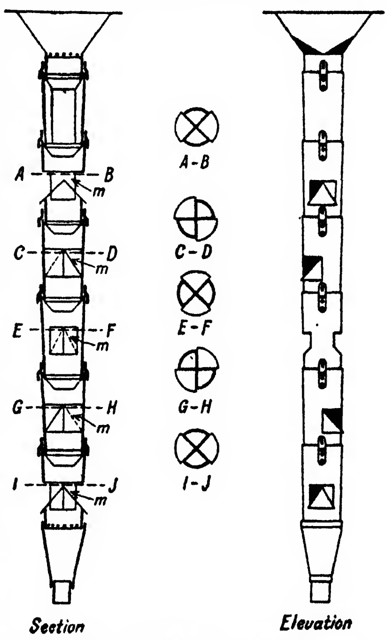

FIG. 8. Whistle-pipe sampler.

Fig. 8 (*Warwick*) shows details of an improved type of whistle-pipe sampler, in which material is fed at each cut to a splitter m that divides the stream into quarters. Opposite quarters are rejected, the other two continue and are again split in the same manner. In this design deflectors are spaced at 45° horizontally.

ADVANTAGES of whistle-pipe samplers are cheapness of installation and operation, simplicity, and quick reduction of bulk. No power is needed. DISADVANTAGES are such as to preclude their use when an accurate sample is desired. In the simple type first described, wear on the cutting edges causes displacement thereof so that a changing proportion of the stream is taken as wear progresses. The improved design with vertical cutting edges dividing the stream in quarters avoids this disadvantage. Fuse, waste, rags, wood, and similar materials catch on cutting edges and cause improper splitting and may clog the openings. Clogging cannot be detected during operation. The general objections to machines that cut part of the stream all the time also apply. Uneven wear of cast-iron liners may cause segregation. No opportunity is afforded for recrushing between cuts, hence the whole lot must be reduced to a size commensurate with the bulk of the final sample. Expense of such crushing would be out of the question in a custom sampling mill, and would not be justified in any mill where the ore could be treated in a coarser state than sampling demanded.

Single-split samplers consist of a splitter or divider placed in such a way in a stream of material issuing from a launder or chute as to continuously deflect a portion of the stream into a sample hopper or container. They are more inaccurate than the whistle-pipe samplers and have little to commend them.

Riffle is a stationary sampler for continuous diversion as a sample of a plurality of slices of a stream, parallel to the direction of flow, and usually equally spaced across the stream. It is most used in cutting down large samples by hand to assay weight, but may be used for initial sampling of a mill stream.

Jones riffle (Fig. 9, item *A*) is the most satisfactory device with which to make final reductions in bulk of sample prior to delivery to the assayer. It consists of an assembly comprising an even number of equally sized chutes, adjacent chutes discharging at opposite sides. Ore is fed to the riffle from a scoop. Jones riffles may be procured in the following sizes, or may be made up in any good tin shop.

A form (McCann) in which the sample boxes are placed touching a vertical divider plate permits shorter troughs, which clog less and are easier to clean.

Dimensions, in.	4 × 4	6 × 6	10 × 10	10 × 18
Width of troughs, in.	1/2	1/2	3/4	1
Number of troughs	6	8	10	18

Flat riffle (Fig. 9, item *B*) is used for the same purpose as the Jones riffle, but is less convenient. It has alternate slots closed at the bottom so that half of the material fed is retained in alternate troughs while the other half falls through. In using this riffle, care should be taken that the closed troughs do not fill up and overflow into the open troughs.

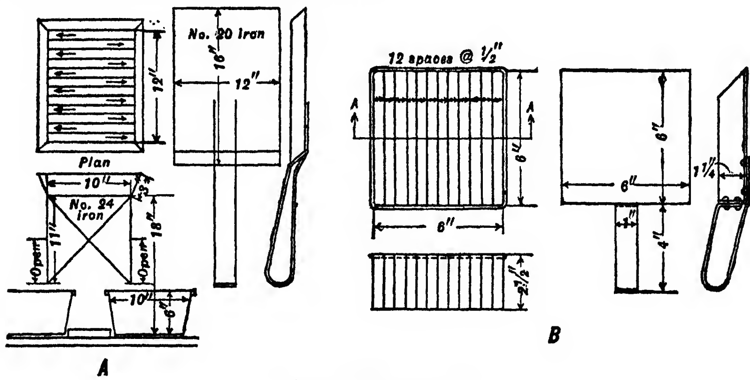

Fig. 9. Riffle sampler.

Use of riffles. Riffles should be of strong construction and carefully handled. Rough treatment causes distortion of the dividing edges between chutes with consequent inaccuracies in samples. Chutes should be wide enough to prevent bridging by coarse particles—at least three times the diameter of the largest particle in the feed and better more. Feed scoops should be of the same width as the total combined width of the riffle chutes; if greater, end chutes receive an undue proportion; if less, chutes receiving the edge of feed stream are underloaded. The same number of riffles should discharge each side, if it is desired to split into halves. Some manufacturers furnish riffles with an uneven number of chutes, so that both end chutes discharge the same side. This will cause material discharged on the favored side to contain an undue proportion of coarse material as well as to weigh more than the other portion. Such riffles should be rejected. Material should be spread evenly across the full width of the feed scoop and delivered to the riffles well toward the center. A good way to feed is to place the loaded scoop with ore at rest thereon so that the edge rests on top of the riffle-chute dividers along a line perpendicular to these and near the edge farthest from the operator; then draw the scoop smartly from under the charge, allowing it to fall evenly on the riffle. It is desirable to keep the edge of the scoop straight and to avoid a scoop that, through long usage, has a turned or uneven edge. For the most accurate work the riffle should be level.

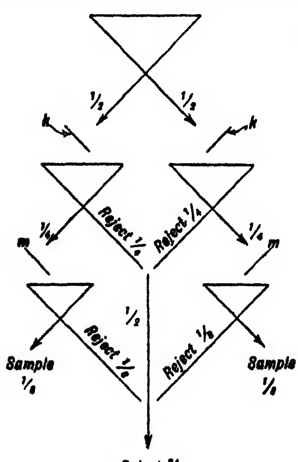

Fig. 10. Riffle bank.

Accuracy of riffle samples was investigated by T. Morris (*CU*) and found to decrease as the ratio of chute width to maximum particle size increased. Using an artificial mixture of 10∼14-m. pyrite and quartz, assaying 35% pyrite, with a riffle having chute widths of 3/16-in., ten 100-gm. lots were riffled and the samples assayed, giving an average result of 35.0 ± 0.01%. Using a 3/8-in. riffle the average of ten runs was 35.2 ± 0.21%, with a 3/4-in. riffle an average of 35.1 ± 0.45% was obtained. This result is in accord with the increment theory (Art. 1); the smaller the chute width the greater the number of increments in the sample.

Bank or combination riffles are usually made of five sets of riffles arranged as shown in Fig. 10 (*TP 86 USBM*), each riffle made up of a number of troughs of equal width, separated by cutting edges, adjacent troughs discharging in opposite directions. Material is fed in a uniform sheet over the first riffle and split into many streams. Half of these discharge one side and half the other. Discharges from the first riffle impinge on inclined plates *k* and fall to a second set of riffles, smaller than the first. These riffles produce

four main streams, two of which unite and pass in to the reject, while each of the others falls to deflecting plates m and then to a third set of riffles, smaller than the second, which again halve the streams. One-half from each of the last riffles is rejected, while duplicate samples, each representing one-eighth of the whole, are furnished by the others. The riffles are supported by a rigid frame or may be so hung that one or more sections can be swung across a falling stream of ore. Such combinations are used for both wet and dry pulps, usually at fine sizes.

This machine makes many cuts of the ore stream and, therefore, has ADVANTAGES over methods that make only two or four cuts. It is simple of operation and, as it is generally used on fine ore, wear on the dividing edges is not great. The DISADVANTAGES are that the device is one of the class that

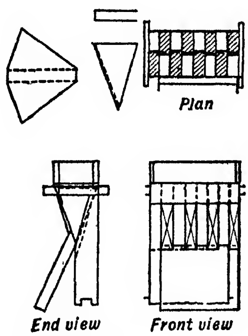

FIG. 11. Nonclog riffle.

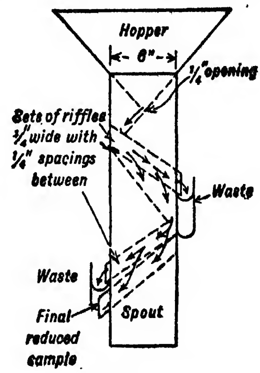

FIG. 12. Wet riffle.

cuts part of the stream all the time; construction is not simple; great care is required to insure that each compartment is of same width as others; there is a possibility that during operation dividing edges will become bent or knocked out of shape so that they do not make a proper division; damp ore and foreign waste clog the riffles, and clogging may not be discovered for some time on account of inaccessibility. Clogging causes one part of the riffle to take no sample or deflects too much into the sample. Tapping with a hammer will obviate clogging, but may deform the riffle edges. If the feed is not carefully delivered to the first riffle, segregation of the coarse and fine material is probable, producing an improper sample. Damp, fine material sticks to the deflecting plates and may cause deflection of coarse pieces with resulting segregation. Riffles are sometimes swung or shaken to avert clogging and segregation.

Nonclog riffle bank (Fig. 11) is used by DETROIT EDISON Co. (*7 #4 C 10*). A bank constitutes 8 riffles. Sample is taken from the vertical spouts of each riffle and thus gains momentum, whereas the sloping discharge chutes of the conventional design cumulatively convert initial momentum into a horizontal component that is lost at each reversal. Clogging is reported substantially eliminated.

Wet riffle (Fig. 12) is used primarily in cutting down large pulp samples, before drying, to a sample size necessary for assaying.

Cone sampler (Fig. 13) was developed to cut down large volumes of coal (*12 #3 Fuel 93*). It consists of two co-axial cones C and C_1, so mounted as to enclose an annular space, wherein are fitted two chutes B and B' diametrically opposite one another. The chutes extend from A, near the base of the inner cone C, beyond the lower edge of the 2-cone structure, which terminates at the lower edge by junction with the upper rim of reject hopper D. Outer cone C_1 terminates at the top in a short cylindrical tube T above which is fitted a slide valve V and hopper H. The apex of the cone C projects well up into tube T. Slide-valve V consists of two overlapped plates with a square aperture cut in each; motion is coupled by the three-link mechanism shown; the holes register over tube T.

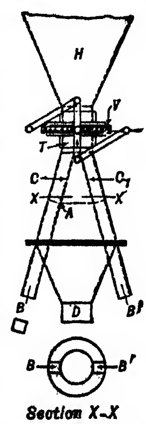

FIG. 13. Cone sampler.

Procedure is to charge hopper H through a funnel held coaxially, thus producing in H a conical heap. This tends toward uniform radial distribution. Slide V is then pulled and coal flows uniformly into tube T onto the apex of C. Chutes B and B' intercept samples. Products fall into suitable containers.

Weight of sample is determined by the ratio of the combined areas of the chutes at A to the area of the annulus at this plane. Hold-up is prevented (with coal) by using cone angles of 75° and a hopper angle >45°. The width of the annular space and the diameter of tube T should be at least five times the limiting size of the material to be sampled.

Accuracy of this apparatus depends almost entirely on the uniformity of axial distribution attained by coning the feed by funnel loading in hopper *H*, and upon the uniformity of the draw through the opened slide. Tests on mixtures of <1/4-in. clean coal and washery dirt were sampled by coning-and-quartering and by riffling, and in each case the rejects were sampled in the cone apparatus. Maximum deviations of ash analyses from average in the case of cone *vs.* riffle samples (5 tests) ranged from −0.32 to +0.33, and for cone *vs.* coning-and-quartering (5 tests) the range was from −0.45 to +0.45. MAXIMUM DIFFERENCE between cone and riffle samples was 0.55, and between cone and cone-and-quarter, 0.70. MAXIMUM DEVIATION from average should be ±0.2 and the maximum difference between two samples 0.4, for an 11.5% ash content.

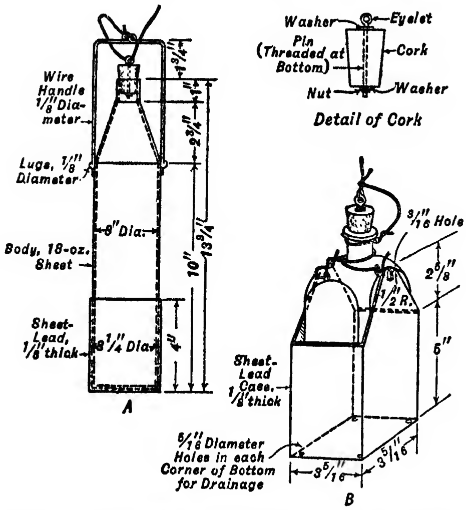

FIG. 14. Containers for bottle sampling (*after A.S.T.M.*).

Sampling liquids. Methods vary according to whether the liquid is stationary or in movement.

Stationary liquids in tank cars, tank trucks, ship tanks, or the like, are sampled by means of a weighted bottle of suitable capacity. Two forms recommended by *ASTM D 270–33* are shown in Fig. 14. Five samples are taken, one with the bottle mouth 1/10th of the depth of the liquid below the surface, three at mid-depth, and one 1/10th of the depth from the bottom. These are composited to give the tank sample. For horizontal cylindrical tanks eight mid-depth samples are taken. To take the sample, the stoppered bottle is lowered to the proper depth and there uncorked by a quick jerk on the string; when full, as evidenced by cessation of air bubbles, it is withdrawn quickly.

Can- or drum-contained liquids may be sampled by means of a glass or metal thief, two forms of which are shown in Fig. 15. In form *A*, the top hole is closed by the thumb and the thief thrust into the container to the desired depth, the thumb is removed to allow liquid to enter and replaced for withdrawal of sample. Samples taken from different levels are composited. Size is proportioned to the container. Form *B*, suitable for tank

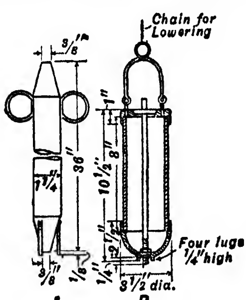

FIG. 15. Thiefs for sampling liquids (*after A.S.T.M.*).

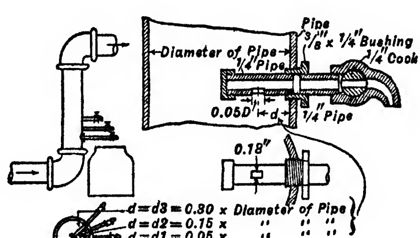

FIG. 16. Enclosed-stream sample connection (*after A.S.T.M.*).

cars, fills from a fraction of an inch from the bottom when the pin strikes and lifts the conical top and bottom valves.

Flowing liquids may be sampled by means of a dipper or a pulp sampler when a free or open discharge of a stream exists, otherwise they are sampled by bleeding the pipe within which they flow. This is done by drilling and tapping the pipe to take a bushing, which holds a short nipple capped at one end and slotted as shown in Fig. 16. A plug cock is attached externally to the bushing by means of another nipple. If desired, two or three such bleeders, radially disposed around the pipe, may be used to insure sampling of all portions of the stream. If the pipe diameter is too small to permit insertion of

bleeders, a short vertical nipple of 2-in. pipe is inserted into the pipe line at some suitable point and the bleeders attached to this nipple. In operation, the cocks are opened as nearly as possible to the same angle of opening and the drips from each cock are caught in a common sample container.

Thin liquid pulps containing fine particles may be sampled in much the same way that liquids are sampled, if not too great precision is required.

One such approximation, used at KALGOORLIE STATE BATTERY (*116 Aa 571*) to cut down larger samples, is shown in Fig. 17. It consisted of an 18-in. cone *A*, of about 6-gal. capacity, mounted on a light angle-iron frame, a head-frame *C* carrying a slotted stirrer *D*, and four outlet pipes *E*, controlled by a common plug at *B*. Head-frame and agitator were removable to facilitate cleaning. Pulp was first thoroughly agitated by turning hand crank *F*, whereupon plug *B* was released by the handle shown and four samples were run to separate containers.

THIEF was used to obtain the results shown in Sec. 15, Figs. 19 to 21; the consistency in variation from point to point indicates reasonable accuracy. DIP SAMPLES are not, however, to be depended upon for liquid pulps of any degree of fineness, for the reason that, if agitation is sufficient to prevent gravitational separation the probability is very strong that it will cause inertial segregation.

Jones riffle with 1/8-in. slots, fitted with a feed hopper, is used at WRIGHT-HARGREAVES (*145 #5 J88*) to split wet pulps.

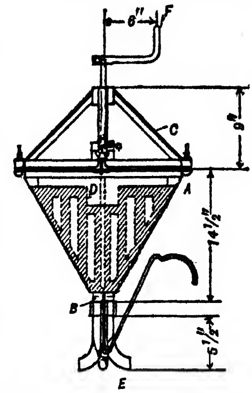

FIG. 17. Kalgoorlie distributor splitter.

Moving Machine Samplers

Principle. These samplers are designed to take all of the stream a part of the time. Their performance, as judged by the accuracy of the samples, depends upon the speed with which the stream is cut and the frequency of the cuts. The setting of these variables by the operator should be made according to the known variability of the stream along its length and across its section. Constant variability in cross-section, no matter how complex, presents no difficulties provided the stream is cut at a uniform rate, so that the same amount of material is taken from every element of cross-section. In Fig. 18, item *A*, the parallelopiped *ABCDEFGH* represents the stream, and planes *K* and *L* the limiting planes of the portion of the stream taken by the cutter. The curves *IJ* (GRADE CURVES) are so constructed that the areas thereunder represent weight of valuable mineral and are all identical, *i.e.*, the value changes across the stream but not longitudinally. The volume of material taken by the cutter depends upon the inclination of the limiting planes *K* and *L* to the cross-sectional plane *ABCD*, the greater the inclination the larger the volume taken. This inclination depends upon the relative rates of movement of

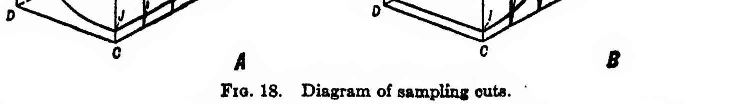

FIG. 18. Diagram of sampling cuts.

cutter and stream. Assuming these rates constant, at values not necessarily equal, it follows, since the inclination of the planes *K* and *L* is constant, that the same volume of the stream will be taken per cut. It also follows that volume taken per cut below the surface generated by the grade curves *IJ* will also be constant, and since the ratio of this volume to the volume of the cut is the assay, the assay will be constant. This is true no matter how complex the cross-sectional variability, provided there exists no longitudinal variability and provided cutter and stream velocities are constant. If the stream rate increases when the cutter is in the high-grade region of the stream, the assay of sample will be high; a similar result is obtained if the cutter slows down in this region, assuming constant stream rate; the converse is, of course, also true.

Longitudinal variability, in the absence of sectional variability, is shown in item *B*, where *IJKLMNOP* is the "grade" surface of the stream *ABCDEFGH*. It is apparent from inspection of this diagram that the volume, below the "grade" surface, intercepted by the limiting planes *Q*, *R* of the cut will, in general, be different for different cuts, unless the grade surface is harmonic. In this case, the frequency of the cuts must equal the frequency of repetition of the surface. Mathematical study of this problem leads to several conclusions of practical importance.

1. *Grade surface repetitive.* Two methods of obtaining correct samples may be used, *viz.*, (*a*) increase cutter speed so that limiting planes are nearly parallel with cross-sectional plane *ABCD* and divide the wave length into a number of increments in accord with the accuracy desired, speed from increments located at the *maxima and minima* of the grade surface (see Fig. 19); (*b*) if the cutter speed cannot be increased to the rate required by (*a*) it should be decreased to such a rate that one end of the limiting planes intercepts a minimum and the other end intercepts a maximum. This procedure is not feasible when the wave length is long because the sample will be too large. Other frequency patterns yielding accurate samples may be determined.

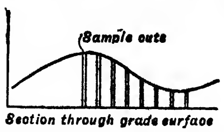

FIG. 19. Spacing sample cuts for harmonic longitudinal variation.

2. *Grade surface nonrepetitive.* Any constant cutter frequency and cutter speed will, over a short period of time, give accurate samples. As a matter of fact, cutter speed and frequency may be variable and still provide accurate samples provided the patterns of cutter variation and grade surface variation are in no way synchronized to miss maxima or minima consistently.

Longitudinal variability is more prevalent than is commonly supposed, especially with spotty ores, or when sampling follows a machine that is not fed at a constant rate or with a constant grade of feed, or when sampling the discharge of a bin wherein stratification of values has occurred. The well-known accuracy of machine-cut pulp samples is due not only to the larger number of particles taken per unit weight of sample, but also to the usual slight longitudinal variability, although cross-sectional variability may be high.

When streams are variable in both directions, the best practice appears to be to maintain uniform cutter and stream speeds, thus eliminating errors due to cross-sectional variation in value, and to adopt a cutter frequency depending upon the characteristics of the longitudinal variation.

Requirements for accurate machine sampling are:

1. The sampler should take the whole of the stream part of the time.

2. Equal percentages should be taken from all parts of the stream. This necessitates that the cutter travel at a uniform rate while passing through the stream, and the scoop move completely across and out of the stream at each cut; otherwise one side will be unduly weighted in the sample.

3. The interval between cuts should preferably be constant.

4. Cuts should be frequent enough to insure representation in the sample of the most abrupt change in the character of the stream.

5. The distance between cutting edges should be great enough to allow the largest pieces of material free passage between them; this distance should be at least three times the diameter of the largest piece, better four times or more.

6. The depth of the scoop should be sufficient to prevent material from bounding or splashing out.

7. Scoops with closed bottoms should be large enough to hold all of the material taken in one cut without danger of overflowing. The opening to discharge the sample should be large enough to empty the scoop quickly and prevent sedimentation.

8. Feed should be constant; if the stream is intermittent, the cutter may receive no sample during some of its passages.

9. Speed should not be great enough to knock away pieces that should go into the sample. In a revolving sampler, speed should be so low that centrifugal force will neither throw material out nor prevent discharge.

10. The stream delivered to the cutting edge should be as narrow as possible in order to minimize the time of passage of the cutter therethrough. The limit of this contraction is determined by the size of the largest particle.

11. The ore should be thoroughly mixed and all devices that tend to cause segregation eliminated.

12. The drive should produce uniform motion of the cutter. Relatively high speeds prevent jerky motion. Loose belts should be avoided. It may be advantageous to reduce from a high-speed belt-driven countershaft by gears.

Dry- *vs.* wet-pulp sampling. The fundamental difference between these two sampling problems lies in the difference in maximum particle size that ordinarily goes with the difference in moisture content.

Dry feeds are ordinarily relatively coarse and nonhomogeneous; consequently large samples are required, made up of a large number of cuts. For this reason the samplers usually run continuously, and timing of cuts is done by the sampler-driving mechanism as a pure incident of its function in moving the sample cutter. As a result, most dry samplers are of arc-path types, rotary motion being most simply available.

Wet feeds are normally fine and either well mixed or of reasonably constant variability across the stream and of relatively gradual longitudinal variability. Hence samples may be small in volume, and the allowable sampling interval is correspondingly long. This calls for intermittent operation, which involves use of a timer. In general, design has developed along the lines of making the timer the primary element of these apparatus, either making it the means of driving the cutter as well as timing it, or making the drive a simple mechanical or electrical system responding to the timer impulses.

Arc-path mechanisms have proved to be simplest in design for wet-pulp sampling also, hence they predominate. On the other hand, cutters with straight-line travel are more susceptible of sturdy construction and ready inspection; they tend to be more reliable and accurate; and as a result predominate in large mills.

General principles of sampler construction. In order to put the foregoing principles into effect in sampler design, it is apparent that the assembly must include (*a*) means to prepare the stream for sampling, (*b*) a proper cutter, (*c*) means to move the cutter into, across, and out of the stream in (*i*) proper direction, (*ii*) at suitable speed, (*iii*) at correct intervals, (*iv*) at a constant rate, (*v*) in correct position. Additionally (*d*) construction should be rugged, and (*e*) parts should be easily accessible, both for observation and repairs.

Streams are always sampled when falling freely under the influence of gravity. Since transverse segregation does not affect accuracy, if it is reasonably constant in character, the stream may be that delivered by a conveyor, chute, or launder, although some sample designers prefer to pass the stream through a short vertical chute or pipe before cutting, attempting thus to effect admixture and contraction.

Cutters are of different shapes according to the path that they travel in the stream. Those that follow rectilinear paths must have parallel cutting edges; those that travel on an arc must have the edges on radii of the arc. The spacing of the cutting edges must, of course, be sufficient to permit entry of the largest particle in the stream when presented with its longest dimension parallel to the plane of the edges; preferably spacing is several times this distance unless such spacing requires excessive speeds to minimize sample weight. The cutter box is designed of sufficient size to prevent overflow, and of such shape as will (*a*) prevent it from deflecting any of the stream outside the vertical planes of the cutter edges into the receiving opening, (*b*) insure complete discharge of sample, (*c*) lead the sample without spill to the sample container. Cutting edges should be straight, and so constructed that they will remain straight or can be replaced readily in case of deformation through shock or abrasion; they should be as sharp as is consistent with the service. Forms of cutters for different services are shown in subsequent figures.

Actuating means (DRIVE) constitutes the greatest variable in sampler design. Basic classification is possible on the shape of path in the stream, this being either an arc or a straight line. The cutter may move continuously or intermittently. Timers for intermittent mechanisms are actuated by waterflow, intermittent gear or cam mechanisms, or by electrical impulses. Position of the cutter path is determined by the constraint of the actuating mechanism, or by independent guides; in either case it should be such that the cutter edges do not approach nearer to a fixed surface, while in the stream, than 1 1/2 times the maximum dimension of the largest particle in the stream.

Examples selected from the multifarious designs follow. Selection was made on several bases: primarily accuracy, sturdy design, wide use, and simplicity. Sometimes, but by no means always, the four coincide.

Arc-path Samplers

The best-known of the dry-ore samplers are of this type. They are built in both revolving and in swinging or oscillating forms.

Vezin sampler (Fig. 20) is of the rotary-arc type. It consists of two hollow truncated cones, *a* and *b*, joined base-to-base, with one or more scoops *c* attached to the upper cone, all mounted on a vertical shaft. Ore fed through chute *d*, which may be vertical or inclined, normally passes into hopper *e* and is rejected through spout *f*. As the sampler revolves, chutes *c* cut through the stream and divert parts into the conical chamber and through spout *g* as sample. The inventor recommended an inclined chute delivering ore so that the horizontal component of velocity is the same as that of the cutting edges. This gives the effect of a piece falling vertically on these edges. Warwick (*loc. cit.*) states that the mode of delivery, whether vertical or inclined, has no effect on the accuracy of the sample.

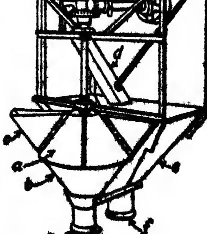

FIG. 20. Vezin sampler, single.

This sampler is made by a number of manufacturers; the machine should be investigated before purchase to see that the cutting edges are radial to the axis of rotation, and the sides of the scoops vertical; other-

wise the scoop takes more from one part of the stream than from another. In Fig. 21, item *A*, the edges are radially placed, the angular velocity is the same at all points, and all parts of the stream, therefore, flow into the sample for the same time. This gives a correct cut. The shape is shown in Fig. 22, items

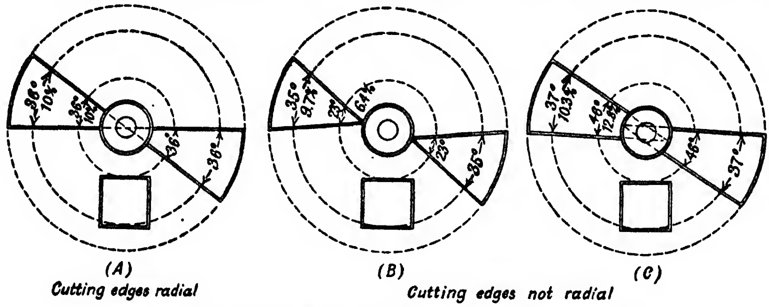

FIG. 21. Arrangements of cutting edges in Vezin-type samplers.

C and *D*. In Fig. 21, item *B*, the lines of the cutting edges intersect on the scoop side of the center, the arcs subtended increase from inside to outside of the described annulus, and a smaller proportion of the stream is cut from the inner edge than from the outer. The opposite case is illustrated in item *C*.

Proportion of stream length taken for sample is determined by the ratio of the number of degrees of arc subtended by the sample spouts to 360°. For a 10% cut a single sample spout should subtend 36° of arc, or with two spouts each should subtend 18°. The speed has no effect on the amount taken for the sample but affects only the FREQUENCY of the cuts; frequency can be varied also by changing the number of scoops. Usually one or two scoops are used, sometimes four. Two samplers are sometimes mounted on opposite sides of the same reject hopper in order to take duplicate samples. SPEED should not exceed 3 f.p.s. at a point on the scoop at the center of the feed stream, in order to prevent knocking pieces out of the stream, throwing them out of the scoops by centrifugal force, or hindering discharge. Width of scoop should be at least 4 times the diameter of the largest piece of material at the center of the stream and the opening into the cone should be at least 2.5 times this maximum diameter. Cutting edges should be made of hard, brittle steel to avoid distortion and wear; chips lost will probably be small and not materially affect operation; but bending changes the whole aperture.

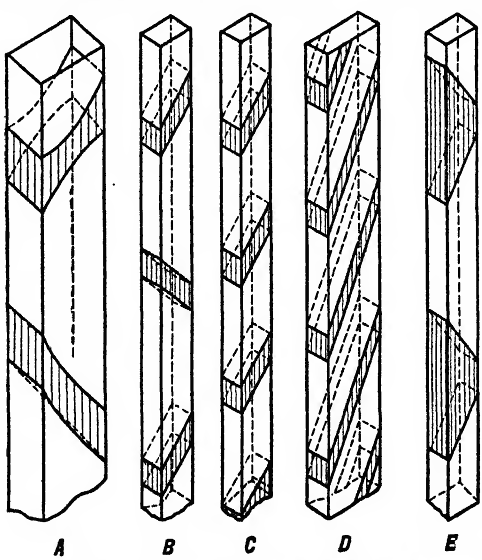

FIG. 22. Cuts taken by various samplers.

Fig. 23 shows a simple and efficient design for cutting edges used in sampling COBALT silver ores. The scoop is made of tempered steel, tapered for a short distance at the top to make a knife edge. Small wedge-shaped pieces of steel are placed between the scoop walls to hold the edges rigidly in place. For ordinary use such careful sharpening of edges is not necessary or common, but Cobalt ores were difficult to sample and it was necessary to take every precaution to attain accuracy.

ADVANTAGES of Vezin samplers are the ability to take an accurate sample; simplicity of construction; and easy accessibility for observation and repair. DISADVANTAGES are the head room required, danger of clogging, lack of ruggedness, possible improper construction of scoops, and delivery of feed in a manner to cause segregation and inaccurate sampling. The machine should be watched constantly to detect lodgment of foreign material on the cutting edges and to be sure that the scoops are not clogged. Hammers or mallets should be used only with the greatest care, if at all, to free clogged chutes on account of danger to cutting edges.

Sizes are shown in Table 21.

Table 21. Sizes and weights of Vezin samplers

No.	Max. size feed, in.	Wgt., lb. single	Wgt., lb. duplicate
1	1	500	850
2	2	850	1,300
3	4	900	1,600

Chas. Snyder sampler is similar to the Vezin, except that it has four sample scoops and the feed chute, instead of being square or rectangular, is annular, and extends over an arc of 90°. As a result there is a sample scoop under the feed stream at all times. Feed in the vertical feed chute is scattered by a number of short cross rods introduced in an attempt to minimize segregation.

The scattering of the stream tends to defeat the end sought in keeping a cutter in the stream at all times.

Cascade sampler (*12 #9 Fuel 313*) is a combination of the cone sampler (Fig. 13) and the Vezin, used for cutting samples down to predetermined and not necessarily equal fractions. It consists (Fig. 24) of a stationary conical hopper *A*, truncated at its apex to give an orifice *C*, which is fitted with a sliding shutter *D*. Orifice is about 5 times limiting diameter of feed. Attached to the lower end of the hopper is an outer cone *F*, which serves to confine material, and to support an inner cone *E* by means of four thin metal plates *G*, placed radially. The apex of *E* is located about 1 1/2 in. below the orifice. This assembly is suspended by cable or the like over a rotating bin *B* divided radially as desired (90°, 60°, and 30° in the figure). The tub floor slopes to a discharge hole *H* closed by a suitable stopper. The bin is rotated at 40 to 60 r.p.m.

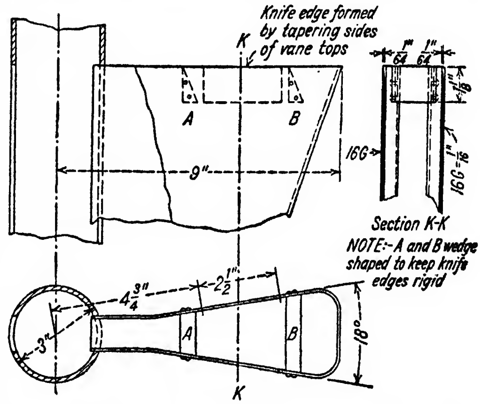

FIG. 23. Cutting edges on Vezin samplers at Cobalt.

In batch operation, the hopper is filled and the bin, with outlets closed, is brought to speed, whereupon the shutter is opened. Material can be added during operation if the bin is large enough. Reported agreement in ash analyses between various cuts on <1/8-in. coal is excellent, being equal to the limits set by assay procedure; performance with <3/8-in. coal was almost as good. On a weight basis, the combined 90° compartments, which should deliver a 50% cut, actually delivered 49.1%, with an average deviation for 4 runs of 0.05%; the 60° compartments gave a 33.5% cut with average deviation = ±0.1% as compared with the theoretical figure of 33.33%; and the 30° compartments yielded a 17.5% cut, average deviation = 0.13%, compared with the theoretical 16.67%.

Umpire sampler (Fig. 25) used for cutting down dry samples for assay, has two buckets revolved in opposite directions by means of bevel gears. Each bucket is divided into four compartments by plates at right angles, two opposite compartments being open at the bottom while the other two are closed.

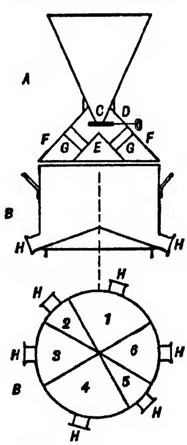

FIG. 24. Cascade sampler.

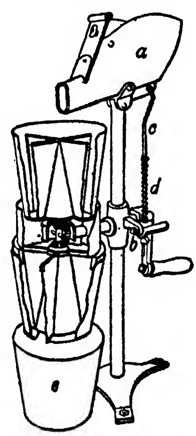

FIG. 25. Umpire sampler.

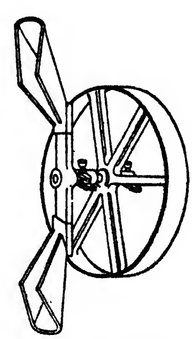

FIG. 26. Simplex sampler.

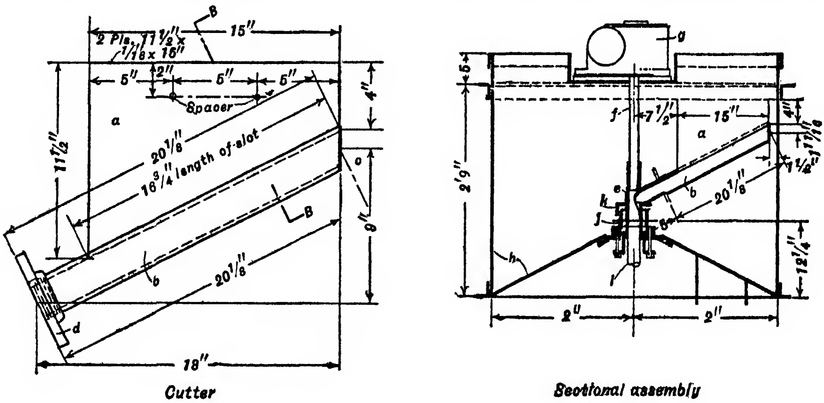
Material is fed from a scoop *a* that is shaken by a cam *b* striking a strap *c* attached to the scoop and to the coiled spring *d*. The sample passing through the second rotating bucket is caught in a bucket *e* and represents one-quarter of the material fed to the machine.

Simplex sampler (Fig. 26). The machine is simple and cheap, and on that account has had wide use. It is, however, notoriously inaccurate except for fine bone-dry ore; under other circumstances some material splashes out of the sample chutes while these are in the stream, and moist material

either rides the scoop to the top of its path and drops back into the stream or gradually fills the scoops more or less completely. The finer part of a long-range feed is always favored for the sample.

Rotary wet-pulp samplers are unusual.

The form shown in Fig. 27 was designed and used at Bertha Mineral Co. (*132 J 480*). It consists of a sample cutter comprising radial vertical walls *a* of 1/16-in. rolled manganese-steel plate, welded to



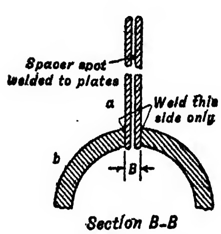


Fig. 27. Rotary wet-pulp sampler at Bertha Mineral Co.

cover plates at the ends, and to the supporting inclined 2-in. extra heavy pipe *b* at the bottom. A welded cover plate *c* closes the outer end of *b*. The other end of *b* is threaded into a 2-in. standard pipe flange *d*, which is bolted to a suitably inclined seat on casting *e*, keyed tightly to and supported by shaft *f*, extending downward from gear box *g*. The gear box with its 1/4-hp. driving motor is supported on angles on the top of cylindrical tank *h* within which the sampler rotates, and through which the pulp stream falls. Cutting edges are beveled at 60° to the vertical from the outside to a 1/64-in. inner edge. Width of slot at 15 in. from center of rotation is made 1/16-, 1/8-, or 15/16-in. according to the service. The cutter delivers to the supporting casting, into the bottom of which is screwed sample-delivery pipe *i*. Stuffing box *j* under splash shield *k* protects against leakage into the sample, and is itself largely protected by the upward sloping conical bottom of tank *h*, which insures nonsubmergence.

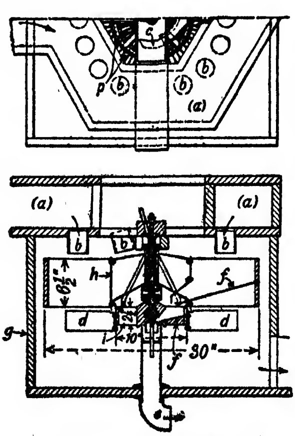

Fig. 28. Borcherdt sampler.

Speed of rotation determines the frequency of the cuts, but not the sample ratio; quantity of sample taken depends upon the ratio of average cutter width to average circumferential travel. For a 1/16-in. slot and an average radius of 15 in. the fraction taken as sample is about 1/1,500.

Borcherdt sampler (Fig. 28) is of rotary type, and uses the pulp stream for motive power. It consists (*101 J 524*) of two wheels *h* and *i* mounted on ball bearings on a vertical shaft. Each wheel is divided into a large number of equal pockets by means of thin pieces of sheet steel, the plane of each sheet passing through the axis of rotation. One pocket of each wheel is fitted with a false bottom *f* so arranged that any material entering the pocket is discharged toward the center of the wheel; the remaining pockets are open. The proportion of the stream cut as a sample depends on the number of pockets on the wheel. Pulp is delivered to the upper wheel from a covered box *a* through a number of

short pipe nipples *b* slightly inclined so that pulp passing from them causes the upper wheel to rotate. Pulp caught by the closed pocket of the large wheel is delivered to a distributor *c* which spreads it over about one-third the area of the smaller wheel. The latter is rotated by the action of the falling pulp on eight inclined paddles *d* fastened to the periphery. Pulp caught in the closed pocket of the small wheel is delivered to the center and discharges through pipe *e*, passing out of the bottom of box *g*, which encloses the apparatus. The main pulp stream falls through both wheels and discharges through a launder let into the side of box *g*. The wheels rotate in opposite directions at about 7 r.p.m. for the larger and 13 for the smaller. The sampler works without splash on tailing carrying 180 tons of solids and 1,440 tons of water per 24 hr.

Vertical-swing rotary sampler in homemade form as used at the Questa concentrator of the MOLYBDENUM CO. OF AMERICA to sample tailing is shown in Fig. 29. Pulley *A* is mounted loosely between collars on a length of 2-in. pipe *B*, one end of which passes through a bearing *C*, mounted on the open-topped junction box *E*, and continues through a 90° elbow, another length of pipe, and a second elbow to the cutter *D*. This comprises another 6-in. length of pipe, capped at the outer end and slotted longitudinally as indicated. As pulley *A* turns, stud *G* set in one of the spokes strikes a long setscrew *F* attached to one of the collars, causing it to turn. When the cutter passes its highest point of travel, it falls and passes through the pulp stream, gaining enough energy to carry it more than halfway up the other half of a complete revolution. Here a ratchet *G* and a spring arrangement prevent it from falling. A sampling ratio of 1 : 900 is reported (*IC 6651*).

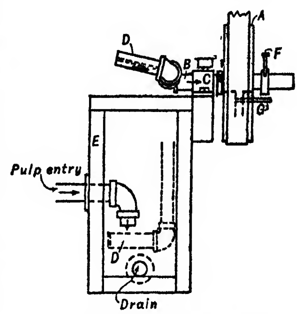

FIG. 29. Vertical rotary sampler.

Although the rate of travel of the cutter through the stream is not uniform, and the cutter takes more material from the edges than from the center, excellent results are reported when used to sample tailing.

Martin sampler was used to sample moist, sticky flotation concentrate at GARFIELD smelter. The machine was mounted on a traveling gantry. A 1 1/4-yd. clamshell bucket unloaded concentrate from 75-ton flat-bottom railroad cars and dumped through a grizzly into a 20-ton hopper. The bottom of the hopper, 9 ft. square, consisted of a belt conveyor which carried material through a 6-in. slot 9 ft. wide in one side and discharged onto a "chopper" consisting of eleven 15-in. revolving disks spaced 12 in. on a shaft with No. 12 spring-steel wires threaded through holes near the circumference parallel to the shaft. This cut the stream into strips which fell onto a 30-in. revolving hollow cylinder with a 16-in. section of the surface cut out along the entire length, making a 1/10 cut. A 12-in. conveyor inside the cylinder carried the sample to a smaller "chopper," thence to a second cylinder cutting out 1/15th and thence by another axial conveyer to a sample car. Rejects passed to a large conveyer which delivered to the bedding bins. (*114 P 17*).

Oscillating and swinging arc-path samplers constitute a considerable group in both dry- and wet-pulp sampling.

Brunton oscillating sampler (Fig. 30) consists of a hopper *a* which receives ore and discharges through vertical chute *b* to an oscillating deflector consisting of two reject-deflecting surfaces *m*, and a sample-deflecting surface *n* placed between and separated from the surfaces *m* by cutting edges. The machine is so arranged that sample and reject are discharged in opposite directions. The oscillator is made of stiff, strong sheet metal and is attached to shaft *p*, which imparts an oscillating motion in a vertical plane to the cutter, by means of a counterbalanced crank and connecting rod. A housing of sheet iron surrounds both chute and oscillator. The sampler is usually arranged to take a 20% cut, but by the use of elliptical gears on the driving mechanism a 5% cut can be obtained. The cut may also be varied by changing the size of the sample-deflecting spout.

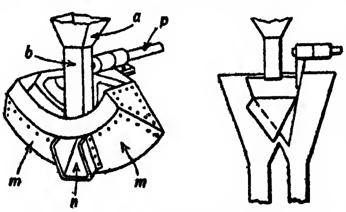

FIG. 30. Brunton oscillating sampler.

At each oscillation the sample spout passes completely through and out of the stream. The cutting edges are short and made of special steel to prevent warping and excessive wear. The side walls of the sample spout should be in planes that pass through the center of the oscillating shaft; otherwise the angular sampling distance will change as the cutting edges wear. The speed may be as great as 72 oscillations per min. Rapid motion aids materially in discharging, especially if the ore is wet or sticky, and tends to keep the cutting edges free from accumulations of foreign waste.

ADVANTAGES: The sampler requires but little headroom, is easily accessible for examination and repair, and is quickly cleaned. DISADVANTAGES: The machine takes more material from the sides of the stream than it does from the center, as shown in Fig. 22, item *A*. This error decreases with increase in distance of cutter edges from center line of shaft, and is normally small.

Snyder sampler (Fig. 31) consists of a pan-shaped plate *a* with one or more sample spouts *b*, supported on and rotated by a horizontal pulley-driven shaft *c*. The plate and spouts are usually a single strong casting but may be fabricated of good sheet steel. Feed enters through chute *d*, the reject is deflected by the conical plate, and the sample

passes through the spout into the sample hopper. To prevent change in sample weight as the cutting edges wear, the side walls of the sample spout should lie in planes that pass through the axis of rotation. Amount taken for sample is varied by changing the size or number of sample openings; frequency of cuts is varied by changing the speed of rotation or number of openings. The shape of the cut is shown in Fig. 22, item *B*. Three sizes are made: 66-, 44-, and 28-in. diameter, for 4-, 2 1/2-, and 1-in. maximum particles, respectively.

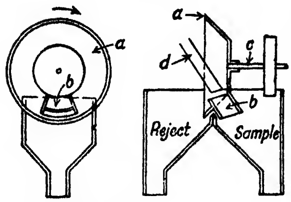

FIG. 31. Snyder sampler.

ADVANTAGES. The machine is simple in construction, easily cleaned and repaired, and can be readily observed during operation. Foreign waste that catches on the cutting edges is readily freed as the disk revolves. Little headroom is necessary. One disadvantage is that with wet or sticky ores, fine material adheres to the reject-deflecting surface and as the disk revolves falls through the sample opening, thus salting the sample; another, that more material is taken from the sides of the stream than from the center.

Rocking whole-stream cutter (Fig. 32), water-timed and solenoid-actuated, was used at YELLOW ASTER to sample mill feed and tailing. Operation is as follows: Constant-head water flowing continuously from a 1/8-in. valve *B* is caught by bucket *A*, hinged as indicated, and held upright by spring *C*. When the water reaches a level at which its torque overcomes the tension of *C*, the bucket tilts suddenly (increasing torque), closing the 110-v. circuit in the mercoid tube *D*, which is mounted on the outside of the bucket. Current then flows to the holding coil *E* of a 440-v. magnetic switch *F*, which closes the 440-v. circuit through solenoid *G*. The solenoid core, attached to the crank on the axis of sample cutter *H*, pulls the cutter into position *I* where it intercepts the whole stream in the chute until the emptied tilting bucket returns to upright position under the pull of *C*, and breaks the solenoid circuit, whereupon spring *J* pulls the cutter out of the stream.

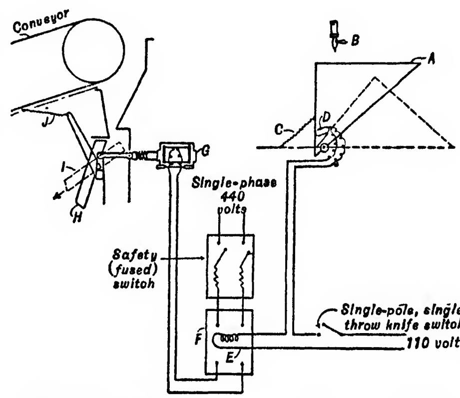

FIG. 32. Whole-stream water-timed rocking sampler.

Frequency of cut depends upon the time required to fill the tilting bucket to tilting level. Shape of cut is shown in Fig. 22, item *E*. At YELLOW ASTER a cut was made every 16 min.

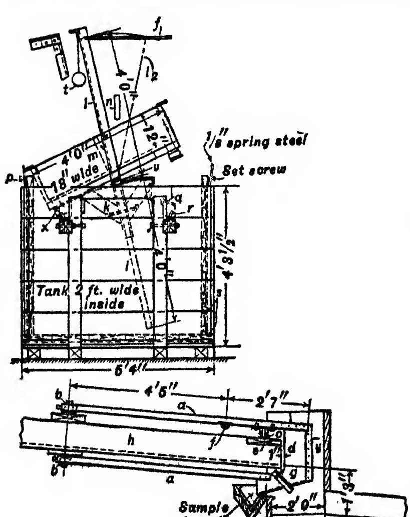

FIG. 33. Tilting-box sampler.
